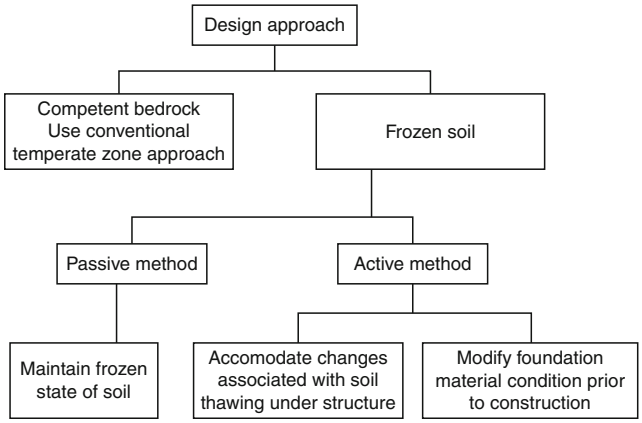
The age of palsas varies from a few years to thousands of years. In the discontinuous permafrost zone of West Siberia, the formation of palsas is a contemporary process on lacustrine-fluvial plains and flood plains in the northern taiga and southern forest-tundra. During the last 30 years, height of some palsas has increased from 30 to 200 cm with a maximum rise occurring in the coldest winters (Ponomareva and Shur, 2008). This process can be occasionally reversed by settlement due to thawing of the ice-rich core of a palsa from its base. Surface of palsas is often affected by dilation cracks with a possible impact of thermal cracking.

Engineering design for permafrost

Knowledge of the permafrost characteristics described above is essential to the proper engineering design of structures in permafrost terrain. Two main factors for designing structures on permafrost ground are the thaw settlement of thawing permafrost and frost heave associated with soil freezing. The first step for designing structures in permafrost regions is to answer the question: "can a structure tolerate a possible thaw settlement if permafrost thaws beneath it?" The answer to this question determines the appropriate design approach shown in Figure 7. The two main approaches, "*passive*" and "*active*" were developed in Russia by the 1930s (Muller, 1947) and are also known as Principle I (use of soil in the base of structures in its permanently frozen state) and Principle II (use of soil in thawing or thawed state).

Passive method – maintain frozen state of soil

The passive method of maintaining soil in a frozen state is typically used in permafrost regions. In general, it is easier to protect continuous permafrost than discontinuous. There are different engineering means to protect permafrost from thawing. They usually take advantage of the cold climate and are based on two simple principles: (1) separation of the floor of a structure from the soil surface; and (2) chilling soil in winter and/or protecting it from warming and thawing in summer. Combining these principles brings the best results.



Permafrost, Figure 7 Design approaches for permafrost regions.

Open naturally ventilated air space (crawl space) beneath a building erected on piles or posts is a very effective and widely used mean of permafrost protection. Flow of cold winter air and absence of snow under a building effectively chills soil in winter and the shade from a building protects the soil surface under it from direct solar radiation. Well-designed and operated open air space reduces permafrost temperature and increases its bearing capacity. This method has limitations, however, and cannot be used for large buildings with heavy floor loads. To protect permafrost under such buildings, use of ventilated ducts next to foundations has been implemented with mixed success. Ice blockage in ducts often impairs this method and compromises integrity of foundations. Foundations with ventilated air space and ducted foundations have been used for decades.

Thermosyphons are relatively new systems for providing permafrost stability. Vertical or inclined, they can be designed as parts of foundations (thermal piles) or can be located close to foundations as freestanding chilling devices. There are two types of thermosyphons: one phase and two phases. In one-phase thermosyphons, liquid circulates in winter due to its different density along the thermosyphon – cold and heavier liquid in the aboveground part moves downward and replaces warmer and lighter liquid in the underground part of a thermosyphon. One-phase thermosyphons have been widely used in Russia in combination with open air ventilated foundations to chill warm permafrost under multistory buildings and support frozen cores of dams. In two-phase thermosyphons, heat exchange between soil and ambient air occurs through a cycle of phase transitions, first from liquid to vapor in the embedded part (a radiator) and then from vapor to liquid in aboveground part (a condenser).

First implemented by E. Long (1963) in Alaska, two-phase thermosyphons have been widely used everywhere in the permafrost regions.

Active method

Accommodate changes associated with permafrost thawing under structure

If permafrost under heated buildings is not protected by special means, it will lead to the formation of a thaw bulb. In thaw-sensitive permafrost, which has excess ice and settles upon thawing, thawing can lead to differential settlement and have severe impact on structures. Most buildings cannot tolerate settlement greater than about 20 cm. The settlement is a product of both depth of permafrost thawing and thaw strain of ground. Thaw strain of thawing permafrost varies from almost zero to about 0.8–0.9 and most permafrost ground have a thaw strain greater than 0.2. Application of the active method to accommodate changes associated with permafrost thawing requires detailed information on soil properties and accurate prediction of thaw depth and potential thaw settlement. Unexpected factors can make structures more vulnerable to thaw settlement than originally predicted.

Modify foundation material conditions prior to construction

The active method of modifying ground conditions prior to construction can be applied if ground is generally thaw-stable. A thin layer of thaw-unstable permafrost over bedrock or over thaw-stable soil can be replaced with thaw-stable soil. Preliminary thawing is the other method of soil modification prior to construction. Initially developed for mining in permafrost, this method also has been used for civil engineering projects. It is effective in coarse-grained ground, but preliminary thawing of ice-rich, fine-grained ground can create big problems. Steam, water, and electricity are used for thawing.

PERMAFROST ON ASTEROIDS

William C. Mahaney
Quaternary Surveys, Thornhill, ON, Canada

Definition

Asteroids, especially Near Earth Objects (NEOs), are considered to be dry, barren piles of rock, either C-, E, S-, or

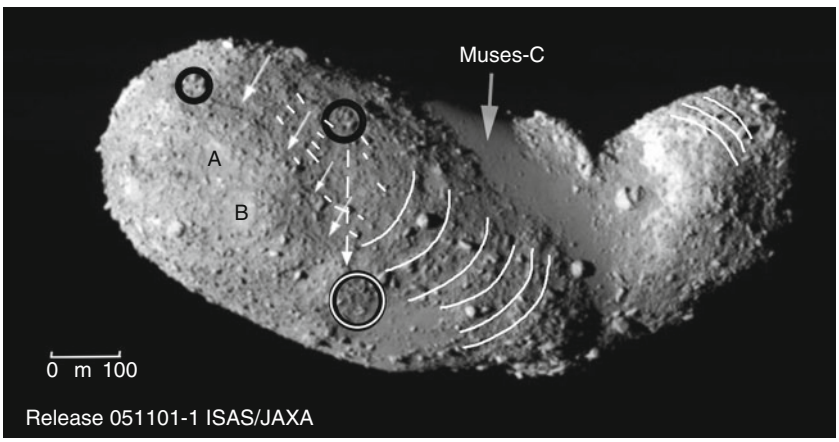
M-type bodies (Asphaug, 2007). A recent engineering feat carried out by the Japanese Aerospace Agency (JAXA) resulted in the successful rendezvous (2005) of the Hayabusa Space Craft with Asteroid 25143-Itokawa, located some 320 million kilometers from Earth. Itokawa is small by comparison to Ceres and Eros, two much larger stony asteroids; Eros was imaged by Near-Shoemaker (2000), orbiting 50 km above the surface (Asphaug, 2007) and showing considerably greater relief than is present on Itokawa. Imagery of Eros from orbit and controlled descent to the surface is available at *nssdc.gsfc.nasa.gov/planetary/near.html*. The presence of universally segregated rubble on Itokawa (Mahaney, 2009; Mahaney and Kapran, 2009; Mahaney et al., 2009) approximating polygonal ground, talus, stone-banked lobes, and debris flows on Earth should come as no surprise as similar features have been observed on Eros. When NASA's Dawn Mission reaches 4-Vesta in 2011, and Ceres in 2015, it may well record a surface geology rife with periglacial landforms requiring the presence of permafrost. The existence of permafrost should also come as no surprise since all asteroids are thought to have encountered comets since the dawn of the solar system.

Permafrost and asteroids

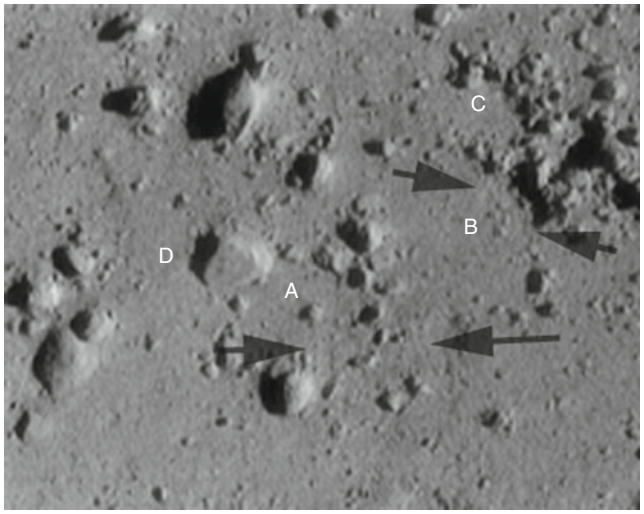
Imagery of asteroid 25143-Itokawa (Figure 1) released by the JAXA Science Team (2007) reveals prominent cold environment mass wastage landforms similar to those on Earth, including debris flows, patterned ground, stone-banked lobes, and talus. These geomorphological features, not previously recognized in the published literature from the Hayabusa Mission to Itokawa, are of significance because in the terrestrial environment they indicate the presence of permafrost and periodic release of meltwater. The existence of periglacial landforms suggests periodic, if not episodic, changes in surface thermal characteristics of sufficient magnitude to melt permafrost caused by orbital changes and high variation in aphelion and perihelion of Itokawa. The presence of landforms requiring moisture further suggests that Itokawa may have a detailed paleohydrological record, and with it, the possibility of either extant or fossil microbial life. Indeed, similar periglacial features on the surface of Eros (NASA, Near-Shoemaker Mission 2000; Figure 2) suggest permafrost may be far more prevalent on asteroids than previously thought. Future sampling missions to asteroids should consider targeting evidence for water release and associated large macroscale landforms.

The assumption that impacts on asteroids result in vibrational sorting of fines and coarse debris producing near uniform and universally continuous sheets of regolith (Miyamoto et al., 2007), has been reassessed (Mahaney, 2009; Mahaney and Kapran, 2009; Mahaney et al., 2009) after the recent release of imagery from the Hayabusa Mission to Itokawa (http://www.jaxa.jp). Regolith is used in the same sense as on Earth, referring to unconsolidated, undifferentiated, and largely incoherent loose rock material mantling bedrock, often partly weathered with a surface soil in terrestrial environments. In the case of Itokawa (Miyamoto et al., 2007; Asphaug, 2007), the entire mass is a loose assemblage of mineral debris, of basaltic composition (Abell et al., 2007), ostensibly indurated with a high porosity of 30–40% (Abe et al., 2006; Cheng et al., 2007). Analysis of regolith evolution at the asteroid surface, however, reveals landform distributions similar to periglacial areas on Earth.

At the end of November, 2005, the Hayabusa spacecraft carried out a series of remarkable engineering feats,



Permafrost on Asteroids, Figure 1 Image of Itokawa taken by the Hayabusa Mission (JAXA-2005) showing the rubble-strewn surface. Arcuate-shaped lobes are identified in white, hydrological sources with black rings, prominent debris flow trough by arrows, meltwater trough by *dashed arrow*, hydrological sink by *black/white circle*, and talus by individual clasts marked in *white* with orientation on an artificial horizon to the southeast. The Muses-C is a fine-grained accumulation of sediment from topographically higher adjoining areas. Sites A and B are impact craters. The surface channel system to the right of Muses-C may be slope wash from meltwater release at the top. Tonal contrast is a measure of nanophase secondary Fe accumulation: white is young; varying shades of gray are old (Hiroi et al., 2006). (Credit: ISAS/JAXA released image 051101–1.)



Permafrost on Asteroids, Figure 2 Surface of Eros (NASA Web site; Near-Shoemaker's descent image 0157417133) – 12 m across, taken at 250 m; rock cluster upper right is 1.4 m across showing debris flow features (*arrows*) complete with source areas, troughs with levees and sinks. Circular accumulations of clasts could be borders of polygons (*capital letters* show polygon centers) and nested clasts in upper right might signify a boulder-cored frost boil feature (Harris and Matthews, 1984). (Credit: NASA.)

including precise navigation tests and two touchdowns on the asteroid surface, the latter sufficient to collect a small sample for return to Earth (Miyamoto et al., 2007) by 2010. While the resolution of imagery taken by the cameras aboard the spacecraft is at a scale only sufficient to identify major and some minor landforms amidst the collection of rubble on the asteroid surface, some of the regolith is well segregated into distinct landform assemblages as shown below in Figure 1. Earth analogue examples of these landforms are illustrated in Mahaney (2009) and Mahaney et al. (2009).

Grain-size calculations carried out by Miyamoto et al. (2007) indicate that Itokawa is covered with unconsolidated gravels, distributed across the surface by vibrational effects giving rise, in part, to an imbricated sheet mass in some instances. Fines are either electrostatically elevated and lost to space by solar radiation pressure, ejected following impact, and/or taken up by filling holes created by enveloping larger gravels. The three major "smooth terrains" identified on Itokawa, the largest being the Muses-C region (Figure 1), act as topographic lows for the accumulation of fine-grade size material, with slopes $<8^{o}$. Above these depressions, the larger size gravels, consisting of pebble through boulder size clasts, are aligned with directions parallel to local slope and gravity, their present spatial pattern compatible with vibrations caused by meteorite impact and response to local microgravity. Granular convection models (Miyamoto et al., 2007), which explain gravel distributions on Itokawa, are supported by laboratory experiments on vibration tables and models of global shaking from meteorite collisions (Bruzzone et al., 2008). All these experiments and models rely on smaller particles descending along a slope angle that falls within the friction angle of the particles. Despite the higher inclination of coarse terrain (Scheeres, et al., 2004), such particles remain in areas of higher gravitational potential (Fujiwara et al., 2006) until a future impact event results in their movement or until they are disturbed by movement with a hypothesized active permafrost layer (Mahaney, 2009; Mahaney et al., 2009).

Despite the coarse accumulation of gravels into mounds and ridges, as shown in Figure 1, there are also areas with pebble debris and finer matrix material including sand and possibly finer silts and clays. As indicated, not all fine material escapes into convection cells below the asteroid surface. The corollary of rough terrain with imbricated gravel surfaces on Earth, as proposed by Miyamoto et al. (2007), matches only part of the surface jumble of clastic debris shown in Figure 1. The remainder, where strong long-axis clast orientations match the slope, is more analogous with talus accumulations on Earth (although the slope angle is $<27^{o}$ [Scheeres, et al., 2004]), where gravity-induced migrations of clasts are clearly shown. Some of the chaotic terrain on Itokawa is presumably in areas recovering from the last vibration event as proposed by Miyamoto et al. (2007), while others are partially sorted in response to a small microgravity component that redirects the downslope movement of clasts toward local depressions.

Coarse accumulations of large gravels into mounds and ridges on Itokawa is in places chaotic, as indicated above, while in others clasts group into forms resembling stone-banked lobes, i.e., landforms often observed in periglacial areas on Earth (Mahaney and Spence, 1984). Additionally, the presence of polygonal ground on Itokawa (and on Eros; Figure 2) argues for an active layer in permafrost, complete with segregated ice lenses capable of sorting clastic material. Similar features are reported on Mars near the equator from analysis (Balme et al., 2008) of HIRISE (High Resolution Imagery Science Experiment) imagery. On Earth, these landforms owe their origin to a source of coarse and fine clastic debris, sourced either from moraine material or from mass-wasting processes, such as frost riving and solifluction (Mahaney and Spence, 1984; Vieira and Ramos, 2003). Similar structures, although with less relief, are present in the Dry Valleys of Antarctica (Mahaney et al., 2001) and all bear a close similarity to ridges on Itokawa. Given the close correspondence between mean surface temperatures on Itokawa (−73°C) and in Antarctica (−65°C), it is plausible that similar forms may equate to similar processes, the cold dry climate of Antarctica (Mahaney et al., 2001) being not that different from the cold, barren, ice-choked worlds of Itokawa and Eros. While permafrost likely assists in the development and evolution of stone-banked lobes in the middle latitude mountains of Earth, and polar areas as well, current models of asteroid evolution do not consider the possibility of permafrost, or that of an associated active

layer, occasionally forming due to a minor or major change in incoming radiation.

Close examination of Figure 1 shows chaotic mounds of large gravels. In the upper left of Figure 1, a debris-flow trough is observed, following a circuitous route approximately 250 m from northwest to southeast – direction on the figure is calculated using an artificial horizon to navigate from the source to termination. The boulder mound might owe its relief to fine material atop permafrost with the active layer accumulating moisture and heaving, much as in boulder-cored frost boils (Harris and Matthews, 1984) and polygons on Earth. Branching off the chaotic boulder mound, levee ridges on either side of the main drainage trough, outlined in the figure show a distinctly finer texture than the terrain through which the debris flow channel is cut, thus suggesting lower-flow regime clast-charged meltwater discharge. The very fact that debris flows exist on Itokawa indicates the presence of permafrost, a frozen sediment bed over which meltwater could flow suggesting at least one cycle of warming that produced sufficient discharge of meltwater to send a charged liquid mass downslope for a considerable distance. Even if the debris-flow channel bed were to thaw, meltwater could flow easily over terrain shown in the close-up imagery of Figure 2A, E, and F in Miyamoto et al. (2007), where bulk density of the sediment appears high enough to retain moisture, not unlike debris flows in the tropical mountains of Earth (Mahaney, 1990; Figure 6A). The fact that the levees remain in place argues for a recent age, as meteorite bombardment would have rearranged clasts into random or semi-oriented clast distributions on the slope.

From another boulder mound to the north of the debris flow system shown in Figure 1, a series of longitudinal ridges and troughs lie oriented south toward the near-termination area of the debris flow at site C. These forms resemble channels cut by water, and their orientation indicates the termination zone may be a sink area, where moisture generated by changes in the surface thermal regime of the asteroid is channeled.

The evidence for the presence of water in isolated areas on Itokawa suggests something of a puzzle as to what produced the melting. The albedo of the asteroid at 0.19 is low, which implies that solar absorption is high when orbital variations take it across Earth's orbit nearer to the sun. The wide variation in perihelion (0.9533) and aphelion (1.6948) (http://NEODyS25143-Itokawa) leads to variable radiation receipt, possibly strong enough when accompanied by solar radiation outbursts to melt underlying permafrost, thereby providing sufficient moisture to initiate mass-wasting events. Even if the asteroid has a paleohydrological record, it is necessarily short-lived, as seismic/vibration events will lead eventually to the redistribution of spatial networks of clasts, either randomly dispersed or aligned with the regional slope, i.e., talus-like bodies (Mahaney et al., 2009).

Because water is the only geologic agent capable of producing debris flows, and in addition the asteroid is of insufficient mass to generate liquid methane, meltwater may well be an agent that assists in the minor lubrication of stone-banked lobes in other areas on the surface (Figure 1). Moreover, the presence of liquid water on what is considered to be a barren, dry world opens up the possibility of the presence of microbes (Mahaney et al., 2001), either extant or fossil, the probability of which is enhanced by the asteroid lithology where Fe exists in ample supply. As indicated by optical measurements (Hiroi et al., 2006), which show higher amounts of nanophase-Fe on darker patches of Itokawa relative to lighter surfaces, the chondrite olivine-pyroxene composition is a lithology conducive to the development of microbes. As microbe physiology requires water in liquid form, together with iron for respiration processes, it might behoove asteroid researchers working on Itokawa to focus on the chemical composition of light-toned surfaces to determine if salts are present. Adsorption of water to surface clasts in the vacuum of space might be explained by recourse to surface particle energy, mineral orientation, pore presence, crystal defects and dislocations, and chemisorption (de Leeuw et al., 2000; Stimpfl et al., 2006). Much as in the Dry Valleys of Antarctica (Mahaney et al., 2001), concentrations of salts in the near-surface environment of Itokawa would lower the freezing temperature of water to a point where microbial colonies might evolve and persist.

Given the prevalence of periglacial landforms on Itokawa and Eros, future sampling missions to asteroids (i.e., NASA's Dawn Mission) should consider targeting evidence for permafrost and meltwater release.

Summary

Near Earth Objects (NEOs), long considered to be dry, barren rock piles, either C, E, S, or M (i.e., carbonaceous, enstatite-achondrite, stony, metal) type bodies often reveal universally segregated clast distributions of landforms approximating periglacial environments on Earth. If permafrost exists on asteroids such as Eros and Itokawa it may well be present on other asteroids and these bodies may carry a hydrological record that reflects their ancient histories and encounters with comets over the lifespan of the solar system. With the arrival of NASA's Dawn Mission at 4-Vesta in 2011 and Ceres in 2015, we may have new clues about the presence/absence of periglacial landscapes. Imagery from 21-Lutetia, a probable M type asteroid will be available in 2010 from the Rosetta Space Probe (European Space Agency, ESA), launched in 2004, which also returned (2008) imagery from 2867-Steins, an E type asteroid. The Steins imagery from 800-km distance showed numerous craters, large-scale surface ruptures, numerous scalloped-shaped depressions, round raised mounds that could be periglacial in origin, and long raised ridges of unknown origin.

Definition

Permafrost and active layer – see entry *Permafrost*

Introduction

Permafrost is defined as a thermal condition in which the temperature of the ground (soil or rock) remains continuously below 0°C for 2 years or more (Brown and Pewe, 1973). Most permafrost, however, has existed for much longer and under the cold climates of the Arctic can extend to thicknesses of up to several hundred meters. The upper part of the ground above the permafrost that thaws each summer and refreezes in the winter is called the active layer.

Factors influencing permafrost–climate relationships

The atmospheric climate is the main factor controlling the formation and existence of permafrost (Brown and Pewe, 1973). Although a general relationship exists between air and ground temperatures, local environmental factors play an important role in determining the heat transfer between the ground and the air. These conditions include aspect, elevation, snow cover, vegetation, the presence or absence of an organic layer, surficial materials, soil moisture content, and drainage (French, 2007). These factors determine the ground surface temperature on which the spatial distribution, thickness, and temperature of permafrost are highly dependent. A change in climate may result in changes in ground temperature and permafrost distribution but the magnitude and the rate at which these changes occur will vary depending on the site characteristics.

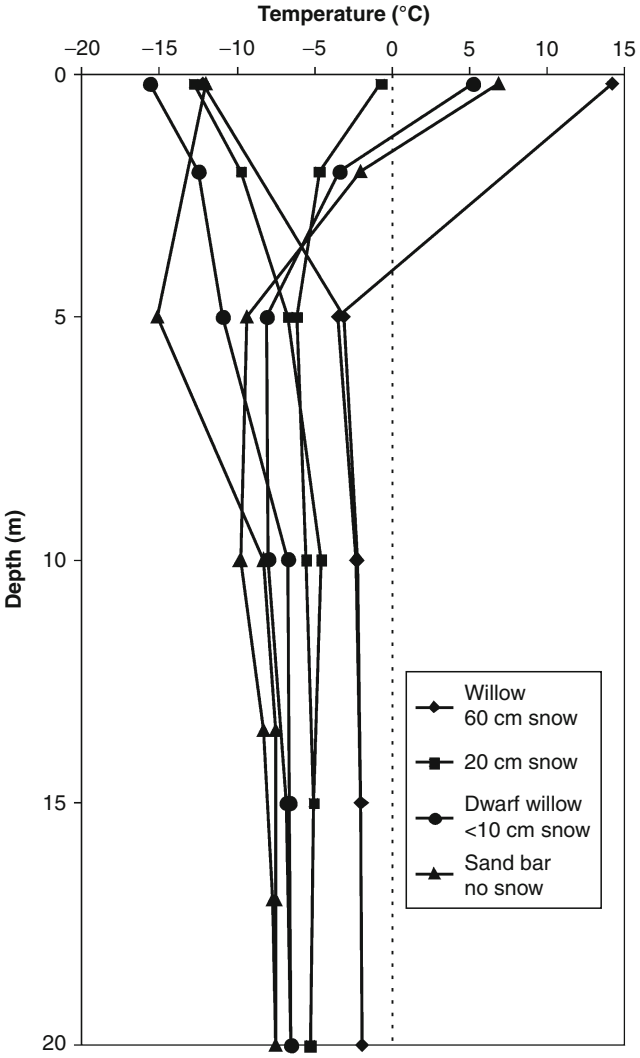
Snow is an effective insulator due to its low thermal conductivity. During the winter, the snow acts to reduce

the energy exchanges between the air and ground surface so that warmer winter ground temperatures will exist beneath deeper snowpacks. In the discontinuous permafrost zone, snow depth can be an important factor determining the existence of permafrost (Brown and Pewe, 1973). Studies done by Nicholson and Granberg (1973) at Schefferville, Quebec, Canada, where mean annual air temperature is warmer than −5°C, suggest that where the snow depth is greater than 75 cm the ground is well insulated from winter air temperatures and generally not underlain by permafrost. Recent observations at York Factory Manitoba, Canada, show that open, windswept areas with minimal snow cover are underlain by permafrost while the ground in adjacent areas where thick snow covers may build up may not be frozen (Sladen et al., 2009).

In the discontinuous permafrost zone, vegetation has an important influence on the permafrost distribution (Brown and Pewe, 1973). Vegetation provides shade in the summer and in the case of coniferous trees, reduces the amount of snow on the ground in the winter, leading to lower ground temperatures in forested areas compared to treeless areas. Permafrost may therefore be thin or nonexistent in treeless areas compared to forested areas within the discontinuous zone. Above the tree line, warmer permafrost conditions are often found where shrubs, such as willows, are present (Figure 1) as they tend to trap snow during the winter in contrast to open areas where the wind may remove the snow (e.g., Burn and Kokelj, 2009).

The presence and nature of organic material or peat at the ground surface is also an important factor controlling permafrost occurrence and persistence especially at the southern margins of the permafrost zone where mean annual ground temperatures are close to 0°C (e.g., Vitt et al., 1994). The thermal conductivity of peat varies during the year. Peat becomes a good insulator in the summer when it is dry and a good conductor in the fall and winter when it is wet. This characteristic enables permafrost to persist in organic terrain although it may be absent in adjacent mineral soils with no significant peat cover (Figure 2; e.g., Burgess and Smith, 2000). This insulation offered by the peat can therefore act to buffer the ground thermal regime from the effects of long-term climate change as well as reduce the response to shorter-term climate variability (e.g., Halsey et al., 1995; Woo et al., 2007).

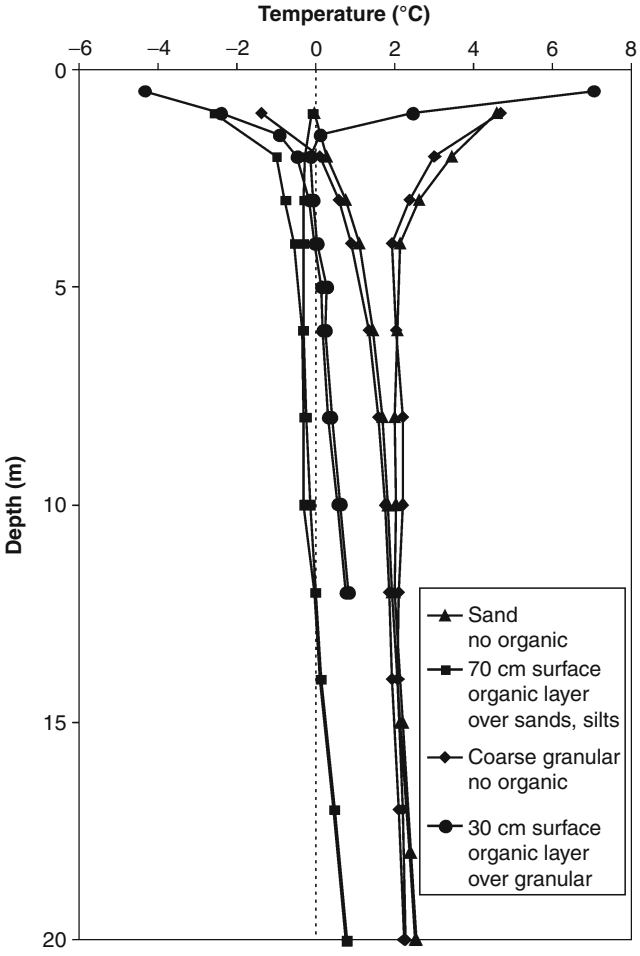
The thermal properties of the underlying soil or rock also play a role in determining the relationship between climate and the ground thermal regime. Fine-grained soils such as clay and silt will generally have a low thermal conductivity while sand and bedrock with a higher quartz content will generally have a higher thermal conductivity. The ground ice content is also important. For ice-rich material, the latent heat effects of thawing are important in determining the rate of permafrost degradation (Riseborough, 1990). The thermal regime of fine-grained soils having high ice contents would therefore be expected to respond more slowly to changes in climate especially as temperatures approach 0°C.



Permafrost and Climate Interactions, Figure 1 Ground temperatures at a site in the Mackenzie Delta, Canada. For each site, the March and July 1992 temperature profile is shown. Where vegetation is able to trap snow, permafrost is warmer than sites where the wind removes the snow (from Burgess and Smith, 2000).

Changes in permafrost conditions over time

Changes in both areal extent and thickness of permafrost have occurred in the past in response to changes in climate occurring at scales of decades to centuries to millennia. Under a cooling climate, permafrost becomes thicker and more extensive regionally while a warming climate results in thickening of the active layer and thinning or even complete disappearance of permafrost. In Canada, for example, warmer conditions existed during the mid-Holocene, 6,000–9,000 years ago with the southern limit of permafrost north of its present position and active layers generally thicker (e.g., Burn et al., 1986; Zoltai, 1995). Cooler conditions followed the mid-Holocene



Permafrost and Climate Interactions, Figure 2 Ground temperature envelopes (maximum and minimum annual ground temperature for 1986) for four sites in the discontinuous permafrost zone near Fort Simpson, NWT, Canada. Although the climate is similar at all sites, permafrost is absent from sites lacking a significant organic layer (from Burgess and Smith, 2000).

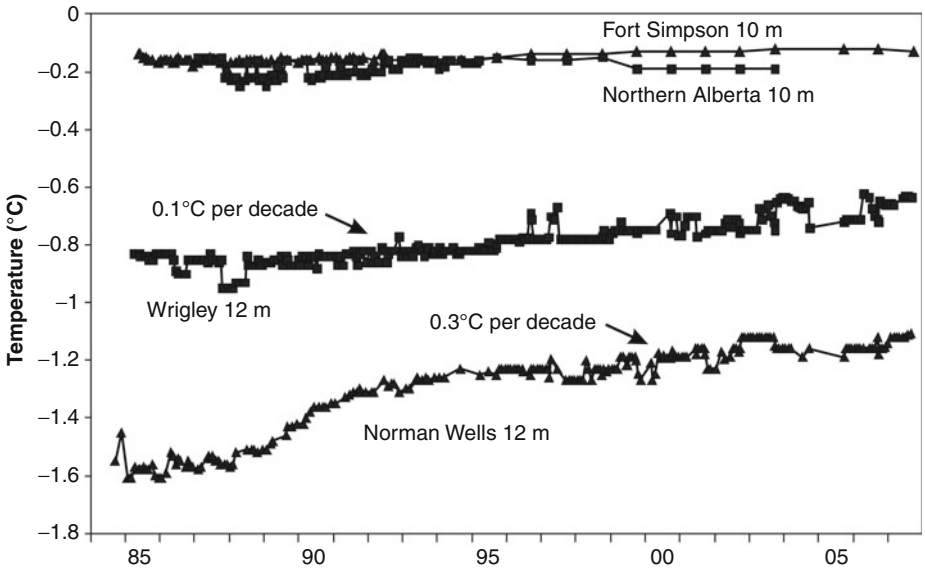
Warm Period about 3,700–5,000 years ago and this was accompanied by an increase in permafrost extent (e.g., Zoltai, 1993; Vardy et al., 1998). During the Little Ice Age between 1550 AD and 1850 AD, air temperatures were colder and permafrost occurred farther south than at present (e.g., Vitt et al., 1994). At the southern fringes of the discontinuous permafrost zone, some of this permafrost still persists in organic terrain (frozen peatlands) at temperatures close to the thawing point due to the insulation provided by a thick layer of peat, while in mineral soils it has largely disappeared (Halsey et al., 1995; Smith et al., 2008). Similar fluctuations in permafrost extent have occurred over the last 20,000 years in northern Eurasia (Lisitsyna and Romanovskii, 1998). Relic permafrost bodies 100–200 m thick, that were formed during colder climates of the Pleistocene, have been mapped in central and southern Siberia (Ananjeva et al., 2003). The top of this relic permafrost can be more than 80 m below the ground surface which indicates that permafrost has been degrading in response to Holocene warming. Relict permafrost of Pleistocene age that has been in existence for at least 125,000 years is also found in central Alaska (French, 2007).

Subsea permafrost also exists which is a relic from periods of lower sea level during the glacial maxima of the Quaternary Period. In the Beaufort Sea, for example, large areas of the continental shelf were above sea level during the Quaternary and thus were exposed to air temperatures which were as much as 18°C lower (Allen et al., 1988) than those currently occurring at the seabed, allowing permafrost up to 700 m thick to form. During interglacial periods and in postglacial time as sea levels increased, these exposed areas were covered by Arctic Ocean water, having bottom water temperatures between 0°C and −2°C, which has gradually warmed the sediments and led to slow degradation of subsea permafrost (Taylor, 1991). Similar bodies of relic subsea permafrost also exist in the Laptev and eastern Siberian Seas (Danilov et al., 1998; Delisle, 1998; Overduin et al., 2008).

More recently, over the past two to three decades, there has been a general warming of permafrost across the circumpolar permafrost region (Romanovsky et al., 2007; Lemke et al., 2007). Observations from permafrost monitoring sites throughout the northern hemisphere, including North America (e.g., Smith et al., 2010), Russia (e.g., Romanovsky et al., 2010), the Arctic and alpine areas of Europe (Harris and Isaksen, 2008), and plateau of central Asia (e.g., Sharkhuu et al., 2008; Zhao et al., 2008), generally indicate that permafrost temperatures have increased though the rate and magnitude of this increase varies regionally. A few examples are provided below.

In northwestern North America, in Alaska and the Mackenzie valley region of NWT Canada, for example, a region which has experienced an increase in air temperature of about 1.5°C over the last century, permafrost temperatures at depths of 10–20 m have increased by a few tenths of degree per decade in the south and central area (Figure 3) to about 1°C/decade in the north (e.g., Arctic Coastal Plain, Mackenzie Delta region) since the 1980s (Kanigan et al., 2008; Smith et al., 2010). Smaller increases in permafrost temperature have been observed in the more southerly, warmer and thinner permafrost as there is greater buffering from air temperature changes by the forest cover and also due to the latent heat required to thaw ground ice as temperatures approach 0°C.

In the high Arctic tundra where mean annual ground temperatures can be as low as −15°C, the ground temperatures are more responsive to changes in air temperature due to the lack of a buffer layer (little vegetation, thin snow cover) and because the cold permafrost conditions mean phase changes are not occurring and therefore the presence of unfrozen water does not obscure the climate signal. At Alert Nunavut (latitude 82.5°N), for example,



Permafrost and Climate Interactions, Figure 3 Trends in permafrost temperatures between 1984 and 2007 at depths of 10–12 m, at sites in the south and central Mackenzie Valley, NWT, Canada. The rate of ground temperature increase is greater for sites having colder thicker (greater than 30 m) permafrost (Norman Wells, 65°52′N 126°26′W and Wrigley, 63°13′N 123°26′W) than those located further south (Fort Simpson, 61°52′N 121°21′W and Northern Alberta, 59°32′N 119°37 W) where permafrost is at temperatures near 0°C and less than 15 m in thickness (updated from Romanovsky et al., 2007).

permafrost at a depth of 15 m warmed by about 0.1°C/year over the last two to three decades (Smith et al., 2010). Similar recent increases in shallow ground temperatures have also been observed in other Arctic regions such as Scandinavia and Svalbard (Harris and Isaksen, 2008).

Observed changes in permafrost temperature are generally consistent with trends in air temperature. However, snow cover variations are also an important factor. Osterkamp (2008), for example, found that warming of permafrost in the late 1980s and early 1990s in Alaska may be primarily a response to a series of thicker snow covers. Similarly, Taylor et al. (2006) suggest that in the high Arctic, changes in snow cover may counteract changes in air temperature so that permafrost temperatures may increase during periods of higher snow cover but lower air temperature.

Changes in active layer thickness have also been observed over the past 10–20 years. However, these changes in active layer often reflect shorter-term fluctuations in climate (compared to the deeper permafrost temperatures) and therefore the record shows a great deal of interannual variability making it difficult to characterize longer-term trends from the shorter records. Russian observations between 1956 and 1990 indicate an average increase in active layer thickness of 21 cm (Frauenfeld et al., 2004) with more recent observations at a limited number of sites indicating a general deepening of thaw (Mazhitova et al., 2008). While there is some evidence of increases in thaw depths in other regions since the 1990s, there is much variation with maximum thaw depths being observed in extreme warm years such as 1998 in Alaska and northwestern Canada (e.g., Osterkamp, 2008; Smith et al., 2009), consistent with responses in other cryospheric components (Atkinson et al., 2006), and in the warm summers of 2002 and 2003 in Europe (Harris et al., 2003).

There is also evidence of permafrost degradation and in some cases complete loss of permafrost in the southern portion of the permafrost zone since the mid-twentieth century (Lemke et al., 2007). Degradation of frozen peatlands has been observed in the southern Canadian permafrost zone in the southern Mackenzie valley, northern Saskatchewan, Manitoba, and Quebec (e.g., Beilman et al., 2001; Beilman and Robinson, 2003; Camill, 2005; Vallée and Payette, 2007; Fortier and Aubé-Maurice, 2008; Smith et al., 2008). Loss of permafrost is also occurring on the Tibetan Plateau, with the lower altitudinal limit of permafrost moving upward by 25 m since 1975 in the Kunlun Mountains (Nan et al., 2003).

The various interactions between climate and permafrost discussed above need to be considered in the development of models to predict how permafrost conditions may change in the future in response to climate change. A variety of empirical, physically based, deterministic and probabilistic models have been developed to predict future permafrost conditions at local, regional, and circumpolar scales (Riseborough et al., 2008). These models are generally driven by the temperature and precipitation outputs from global circulation models. Although the various modelling studies generally predict warmer ground conditions and increased active layer thickness (e.g., Romanovsky et al., 2007; Woo et al., 2007; Riseborough

et al., 2008), the accuracy of results is largely limited by the availability of information on the various environmental factors (e.g., vegetation, organic layer thickness, snow cover, and soil conditions) which influence the relationship between changes in air temperature and the ground thermal regime.

Changes in permafrost conditions can have impacts on both natural and human systems. Warming and thawing of permafrost especially if it is ice-rich can lead to ground instability, such as differential settlement or slope movements, which can have implications for the performance and integrity of infrastructure (e.g., Romanovsky et al., 2007; Prowse et al., 2009). For several years, engineers have developed several risk management approaches and design, construction, and operational techniques to deal with the challenges presented by the permafrost environment including warming and thawing of the ground resulting from construction and operation of infrastructure. These techniques (possibly with modification) along with an understanding of how permafrost conditions may change in response to a changing climate will be required to adapt to future conditions (e.g., Prowse et al., 2009).

Summary

The existence of permafrost and its thermal condition depend largely on the atmospheric climate. However, this relationship between permafrost and climate is modulated by a number of local factors which influence the microclimate at a particular site. Variations in permafrost thickness, temperature, and lateral extent have occurred in the past and will continue in the future, over periods of several decades to centuries to millennia, in response to changes in climate across the entire permafrost region. The magnitude and rate of these permafrost changes will vary regionally, as a function of the regional climatic changes, as well as the regional soil, ground ice, and microclimatic conditions.

PERMAFROST MODELING

Daniel Riseborough
Geological Survey of Canada, Ottawa, ON, Canada

Definition

Permafrost modeling is the use of quantitative methods (analytical, numerical, or empirical) to predict the thermal condition of the ground (temperature or frozen state) in environments where permafrost may be present. Permafrost models may be used to predict the presence or absence of permafrost or to predict ground temperature in one, two, or three dimensions, including changes over time.

Introduction

Permafrost occurs where atmospheric processes and earth material thermal properties combine to permit the ground to remain at or below 0°C for at least 2 years. Existing beneath a ground surface layer that undergoes thawing and freezing annually (the *active layer*), permafrost cannot be detected directly at the surface. Determining the distribution of permafrost in many settings requires extensive field work. Permafrost models are used to predict permafrost conditions where direct field evidence is lacking, or in hypothetical cases such as under a future climate or altered environment.

Models

Permafrost models can be classified as process-based (*analytical* or *numerical*) or *empirical* models. Permafrost models are usually formulated as point or one-dimensional models, often used within spatial models to map permafrost distribution at local to continental and global scales. While most analytical and empirical permafrost models assume a static relationship between permafrost conditions and model parameters, the transient response of permafrost to change is usually studied using numerical models.

Permafrost models link atmospheric climate to ground temperature. The simplest empirical models make a direct link between mean annual air and the presence of permafrost. Many models divide the year into freezing and thawing seasons, using season-long degree-day totals above or below 0°C (freezing and thawing indices) to summarize the annual regime. Models of intermediate complexity may require several parameters to account for the various influences on ground surface temperature. For example, field-based empirical relationships between freezing and thawing indices in the air and at the ground surface (e.g., *n* factors) allow surface temperature to be estimated for areas with similar surface characteristics. The most complete numerical models calculate ground surface temperature by solving the surface energy balance, including snow cover in winter, requiring extensive meteorological inputs; this surface temperature drives calculations of temperature below the surface.

Analytical models

Analytical permafrost models are mathematical functions based on the physics of heat transfer, especially conduction with phase change (freezing and thawing). While real-world environments do not meet the conditions of the few exact analytical models describing the thermal state of the ground when freezing or thawing occurs, several approximate analytical models have been developed using simplifying assumptions. Several permafrost models (e.g., Frost Index, Kudriavtsev, and TTOP models) employ simple models of freezing and thawing to predict the presence or the temperature of permafrost in equilibrium conditions. Models that ignore phase change can be useful, especially in environments with low soil moisture.

Numerical models

Numerical (geothermal) permafrost models can represent relatively complex conditions with relatively small errors. Numerical models divide continuous time into finite time steps and continuous space into finite pieces, creating an array of much simpler conditions that can be solved approximately (Zhang et al., 2008). Numerical models can be implemented in one, two, or (rarely) three dimensions. Earth materials are represented by an array of elements (or nodes) and continuous temperature is represented by temperatures at discrete points, truncated at the model boundaries. Numerical schemes that can solve freezing and thawing problems must deal with the latent heat of fusion. In mountain environments with low porosity rock, the direct effects of freezing and thawing can be small enough to ignore in some conditions. Nonconductive processes such as convection are often ignored due to the low permeability of frozen soil.

Once initial ground temperature conditions and thermal properties are specified, numerical simulations proceed by specifying the temperature (or heat flow) conditions at the model boundaries for each time step. Snow cover may be treated as a distinct layer, or treated as a seasonal transfer function such as the *n* factor. The geothermal heat flux is typically assumed for the lower boundary.

Empirical models

Empirical permafrost models use field-based relationships between permafrost conditions and measurable environmental parameters (such as mean annual air temperature, elevation, potential solar radiation, vegetation type, snow cover, soil and moisture conditions, etc.) to predict permafrost presence or absence. Empirical permafrost models are commonly used in mountainous terrain where large variations in conditions over relatively short distances make it difficult to model using process-based approaches (Harris et al., 2009). Empirical models are developed for particular locations, so their predictive relationships may not give accurate predictions in other regions.

Models based on the BTS (Basal Temperature of Snow) method are widely used in mountain environments, based on the correlation between the ground surface temperature beneath deep snow cover measured late in winter and the presence of permafrost (Lewkowicz and Bonnaventure, 2008). While the correlation between BTS values and permafrost conditions is only moderately strong, BTS is easy to measure, allowing many point measurements can be taken quickly, allowing development of statistically significant relationships with environmental conditions.

Spatial models

Spatial permafrost models aggregate the results of analytical, empirical, or numerical models to predict permafrost distribution at regional to global scales. Spatial models rely on map-based and remote sensing data to supply the model input parameters, and may use climate data from a meteorological network or from climate simulation results. Early spatial models used simple analytical permafrost models, but numerical models are becoming more common within spatial models as they allow for simulation of the transient behavior of permafrost in response to a changing environment.

Summary

Permafrost models include a range of approaches that are capable of predicting the current distribution and future evolution of permafrost conditions at local to global scales, useful for local to global environmental assessments. The past decade has seen the development of spatial models capable of predicting the transient response of permafrost to changing climate. As models and the data necessary to work with them continue to improve, future advancements may integrate permafrost dynamics with environmental evolution.

PERMANENT/PERPETUAL SNOW LINE

Monohar Arora
National Institute of Hydrology (NIH), Roorkee, UA, India

The altitude above which or the latitude beyond which snow does not melt even during summer is usually called the permanent snow line. Factors that affect the location of the snow line are prevailing weather conditions, particularly solid precipitation and temperature. In the Himalayan region, the permanent snow line varies from west to east, but can be considered as 4,500 m above mean sea level. Beyond the tropics, the snow line becomes progressively lower as the latitude increases, to just below 3,000 m in the Alps and falling all the way to sea level itself at the ice caps near the poles.

PHYSICAL PROPERTIES OF SNOW

Florent Domine
Laboratoire de Glaciologie et Géophysique de l'Environnement, CNRS, Saint Martin d'Hères, France

Definition

Snow Crystal Structure (qv). Ice crystals formed in the atmosphere by the condensation of water vapor or the freezing of water droplets (i.e., riming).
Snow cover or snow pack or snowpack. The accumulation of snow crystals on the ground.
Snow (qv). Can refer either to snow crystals in the atmosphere or to snow on the ground. Here snow means snow on the ground, and the discussion is limited to dry seasonal snow.
Physical properties of snow. The range of values that characterize the physical behavior of snow.

Introduction

Dry snow on the ground is a porous medium formed of air, ice crystals, small amounts of chemical impurities, and sometimes also containing microorganisms and macroscopic impurities in the form of vegetal and geological debris. Falling snow crystals have a wide range of shapes such as plates, dendritic crystals, columns, and irregular crystals, and their deposition conditions are affected by variables such as temperature, wind speed, and state of the surface. The density of snow as it deposits onto the ground is therefore highly variable, and usually in the range 10–200 kg m^{-3}, with the result that other physical properties also show wide ranges of values.

Because ice has a high vapor pressure (165 Pa at −15°C, 610 Pa at 0°C), the vertical temperature gradient that forms within the snowpack generates sublimation of crystals and condensation of water vapor that modify the size and shape of snow crystals, resulting in changes

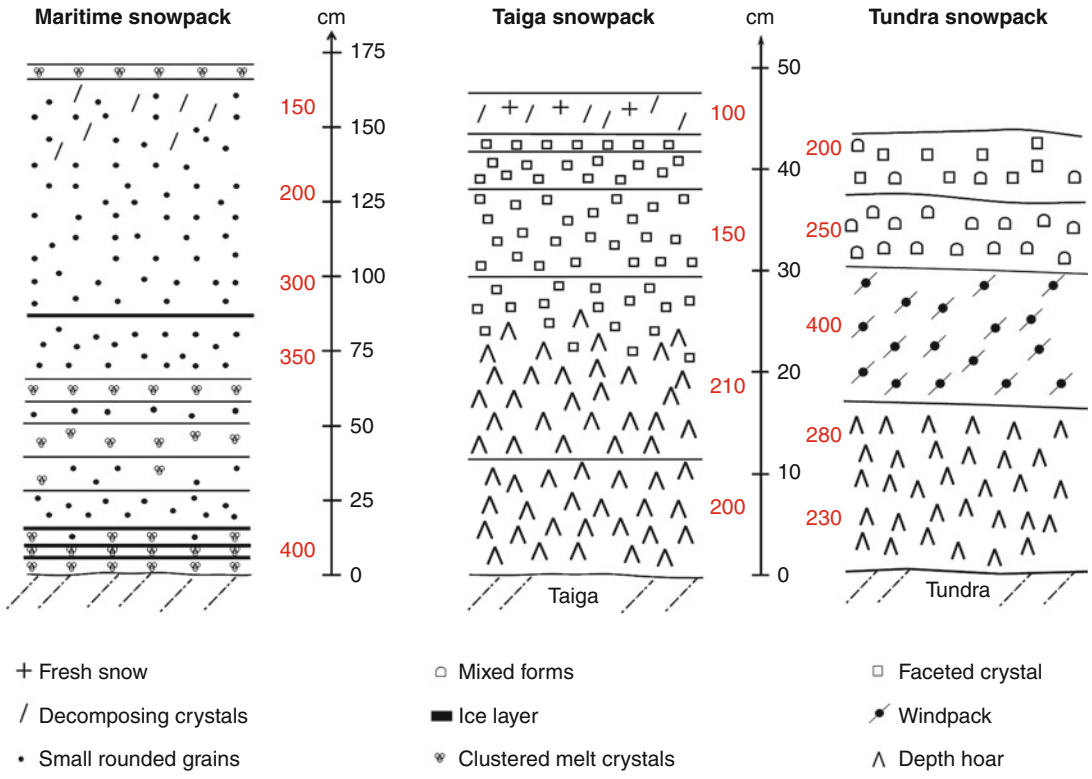
in macroscopic physical variables such as *Snow Density* (qv), albedo, thermal conductivity, permeability, and hardness. These physical changes have formed the basis for the definition of *Snow Metamorphism* (qv) (Colbeck, 1982). One further distinguishes "dry metamorphism" that takes place at $T < 0°C$ from "wet metamorphism" that takes place at 0°C and where the presence of liquid water is observed.

Impurities contained in snow can be chemically inert such as mineral dust particles, but *Chemical Processes in Snow and Ice* (qv) such as the photolysis of impurities can produce changes in the *Chemical Composition of Snow, Ice, and Glaciers* (qv). These chemical processes are affected by the physical properties of the snow. We review here the ranges of values of selected snow physical properties, how they are affected by climatic variables, and briefly discuss how they in turn affect snow chemical properties.

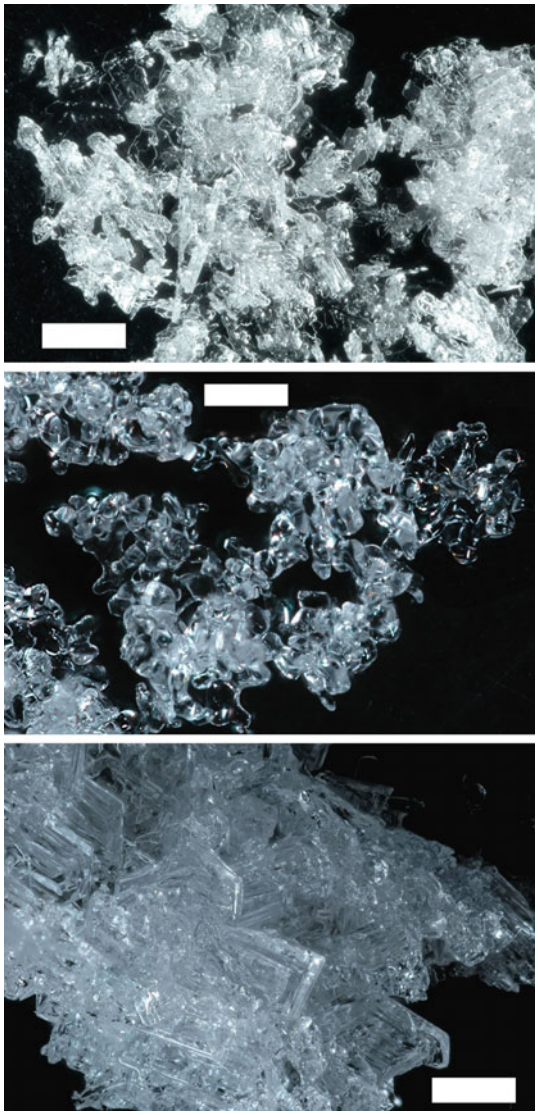
Snow metamorphism and climatic variables

As detailed by Sturm et al. (1995), climatic variables, and especially wind speed, temperature, and the amount of precipitation determine the conditions of snow metamorphism, and especially the temperature gradient in the snowpack. At the beginning of the winter season, the ground is at 0°C, and the atmosphere may have already cooled down to −30°C, so that temperature gradients in excess of 100°C m^{-1} can exist in the thin early season snowpack. These generate large water vapor fluxes that produce sublimation and condensation of snow crystals, leading to the formation of faceted crystals that turn into depth hoar crystals once their size exceeds about 1–2 mm (Akitaya, 1974). This process is especially efficient in the boreal forest, where snow is sheltered from wind and remains of low density, therefore facilitating water vapor transport and the growth of large crystals (Sturm and Benson, 1997; Taillandier et al., 2006). In the Arctic tundra, the process also takes place but less efficiently because the higher wind speeds result in denser snow. In late winter and spring, temperature gradients have decreased because the snowpack is thicker and the ground has cooled, with the result that depth hoar cannot form anymore on the tundra, and the basal depth hoar layer is then topped by a hard windpack formed of small highly sintered rounded grains (Dominé et al., 2002).

In midlatitude regions, conditions are very different with warmer temperatures and more abundant precipitation. Depth hoar forms less frequently, small rounded grains predominate, and melt-freeze structures are common (Sturm et al., 1995). Figure 1 illustrates the layering structure for three different snowpack types that form in the boreal forest (taiga), tundra, and maritime regions. Figure 2 shows clusters of crystals sampled in fresh snow, layers of small rounded grains and Arctic depth hoar. The



Physical Properties of Snow, Figure 1 Typical stratigraphies of the maritime, taiga, and tundra snowpacks. Bold numbers next to the stratigraphies are density values, in kg m^{-3}.



Physical Properties of Snow, Figure 2 Photomicrographs of clusters of snow crystals sampled on the ground. *Top*: Fresh Arctic snow comprised of dendritic crystals and columns, deposited under windy conditions. *Middle*: 2-weeks old snow sampled in a low elevation area of the French Alps, 2 weeks after deposition, in a snowpack classified as maritime. Precipitating particles cannot be recognized; grains are rounded and have started to sinter. *Bottom*: Arctic depth hoar crystals, of density 300 kg m^{-3}, about 3 months old. In this high density depth hoar, grains have remained small and the sample is unusually cohesive for depth hoar. Scale bars: 1 mm.

structures of these snow layers are quite dissimilar, and very different physical properties are expected in snow, as determined by climatic conditions.

Physical properties of snow

Variables such as density, albedo, light *e*-folding depth, specific surface area (SSA), crystal size and shape, thermal conductivity, permeability, diffusivity, and shear resistance are required for a complete physical description of the snowpack. These are reviewed in several publications such as Domine et al. (2008) and Petrovic (2003). This entry will only discuss density, SSA, albedo, and thermal conductivity.

Snow density

Density is the most widely studied snow physical property. It is defined as the mass per unit volume, and it is usually measured in the field or the laboratory by weighing a sample of known volume. Even though density is a very intuitive concept and many attempts have been made to correlate most physical properties to density, it is clear that density alone cannot be used as a descriptor of other snow properties.

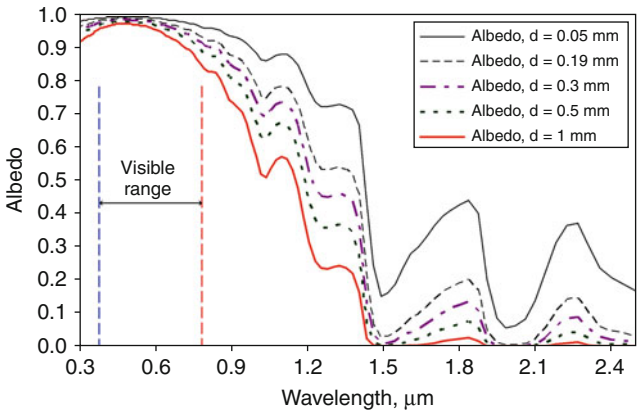
Snow density shows a wide range of values: from less than 10 kg m^{-3} for fresh cold dendritic snow to more than 600 kg m^{-3} for very hard windpacks and snow subjected to numerous melt-freeze cycles. Physical processes producing density changes include compaction by the weight of subsequent layers, wind-drifting, and dry and wet metamorphism. Precipitated snow (density in the range 10–200 kg m^{-3}) is subject to settling and compaction. Wind-drifted snow often forms thick layers of small rounded grains that subsequently sinter well to form hard windpacks with densities 300–600 kg m^{-3}. High temperature gradient metamorphism produce upward water vapor fluxes that compensate the effects of densification, so that density in the boreal forest snowpack is vertically fairly constant around 200 kg m^{-3} (Sturm and Benson, 1997; Taillandier et al., 2006). The appearance of liquid water usually leads to crystal rounding, compaction, and density increase. The range of snow density for a variety of snow types are reported in Table 1.

Specific surface area and grain size

Another intuitive snow property is grain size. However, the definition is unclear and observer-dependent. For example, what is the size of a dendritic crystal 5 mm in diameter but 40 μm in thickness? Likewise, what is the size of a 10 mm hollow depth hoar crystal with 200 μm thick walls? At present, it is more and more accepted that specific surface area (SSA) is physically more meaningful and should be used preferentially to grain size. SSA is the surface area per mass unit. Snow SSA values range from over 150 m^2 kg^{-1} for fresh snow to less than 2 m^2 kg^{-1} for melt-freeze crusts (Domine et al., 2007). If snow crystals are assumed to be spheres, then SSA = $6/\rho_{ice}\, d$, where d is the sphere diameter and ρ_{ice} is the density of pure ice (917 kg m^{-3} at 0°C). Thus, the above SSA range translates to sphere diameters of 44 μm to 3.2 mm. This diameter is called the *effective grain size*, it is objective and should be used preferentially to cursory intuitive observations. Snow SSA usually decreases during metamorphism, and adsorbed impurities are therefore released to the gas

Physical Properties of Snow, Table 1 Typical ranges of values of selected physical variables for the most frequent snow crystal types in surface snow (top 50 cm). Data from Domine et al. (2008) and references therein

Physical variable	Fresh snow	Rounded grains, maritime snowpack	Rounded grains, windpack	Depth hoar	Melt-freeze layers
Density (kg m^{-3})	10–200	150–350	300–600	150–320	150–450
Specific surface area (m^2 kg^{-1})	35–160	11–30	15–38	7–22	2–5
Visible albedo (0.38–0.78 μm) pure snow	0.98–0.99	0.96–0.975	0.965–0.978	0.95–0.97	0.94
Thermal conductivity (W m^{-1} K^{-1})	0.025–0.12	0.08–0.3	0.2–0.6	0.03–0.15	0.1–0.6



Physical Properties of Snow, Figure 3 Spectral albedo of snow calculated for samples made of spheres of diameter d: 0.05, 0.19, 0.3, 0.5, and 1 mm, corresponding to SSAs of 131, 34.4, 21.8, 13.1, and 6.5 m^2 kg^{-1}. The range used to obtain the visible albedo values in Table 1 is shown. Calculations were made using the DISORT code of Stamnes et al. (1988), with diffuse light conditions.

phase, so that their concentration in snow decreases (Taillandier et al., 2006).

Snow albedo

SSA, or effective grain size, is useful to evaluate snow optical properties. In particular, the calculation of snow albedo, that is, the hemispherical reflectance, requires the knowledge of snow SSA (Grenfell and Warren, 1999). Snow albedo is determined by scattering and absorption. In the visible, ice is a very weak absorber: its absorption coefficient is very difficult to measure but could be lower than 10^{-3} m^{-1} at 390 nm (Warren et al., 2006). As a result, absorption of visible radiation by snow is determined by impurities such as soot particles, whose concentrations in snow are highly variable (Flanner et al., 2007). Figure 3 shows calculated albedos for pure snow. It is obvious that in the visible, albedo depends little on effective grain size. This is because the probability that an incident photon is absorbed by ice is so low that it can undergo a long and tortuous path in the snow until it is reflected. This will almost not be influenced by the number of reflections onto snow crystals. In the IR where absorption by ice becomes important, a strong dependence of albedo on SSA appears, because photons are absorbed after a short pathlength in ice, and smaller grains increase the number of reflections and the probability that the photon will exit the snow. The albedo dependence on SSA in the IR is used to infer effective grain size from remote sensing measurements of snow, for example using satellites (Kokhanovsky and Schreier, 2009).

The difference is often made between spectral albedo, that is, the hemispherical reflectance at a given wavelength, and broad-band albedo, that is, the hemispherical reflectance over a given spectral range, usually the visible range or the range of the solar spectrum. Table 1 shows the visible albedo of several snow types, assumed to be free of absorbing impurities.

Thermal conductivity of snow

The thermal conductivity of snow, k_T, is an essential environmental and climatic variable. Snow insulates sea ice from the cold atmosphere and limits sea ice growth (Fichefet et al., 2000). Likewise, snow limits ground freezing and permafrost extent (Zhang, 2005). Snow k_T is very strongly dependent on snow structure, because diffusive thermal transport mostly takes place through the network of interconnected ice crystals (Sturm et al., 1997). Fresh snow k_T can be as low as 0.025 W m^{-1} K^{-1}, that is, more insulating than styrofoam, while very hard windpacks or melt-freeze layers have values as high as 0.65 W m^{-1} K^{-1} (Sturm et al., 1997), similar to light concrete. In models of sea ice growth, an average value k_T = 0.31 W m^{-1} K^{-1} is often used (Fichefet et al., 2000). Values of k_T for different snow types are shown in Table 1.

The value of snow k_T determines the temperature gradient in the snowpack, and therefore the rate of chemical reactions. It also determines the temperature gradient, and therefore the intensity of sublimation-condensation cycles that can release dissolved impurities to the gas phase. This further illustrates that physical and chemical properties of snow are coupled.

Summary

Snow is a porous medium made mostly of air and ice, whose *transformation at the Earth's surface* (qv *Transformations of Snow at the Earth's Surface and its Climatic and Environmental Consequences*) is greatly affected by climatic variables. Because a snow cover is present in

a wide range of climates, from temperate to polar, the physical properties of snow show wide ranges of values: density values varies by a factor of 60, thermal conductivity values by a factor of 25, specific surface area (and effective grain size) by a factor of 80. These properties in turn also affect the reactivity of impurities contained in snow, so that snow physical and chemical properties are linked. Snow therefore interacts with environmental chemistry and climate. It is an environmental compartment that deserves detailed description for complete studies in natural sciences.

PIEDMONT GLACIERS

Monohar Arora
National Institute of Hydrology (NIH), Roorkee, UA, India

Piedmont glaciers form where valley glaciers exit from the mountains and meet flat ground. There they spread out in a fan or lobe shape. Piedmont glaciers commonly are a merger of several valley glaciers. Glaciers of this kind are especially common in Alaska. The lower portion of this glacier is almost flat and covered with so much soil and rock debris that it supports a thick forest. The Malaspina Glacier in Alaska is one of the most famous examples of this type of glacier. It is the largest piedmont glacier in the world.

PINGO

Himali Panthri
Department of Geology, D.B.S (P.G) College, Dehradun, Uttarakhand, India

Synonyms

Cryolaccolith; Hydrolaccolith

Definition

Pingos (Eskimo word *pingurayung* = low hill) also called *bulganniakh* are low mounds and cones covered with soils or mantle deposits having cores of massive ice. Pingos often support vegetation at their top.

Generally 10–70 m high, they may go as high as 90 m and 20–400 m in diameter.

Location

They are generally found in the continuous as well as discontinuous permafrost areas of Canada, Alaska, Greenland, and Siberia. Modern pingos are generally restricted to 65°–75° north latitude. They usually occur in drained lake basins and former fluvial channels.

Origin and growth

Pingos develop when hydrostatic pressure of water causes upheaval of a layer of frozen ground. This upward growth causes dilation and radial cracks which may form fractures, trenches, and gullies. In general, small pingos have closed tops while large ones have open tops often with a crater sometimes accommodating a shallow lake in summers.

On the basis of their mode of formation, pingos are divided into following two categories:

(a) Hydrostatic or closed system pingos
(b) Hydraulic or open system pingos

Hydrostatic or closed system pingos generally found in low lying areas like thermokarst and thaw lakes where permafrost is continuous. During summer months, melting often causes overflow along the banks causing draining of lakes which results into formation of a layer of permafrost above talik; the unfrozen bottom of the lake. Now this permafrost surrounding talik advances into it. Water within the talik gets pressurized due to expansion and freezing of newly forming ice and therefore moves upwards (direction of least resistance) making the ground above it to rise into a dome like, or elongated shape. Hydrostatic system pingos shape.

Hydraulic or open system pingos also known as Greenland type generally occur in valley bottoms, mostly in the areas of discontinuous permafrost. They are called open system pingos because of water flows into permafrost from an outside source (e.g., an aquifer). An ice core develops as the continuously infiltrating water is frozen by permafrost. This expanding ice forces the overlying surface upwards ultimately creating the dome-like form of pingo.

However, formation process of hydraulic pingos is still not completely understood.

Pingos generally grow with the rate of a few centimeters per year. They follow a growth cycle and eventually break down and collapse leaving water filled hollow (known as *ognip*). After a while, another cycle of pingo formation may take place in the same site.

Pingo ice may help in finding past climatic conditions.

PLASTIC DEFORMATION

A. K. Singh
DIAT (Deemed University), Girinagar, Pune, Maharashtra, India

Plastic deformation is a permanent change in shape or size of a solid body without fracture resulting from the application of sustained stress beyond the elastic limit.

Mechanically, snow exhibits viscoelastic properties. The viscous qualities of snow allow it to deform slowly, in some cases, without fracture. The elastic properties of snow allow energy to be stored and this sets the stage for the brittle type fracture. Many materials have well-defined failure criteria but snow does not. How snow reacts to the application of stress is determined by its complex and interrelated physical properties, as well as, the rate of stress application. When snow lies on a slope, the relationship between strength and stress becomes important. In general, the stress condition is simply related to the mass of snow on the slope and the slope angle, but strength is controlled by the complex properties of numerous individual layers. Thus, the process of ice and snow deformation should be divided into stages, each with its peculiar deformation mechanism, depending on the state of the snow, that is, on its structure, density, and temperature. Researchers have shown that the deformation of snow is accompanied by an increase in the number and areas of contacts between individual crystals. The growth of contact areas results in the increase of adhesion. In due time, the mechanically joined but initially separate crystals freeze together. On the other hand, deformation of snow is associated with breaking of structural connections.

Glide and diffusional processes play significant roles in the plastic deformation of polycrystalline ice (glacial ice considered as polycrystalline). Ice deformation is strongly dependent on temperature (factor A in Glen's flow law). Compression experiments show that polycrystalline ice deforms instantly when a stress is applied suddenly.

PLASTIC FLOW

A. K. Singh
DIAT (Deemed University), Girinagar, Pune, Maharashtra, India

Plastic flow is a rheological phenomenon in which flowing behavior of the material occurs after the applied

stress reaches a critical value (yield). The viscosity of the ice (related to the ice temperature), and the nature of the bed over which it flows and the ice/bed coupling mechanisms, all interact to control ice flow rate. Glacier flow is a classical example of plastic flow and is a simple consequence of the weight and creep properties of ice. As ice tends to build up in the accumulation area of a glacier, a surface slope towards the ablation zone is developed. This slope and the weight of the ice induce a shear stress throughout the mass. When subjected to a shear stress over time, ice will undergo creep, or plastic deformation. The rate of plastic deformation under constant shear stress is initially high but tapers off to a steady value. This illustrates what is known as the flow law or constitutive law of ice called Glen flow law by glaciologists: the rate of shear strain is approximately proportional to the cube of the shear stress. It is the basis for all analysis of the flow of ice sheets and glaciers. Ice deformation is strongly dependent on temperature (factor A in Glen's flow law).

Glacier movement occurs by basal sliding and plastic flow of the lower part of the glacier, and passive riding along an overlying rigid zone. Due to friction between the glacial ice and the valley sides and floor, valley glacier flow is fastest at the top center of a glacier and slowest along its margins.

Other studies have suggested that many glaciers and ice sheets do not slide on a rigid bed but ride on a deforming layer of water-charged sediment. This phenomenon is difficult to analyze because the sediment layer may thicken or thin, and thus its properties may change, depending on the history of deformation. In fact, the process may lead to an unsteady, almost chaotic, behavior over time.

PLEISTOCENE EPOCH

Amit Kumar
Department of Geology, Centre of Advanced Study in Geology, Punjab University, Chandigarh, India

Synonyms

Glacial epoch; Pleistocene epoch

Definition

The term "Pleistocene" (Gr. pleistos, "most"; kainos, "recent") was introduced by the British geologist Charles Lyell in 1839. In the geological time scale, it followed the Pliocene epoch and preceded the Holocene epoch of Quaternary period. The Pleistocene covers a period from about 1.8 million years ago to about 11,800 years ago, according to the time scale released by the International Commission on Stratigraphy in 2004.

Pleistocene (Pleistocene epoch, Glacial epoch), also commonly referred to as the Ice Age, represents the extensive glaciation of the northern hemisphere. During that time, there were a number of advances and retreats of the glaciers, which are termed as glacial and interglacial stages, respectively. It was when the world's temperate zones were alternately covered by glaciers during cool periods and uncovered during the warmer interglacial periods that the glaciers retreated. The glaciers of Greenland and Antarctica are leftovers of the last glacial advance, and we presently reside in an interglacial stage termed the Holocene epoch. At the ending of Pleistocene (and the beginning of the Holocene) about 11,000 years ago, the Ice Age ended. It is to be expected that the Earth will experience another glacial advance, perhaps in the next 10,000–20,000 years, and that the glacial/interglacial cycles will continue.

Amit Kumar
Department of Geology, Centre of Advanced Study in Geology, Panjab University, Chandigarh, India

Glaciers have played an important role in the development of landscapes in the middle, high latitudes and also in alpine environments. Glaciers have ability to erode soil and rock mass, and transport of sediment. As a glacier flows downwards hill, there may be an obstruction which causes a development of high-pressure zone on the up-ice side and a low-pressure zone on the down-ice side. Basal ice melts in the high-pressure area and the resulting meltwater infiltrates through cracks present in the bedrock. It results in removal of relatively large fragments of bedrock by direct glacial action, which is known as plucking.

Synonyms

Sub-polar glaciers; Thermally complex glaciers

Definition

Polythermal glacier. A glacier that has a mixed basal thermal regime, consisting of both warm ice (at 0°C) and cold ice (below 0°C).

Introduction

Glaciers are commonly divided into three types according to their basal thermal regime: cold-based, warm-based, and polythermal. Polythermal glaciers are glaciers that have a mixed basal thermal regime. These glaciers have warm ice (at 0°C) in their interior where the ice is thick and is warmed to the pressure melt point, and cold ice (below 0°C) around their margins where ice is thin and on their surface. Typically, it is the thicker, higher-level ice in the accumulation area that is warm-based and it is the snout, lateral margins and surface layer of the glacier that are below the pressure-melting point.

Geographical distribution of polythermal glaciers

Polythermal glaciers are widely distributed around the world. They are particularly a feature of the Arctic: they occur widely on Svalbard and throughout the Canadian Arctic. They also occur in other regions of the world, including the European Alps, the Caucasus, the Polar Urals, and Altai. Polythermal glaciers are probably also common on the Antarctic Peninsula, although there are few specific measurements to substantiate this. In different geographical regions, polythermal glaciers may have markedly different proportions of warm and cold ice. For example, Canadian high-arctic polythermal glaciers typically consist predominantly of cold ice with only a thin area of warm basal ice. Conversely, Svalbard-type polythermal glaciers typically consist predominantly of warm ice with a smaller, thin layer of cold basal ice around the margins and on the surface.

Dynamics of polythermal glaciers

This mix of thermal regimes makes the dynamics of polythermal glaciers complex. The typical polythermal glacier moves by sliding on its bed or subsole deformation where warm-based ice dominates, and moves only by internal deformation where it is cold-based, for example, at the snout and lateral margins. Meltwater tends to follow supra- and englacial routes and well-developed basal hydrological networks are rare. As a result, polythermal glaciers tend to carry a high basal debris load, with debris-rich basal ice zones between 1 and 3 m thick, and debris concentrations of up to 50%. Their surfaces rarely have a substantial cover of debris, although medial moraines are commonly observed in their lower ablation areas.

Superimposed ice (formed by the refreezing of melted snow) is common on the surface of polythermal glaciers. This superimposed ice forms on the glacier surface if there are short periods of positive air temperatures in early winter, often coinciding with rainfall, which cause rapid glacier-wide melting. Percolating water then refreezes to form superimposed ice on the lower half of the glacier, and wetted-refrozen snow and ice lenses at higher altitudes. The formation of superimposed ice has significant implications for the mass balance of polythermal glaciers, because it locally comprises up to 20% of the winter balance and accounts for between 16% and 25% of the annual accumulation. The contribution from superimposed ice to glacier mass balance is therefore potentially very significant on many polythermal glaciers. The equilibrium line, which is not a physically marked feature on many polythermal glaciers, is often somewhere in the superimposed ice zone on these glaciers.

Svalbard, which contains numerous polythermal glaciers, is also famous for its high proportion of surge-type glaciers. An estimated 35% of the glaciers on Svalbard are surge-type. These glaciers are prone to dramatic increases in velocity, often accompanied by rapid frontal advances, followed by periods of quiescence during which velocities are generally low. Surge-type glaciers in Svalbard typically have relatively long quiescent phases (10–200 years) between short-lived surge events (1–5 years). It is not clear why these polythermal glaciers should be prone to surge-type behavior.

Sediments and landforms associated with polythermal glaciers

Field observations of the sediments and landforms produced by polythermal glaciers on Svalbard indicate that these glaciers are strongly influenced by structural glaciological controls on debris entrainment and transport. For example, moraine-mound complexes in front of receding Svalbard glaciers are formed by proglacial and englacial thrusting, folding, and deformation of the ice during glacier flow, particularly during rapid advances or glacier surges. On a smaller scale, a range of glacier structures arrange debris into foliation-parallel ridges, supraglacial debris stripes, and geometrical ridge networks.

Deformation of permafrost is also important in the formation of ice-cored moraines and push moraines in front of polythermal glaciers. Stresses beneath the advancing glaciers are transmitted to the proglacial sediments and can be sufficient to cause proglacial deformation of the permafrost layer. Folding, thrust-faulting, and overriding of proglacial sediments are also possible under these conditions. The nature of the deformation is controlled by the mechanical properties of the sediment, which is influenced by the water content and thermal condition, and whether it is frozen or unfrozen.

Summary

Polythermal glaciers are those glaciers that have a mixed basal thermal regime. They have warm ice (at 0°C) in their interior where the ice is thick and is warmed to the pressure melt point, and cold ice (below 0°C) around their margins where ice is thin and on their surface. They have a restricted geographical range and are particularly common in the Arctic, suggesting that there are climatic controls on their distribution. Proglacial and englacial thrusting, folding, and deformation of the ice are common during glacier flow, as is the deformation of permafrost in proglacial areas.

PRECIPITATION

Donna F. Tucker
Department of Geography, University of Kansas, Lawrence, KS, USA

Definition

Precipitation: Solid or liquid phase water particles that are formed in the atmosphere and that fall and reach the earth's surface. The quantity of such particles that have reached the earth's surface at a given location over a given period of time.

Introduction

Precipitation may take a variety of forms including rain, snow, sleet, and hail. The form depends on whether the water is frozen and also on the formation mechanism of the precipitation. The quantity of precipitation is generally measured in linear units of liquid water (e.g., millimeters or inches) – with an assumption that this measurement is per unit area. Snow accumulation is also measured as depth above the surface.

Formation of precipitation

Condensation of water vapor in the atmosphere may take place when the air is saturated. Air is typically brought to saturation by cooling and this cooling is generally accomplished by upward motion and the resulting adiabatic expansion of the air. The saturation vapor pressure over a curved surface is much higher than that over a flat surface. To form a stable water droplet would require much larger supersaturations than are observed in the atmosphere unless the water condensed on some other substance. Condensation on another substance reduces the radius of curvature of the water droplet. Thus, water vapor requires solid and liquid particles known as condensation nuclei on which to condense. The concentrations of these nuclei vary greatly in the atmosphere from the order of 10–1,000 cm^{-3} (Pruppacher et al., 1997). Larger values are found over the continents and urban areas and these appear due to human influence (Andreae and Rosenfield, 2008). Some condensation nuclei, known as hygroscopic nuclei, have a particular affinity for water and water may condense on them at relative humidities that are less than 100% (with respect to a flat surface of pure water).

Deposition of ice in the atmosphere requires that the atmosphere be saturated and also that the temperature be below the freezing point of water. At temperatures above −40°C, deposition requires, in addition, that suitable particles known as ice nuclei are present. The exact properties that make a substance a suitable ice nuclei are not well known (Cantrell and Heymsfield, 2005). The number of ice nuclei in the atmosphere varies with temperature – more ice nuclei activate at lower temperatures – but averages about 1/L at −20°C. Thus, ice nuclei are considerably scarcer than condensation nuclei.

Water droplets and ice crystals fall under the influence of gravity but their fall is impeded by air resistance. Therefore, they do not continue to accelerate indefinitely but reach a terminal velocity. Cloud droplets are typically 2–50 μm in diameter. To reach the earth's surface in a reasonable period of time, their volume must increase about a million times (Wallace and Hobbs, 2006). Ice crystals must grow larger still.

Water droplets can grow larger by additional condensation. Condensation is favored on larger droplets as well as

on droplets containing dissolved substances. Water droplets can also grow by encountering and merging with other cloud droplets in a process known as collision and coalescence, which also favors the growth of larger droplets as opposed to smaller ones. Precipitation can and does develop in clouds whose temperatures are not low enough for ice crystals to form. Such conditions are more likely to occur in the tropics and subtropics than in middle or polar latitudes.

Ice crystals can also grow larger by additional deposition of water vapor. But since there are relatively few ice nuclei in the atmosphere, ice crystals and supercooled water droplets often coexist in clouds whose temperature is below freezing. The saturation vapor pressure over water is greater than that over ice. Thus, conditions can exist where the water droplets are subsaturated and the ice crystals are supersaturated. The ice crystals grow at the expense of the water droplets in what is known as the Bergeron process. The Bergeron process is responsible for the vast majority of precipitation (including rain) in middle and higher latitudes as well as in tropical thunderstorms. Ice crystals are always six sided but may take a variety of forms: columns, needles, plates, and the elaborate branching structures, known as dendrites, of the stereotypical snowflake. The structure of the ice crystal is dependent on the temperature and humidity of the air in which it forms (Rogers and Yao, 1989). Ice crystals may collide and merge in a process called aggregation. In addition, ice crystals may encounter water droplets that freeze on impact with the ice crystal. This process is known as riming. Aggregation efficiency depends on temperature but riming efficiency is close to one (Houze, 1993).

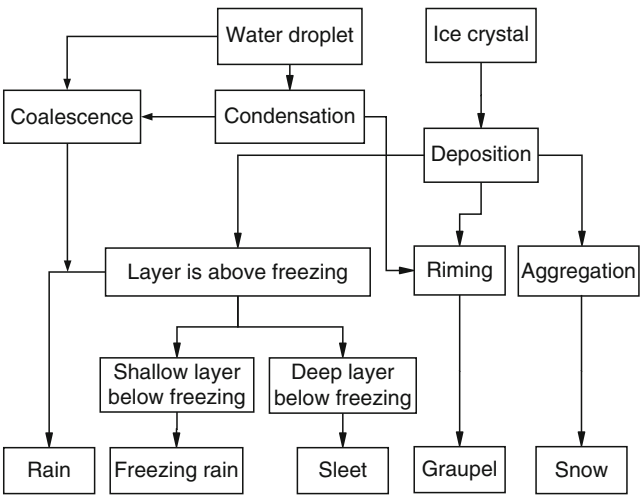
Types of precipitation

Precipitation in the liquid form when it reaches the earth's surface may be divided into two categories: rain and drizzle. The distinction between them is entirely based on size–drizzle drops are less than 0.5 mm in diameter and raindrops are at least 0.5 mm in diameter. Drizzle typically falls from fog or low stratus clouds and generally produces small quantities of precipitation. Rain will fall from nimbostratus or cumulonimbus clouds.

Likewise, frozen precipitation that has experienced a little or no riming and has not previously melted may come in the form of snow or snow grains. Snow is larger in size having often experienced aggregation, especially if the temperature is near freezing. Snow grains are the frozen equivalent of drizzle and typically fall from fog or low stratus clouds. They are small, white, and opaque with diameters less than 1 mm. Snow crystals that are moderately rimed are called graupel, snow pellets, or soft hail. They are white due to their core, which was formed by deposition. They are typically 2–5 mm in diameter and may bounce when they hit the ground.

When ice crystals fall though a thick enough layer that is above freezing they will melt. If they then fall through another fairly thick layer that is below freezing before they reach the ground, they will refreeze. The resulting precipitation is called ice pellets or sleet (in the USA). (In British English, sleet refers to a mixture of rain and snow [Sumner, 1988].) Ice pellets are transparent or translucent because they were formed by freezing liquid and not deposition of vapor. They are less than 5 mm in diameter. If the layer that is below freezing next to the earth's surface is very thin, a falling water drop may not have time to freeze before it hits the ground. In this case, the liquid water drop will freeze on contact with the ground creating a thin sheet of ice. The precipitation is then known as a freezing rain. Figure 1 illustrates the environment in which the various types of precipitation form. Freezing rain (and to a lesser extent, ice pellets) can be extremely hazardous to ground transportation because friction with a surface coated with freezing rain is even less than for a surface coated with snow. Freezing rain can also coat trees and power lines, unlike snow, which will fall off both if accumulations are high enough. Heavy coatings can break tree branches and power lines resulting in substantial damage.

Hail may be considered an extreme case of rimed ice crystals. Hail is greater than 5 mm in diameter. Hail typically has had several coatings of liquid water freeze on it. On larger hailstones, these layers can be seen if the hailstone is cut open. To collect enough water to grow to even minimum size, the embryo hailstone must remain in the cloud longer than other types of precipitation. Although there is some disagreement as to all the processes involved in forming a hailstone, it is generally agreed that the storm must have at least a moderately strong updraft to prevent the precipitation from falling out too soon. Thus, hail falls almost exclusively from cumulonimbus clouds. The shape and thickness of the thunderstorm updraft may be important factors as well as its orientation with respect to the downdraft.



Precipitation, Figure 1 Processes forming different types of precipitation.

Measurement of precipitation

Precipitation has traditionally been measured directly at the earth's surface with a container into which the precipitation falls. Snow drifts easily, so depth measurements (generally over a flat board) must be taken at multiple locations (Sumner, 1988). The water equivalent of snow varies greatly and the depth of snow changes depending on the length of time since the snow fell. Therefore, the liquid equivalent of the frozen precipitation has typically been a more useful measurement.

The standard rain gauge has a wide, usually circular, opening converging to a narrower inner tube. The cross-sectional area of the inner tube is generally one tenth that of the outer opening. The depth of precipitation is measured manually with a specially calibrated ruler. This method can be economically advantageous because of the low cost and durability of the equipment. Its disadvantage lies in the difficulty of determining the rate at which the precipitation fell.

A weighing gauge can record the rate of precipitation accumulation. It measures the change in weight as liquid accumulates in a container. The liquid equivalent of frozen precipitation can also be measured if a known weight of antifreeze solution is in the container. The antifreeze can also reduce evaporative losses of accumulated precipitation. The minimum amount of precipitation recorded depends on the sensitivity of the gauge. This type of gauge is more costly and needs to be calibrated often.

Remote readings of precipitation accumulation are easier with the tipping bucket type of rain gauge. This instrument has a small container that is divided in two. The container pivots around its center in a seesaw manner such that only one side of the container accumulates precipitation at a time. When a known weight of precipitation accumulates in one side of the container, it will tip, empty its load, and allow the other side to accumulate precipitation. The number of tips is recorded electronically. This type of gauge makes no record of less than some minimum precipitation accumulation – less than one tip's worth. It may have difficulty keeping up in very heavy rain and it tends to have more splash errors than other types of direct measurements.

Overall, these direct measurements are subject to a number of errors. One is that precipitation in the gauge may evaporate before it is recorded. Another is that moisture may adhere to the collecting tube and not be measured. The most serious errors occur because catch decreases with increasing wind speed. Gauges are usually mounted as close to the earth's surface as possible to minimize this error. Some gauges may be fitted with a windshield to help reduce this bias. It should be kept in mind that places with high average wind speeds may have precipitation measurements, which are consistently lower than the actual amount that fell (Strangeways, 2007). Even outside of windy areas, errors in gauge measurements trend more toward underestimating rather than overestimating the amount of precipitation that actually fell.

Sensors have also been developed to infer precipitation amounts from detection of individual drops. Drops may be detected optically or by measuring the impact of the drops on a surface. These instruments are relatively expensive and dependent on an algorithm to translate drops detected to rainfall amounts.

Precipitation displays extreme areal variability and it is not usually feasible to have enough gauges to measure most of the variability. Generally, the horizontal resolution of observations is very uneven. Thus, there is considerable incentive to estimate precipitation amounts with techniques yielding more spatial resolution.

Satellite measurements of infrared radiation (IR) in a narrow wavelength band have been related to precipitation. These estimates have been based on the assumption that higher clouds emitting less IR are more likely to be generating precipitation. This method works better in regions, such as the tropics, where most precipitation is convective in nature (New et al., 2001). The total outgoing IR radiation (i.e., wide band of wavelengths) has also been related to precipitation as it is also sensitive to soil moisture. Microwave radiation is more sensitive to cloud water and ice and thus easier to relate to precipitation directly. But the best algorithm for doing so varies by location and season (Kidd, 2001).

Radar reflectivity has also been used to estimate precipitation amounts. To use this technique a drop size distribution must be assumed. Estimates of precipitation may be poor if drop size distribution in a particular storm is unusual. This method cannot directly determine how much of the precipitation in the air will reach the ground without evaporating. This technique is more difficult to apply to frozen precipitation as radar is less sensitive to it. Obviously, it is only applicable in parts of the world with reliable radar measurements.

Perhaps the most promising way of determining how much precipitation has fallen is to combine remotely sensed and gauge data. These methods use the gauge data to reduce the impact of the assumptions, which must be made in remote sensing estimates. They are therefore able to take advantage of the high resolution of the remotely sensed data as well as the greater (but not perfect) accuracy of the gauge data (Young et al., 2000).

Summary

Precipitation takes a variety of forms. We have learned much about how precipitation forms but many unknowns remain. Although precipitation measurement is conceptually simple, in practice, precipitation varies greatly over small areas and doubts concerning accuracy are always present.

PROGLACIAL LAKES

Brenda L. Hall
Department of Earth Sciences and Climate Change Institute, Bryand Global Sciences Center, University of Maine, Orono, ME, USA

Definition

Proglacial lake. Ice-contact lake occurring adjacent to the frontal margin of a glacier.

Introduction

A proglacial lake abuts and extends beyond the glacier terminus. Many proglacial lakes are moraine-dammed, whereas others form in basins created by isostatic depression near the ice margin. These latter lakes commonly are buttressed by the ice itself. Not all ice-dammed lakes, however, are proglacial, so these terms are not strictly synonymous. Some ice-dammed lakes, for instance, form laterally, such as when a glacier dams river flow in a side valley. Possibly the best-known ice-dammed lake was Glacial Lake Missoula, which occupied thousands of square kilometers of western Montana and Idaho before draining catastrophically (many times) to the Pacific.

Proglacial lakes can be ephemeral in nature or persist hundreds, if not thousands of years. The transient nature of some lakes results from several processes, including drainage (catastrophic or otherwise) caused by breaching of the moraine dam or by gradual isostatic uplift. Proglacial lakes also infill with sediment over time and can be replaced by outwash plains or bogs.

The sometimes catastrophic nature of proglacial lake drainage presents a significant problem to society. Rapid outbursts caused by moraine failure or tectonic activity lead to property destruction and loss of life (i.e., Lliboutry et al., 1977; Richardson and Reynolds, 2000; Allen et al., 2009). Even without complete drainage, the surface-level of proglacial lakes tends to vary, because of the changing elevation of outlets (i.e., due to moraine degradation or isostatic rebound), advance or retreat of glaciers, and periods of large recharge (such as the summer melt season or rainfall events).

Proglacial lakes are a product of both glacial and interglacial times. For example, rapid ice recession over the past century has led to the development of new, commonly moraine-dammed proglacial lakes (Figure 1) associated with retreating alpine glaciers. During the last deglaciation, large proglacial lakes abutted the melting ice sheets in both North America and Europe. One of the most famous, Glacial Lake Agassiz, covered more than half a million square kilometers and occupied basins that sloped down toward the retreating Laurentide Ice Sheet over central Canada. Catastrophic drainage of this lake at ~8,200 years before present (Barber et al., 1999) occurred when lake water was able to float the remnant ice sheet and flow out through Hudson Strait. Some have argued that large injections of fresh meltwater into the climatically sensitive North Atlantic Ocean from lakes such as Agassiz caused shutdowns of thermohaline circulation and consequent cooling of the Northern Hemisphere several times during the last deglaciation (i.e., Teller, 2004; Teller and Leverington, 2004; although see Lowell et al., 2005 for an alternate interpretation).

Sedimentation

Proglacial lakes affect both the adjacent glacier and its sedimentation. Calving is a significant ablation process in proglacial lakes, with rates increasing as water deepens (Warren and Kirkbride, 2003). Thus, glaciers attached to proglacial lakes may retreat more rapidly than those terminating on land. Conversely, readvances occur more slowly, because the glaciers must overcome ice loss caused by calving.

Proglacial lakes can produce thick sedimentary sequences. Commonly, the sediments consist of rock flour, fine-grained glacial silt produced by subglacial abrasion. Such flour gives many proglacial lakes a characteristic milky or blue color. Strong seasonal differences in meltwater and sediment input lead to the formation of varves or other rhythmic bedding in some proglacial lakes. The sediments also can include ice-rafted dropstones. In

Proglacial Lakes, Figure 1 Photograph of Ventisquero Holanda (54° 56′S, 69° 07′W), Cordillera Darwin, Chile, with proglacial lake. This lake, which formed over the past several decades, is dammed by a moraine complex at its distal end.

polar regions, rare types of proglacial lakes, known as "proglacial lake-ice conveyors" can transport glacial till on their perennial ice cover kilometers beyond the actual glacier margin (Hendy et al., 2000) and deposit it in seasonally open water near the lake edge.

Proglacial lake sediments afford an opportunity for reconstructing glacier mass balance and climate (i.e., Leemann and Niessen, 1994). Different proxies, such as sediment grain size, preserved in annual layers, can be used to estimate changes in meltwater volume and glacier proximity. In some well-constrained cases, it is possible to estimate not only ice-marginal fluctuations, but (potentially) former equilibrium-line and temperature changes (i.e., Nesje et al., 2001; Shakesby et al., 2007; Thomas and Briner, 2009).

Summary

Proglacial lakes are common features of glacial landscapes. Drainage of large lakes that formed during the last deglaciation alongside the southern margin of the Laurentide Ice Sheet in North America have been implicated in abrupt climate change, although this is an area of ongoing research. The long records preserved in many proglacial lakes are receiving increasing attention as researchers look for high-resolution, continuous proxies of past glacier and climate fluctuations.

Definition

The Quaternary is the youngest Period/System division of the Geological Time Scale and represents 2.6 million years of geological time. It spans the Pleistocene (2.6–0.11 Ma) and Holocene (0.11–0 Ma) Series and includes the present day. It is essentially the "Ice Age" of popular terminology.

The term Last Glacial Maximum or LGM is widely used to refer to the maximum global ice volume during the last glacial cycle corresponding with the trough in the marine isotope record centered on ca. 18 ^{14}C Ka BP (Martinson et al., 1987) and the associated global eustatic sea-level low also dated to 18 ^{14}C Ka BP (Yokoyama et al., 2000).

Introduction

Since the recognition in the mid-nineteenth century that glaciers had been considerably more extensive than at present, the Quaternary has been synonymous with glaciation of the mid-latitudes. Today evidence from both the land and ocean-floor sediment sequences demonstrates that the major continental glaciations occurred repeatedly over what are now temperate regions of the Earth's surface. Knowledge about the number of glaciations has increased, and also knowledge about the extent of the Pleistocene ice sheets. Recent progress can be seen in a comparison between the glacial limits of the northern European ice sheets as summarized by Flint (1971) and by the INQUA Work Group 5 project "Extent and Chronology of Quaternary Glaciations" (2004) (Figure 1). While the maximum extent has undergone comparatively few changes, the Late Weichselian ice sheet has changed fundamentally. Today, a single ice sheet is envisioned instead of Flint's three major glaciation centers. Major differences include the (1) glaciation of the Bering Sea, (2) non-glaciation of the North Sea, (3) non-glaciation of the northern Urals, and (4) limitation of glaciation in Siberia to the Putorana Massif and the Taimyr coast. Extensive ice-rafting, an indication that glaciers had reached sea-level, is found from the earliest cold stage (2.6–2.4 Ma) in both the North Atlantic and North Pacific oceans (cf. Haug et al., 2005). The initiation of conditions that resulted in glaciation are a consequence of the long-term declining cooling trend in world climates that began early in the previous Tertiary Period. Apart from some limited activity in the Eocene, significant glaciation began in the late Oligocene (*c*. 35 Ma) in eastern Antarctica. It was followed by mountain glaciation through the Miocene (23–5.3 Ma) in Alaska, Greenland, Iceland and Patagonia, and later in the Pliocene (5.3–2.6 Ma) in the Alps, the Bolivian Andes and possibly in Tasmania. From the Neogene, glacially derived ice-rafted debris is found in ocean-sediment cores from the North Atlantic region, including the Barents Sea, and areas adjacent to Norway, N and SE Greenland, Iceland and northern North America, and in the Southern Ocean off-Antarctica.

Glaciation during the Quaternary

The climatic variation that characterizes the Earth's climate during the late Cenozoic, and indeed before, is controlled by variations of the Earth's orbit around the Sun that therefore controlled the receipt of solar energy at the Earth's surface. These Milankovitch variations, named

after their discoverer, are responsible for the cyclic climate changes that characterize the Quaternary and indeed much of Earth's history. One of the most critical ways they are expressed is through the development of "Ice Ages" or periods when glaciation extended across large areas of the Earth. The Early Pleistocene (2.6–0.8 Ma) was characterized by climatic fluctuations dominated by the 41 Ka precession cycle, during which relatively few cold periods were sufficiently cold and long to allow the development of substantial ice sheets. Only 14 of the 41 cold stages of that period currently show evidence of major glaciation. They include the Plio-Pleistocene boundary events Marine Isotope Stage (MIS) 104, 100, and 98, together with Early Pleistocene MIS 82, ?78, 68, 60, 58, 54, 52, 36, 34, ?30, and 26 which reach δ18O ocean‰ of *c*. 4.6–5. It is not until the transition in dominant orbital cyclicity to the 100 Ka cycles, which began *c*. 1.2 Ma and was fully established by about 800 Ka ("middle Pleistocene transition"), that the cold periods (glacials) were regularly cold and long enough to allow ice-sheet development on a continental scale, outside the polar regions. However, it is during MIS 22 (*c*. 870–880 Ka) that the first of the "major" cold events that reached critical values of *c*. 5.5 or above δ18O ocean‰ equivalent to substantial ice volumes that typify glaciations of the later Pleistocene (i.e., MIS 16, 12, 10, 6, 4–2). Potentially therefore, it is likely that there were a minimum of 20 periods during which extensive glaciation could have developed during the last 2.6 Ma, with the most extensive (*c*. 5–6 periods) being limited to the last 900 Ka (Tables 1–3).

Precisely where these glaciations occurred and how far they extended is very difficult to determine, given that the remnants of less extensive early glaciation tend to be obliterated and mostly removed by later, more extensive advances. Although this is so in all terrestrial areas, it is especially difficult in mountain regions where the preservation potential of older sequences rapidly diminishes with time and subsequent glaciation. However, examination of the frequency of glaciation through the Cenozoic indicates that glaciation in the Southern Hemisphere having been established first, principally in Antarctica and southern South America, occurred continually from the

early Neogene to the present day. By contrast, Northern-Hemisphere glaciation, although initially somewhat restricted, increased markedly at the beginning of the Quaternary, increasing again in frequency in the latest Early Pleistocene and reaching very high levels in the Middle–Late Pleistocene. While this pattern is not unexpected, the striking increase in ice sheets through the Quaternary clearly emphasizes that worldwide glaciation is in effect a northern-hemispheric phenomenon.

Examination of the evidence accumulated in the INQUA project "Extent and Chronology of Quaternary Glaciations" (Ehlers and Gibbard, 2004a, b, c), supported by other published sources, demonstrates the current state of knowledge. When examining the resulting tables (Tables 1–3), it is important to bear in mind that the stratigraphical control between regions, beyond the range of radiocarbon dating, is weaker than might be desired. This is particularly a problem outside Europe where biostratigraphy is less well developed and the sheer extent of the unexplored regions makes future discoveries likely. Thus, the presentation below can only be a first step toward a comprehensive overview. The correlations applied here are based on the Global Correlation Chart (Gibbard and Cohen, 2008).

Plio-Pleistocene glaciation

Evidence of glaciation is widespread from throughout the Quaternary and indeed the Neogene in the northern hemisphere. The longest sequences are restricted to Alaska, and the adjacent North-West Territories of Canada which, together with Greenland and the Rockies, preserve evidence of glaciation from the Neogene to the present. In northern Canada and Alaska, the oldest till and accompanying ice-rafted detritus in marine settings dates from the Early Miocene, with regionally widespread glaciation occurring in the Pliocene and regularly throughout the Pleistocene (cf. Haug et al., 2005). In adjacent British Columbia, a comparable sequence is found, particularly in the north. Similarly, in Greenland and Iceland, glaciation began in the Miocene, occurring regularly through the Pliocene and onward to the present day in the mountains. Likewise, in Norway, its adjacent offshore and the neighboring Barents Sea, glaciation is recorded from the Early Miocene, Early Pliocene, and Plio-Pleistocene. By the late Miocene, inland ice shields were periodically present in Greenland, especially in the mountainous east, with ice reaching the sea in SE Greenland, while contiguous ice sheets have occurred since the earliest Pleistocene (*c*. 2.3 my) (Funder, personal communication, 2003). In the eastern Rockies of the USA, a much shorter glacial sequence occurs. Here Plio-Pleistocene-aged till is known from Montana, North Dakota, and California. On Mount Kilimanjaro, in East Africa, the first glaciation is recognized at *c*. 2.0 my (*c*. MIS 68). In Europe, glaciation before the Middle Pleistocene glaciation is represented only by ice-rafted material, outside the mountain regions (e.g., in the Netherlands, lowland Germany, European Russia, and Britain). Substantial glaciation of the Baltic region late in the Early Pleistocene is indicated by erratic materials in the Netherlands (1–1.2 Ma; MIS 34–36). Glaciation is also established in the Alps from the Plio-Pleistocene.

In the southern hemisphere, glaciation is much longer established, as noted above. Here the ice already formed in the Late Eocene – Early Oligocene in East Antarctica and built up in a step-like pattern through the Neogene. The present polar conditions were already established by the Early Pleistocene after 2.5 Ma. A similar history is known from the Piedmont areas of Argentina and Chile, where substantial ice caps were established by 14 Ma. Widespread lowland glaciation occurred here between 2.05 and 1.86 Ma (*c*. MIS 68–78), followed by the "Great Patagonian Glaciation" that took place at 1.15–1.00 Ma (*c*. MIS 30–34). Further north, the earliest glaciation recorded in the Bolivian Andes dates from 3.27 Ma, with extensive events at 2.2 Ma (*c*. MIS 82). In Columbia, the record also begins at 2.5 Ma. The earliest records in Australiasia are found in Tasmania and New Zealand from the Plio-Pleistocene (2.6 Ma: MIS 98–104). Only slightly younger is New Zealand's oldest known glacial event (the Porika Glaciation).

The 'glacial' Pleistocene

The 'glacial' Pleistocene effectively begins with ice sheets spreading over vast lowland areas, particularly around the North Atlantic region, and the intensification of global cold period (glacial) climates, in general. It coincides with the 'Middle Pleistocene transition' (1.2–0.8 Ma) when the transition from the dominant 41–100 Ka Milankovitch orbital cyclicity resulted in periods sufficiently cold and long to allow the development of continental-scale ice sheets.

The till sheets of the major glaciations of the 'glacial Pleistocene' are found throughout major parts of Europe and North America, and especially in the lowlands and under the sea. Widespread lowland glaciation began in the early Middle Pleistocene shortly after the Brunhes/Matuyama palaeomagnetic reversal (780 Ka). In Europe, the phases represented include the Weichselian (Valdaian, MIS 4–2), Saalian (Dniepr and Moscovian, MIS 6, 8 and 10), Elsterian (Okan, MIS 12), and the Donian (Narevian, MIS 16). More limited glaciation may also have occurred in the circum-Baltic region during the latest Early Pleistocene (MIS 20 and 22). Curiously, evidence for early Middle Pleistocene glaciation is absent from the North Atlantic and Norway, while it is certainly present in Denmark, the Baltic region, and European Russia. In the Italian Dolomites, glaciation becomes established in MIS 22 (Muttoni et al., 2003). Comparable evidence is also found from north of the Alps in Switzerland and southern Germany. Further to the west, in the Pyrenees, the oldest glaciation identified is of late Cromerian age (MIS 16 or 14). Widespread lowland glaciation again is first seen throughout North America in MIS 22. From this

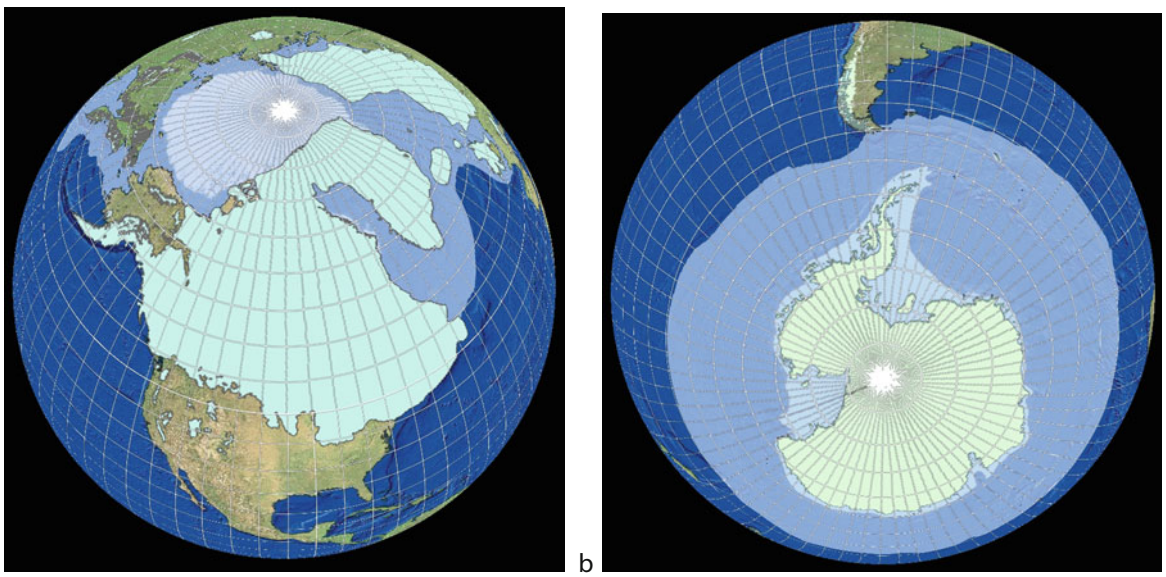
point onward, major ice sheets covered large regions of the continent during the Middle Pleistocene pre-Illinoian events MIS 16, 12, 8 and 6 (Illinoian *s.s.*) and the Late Pleistocene MIS 2–4 (Wisconsinan). In Mexico, the oldest moraines on volcanoes have been dated to 195 Ka and probably relate to a pre-MIS 6 glaciation. Evidence from East Greenland suggests that its quasi-permanent ice sheet may have almost disappeared during the Eemian Stage interglacial (*c*. MIS 5e) (Funder, personal communication, 2003). Glaciation of Tibet and Tianshu is not recorded before the Middle Pleistocene, of which MIS 12 was the most extensive. In Tainshu, older glaciation (?MIS 16) may have also occurred. This apparently delayed glaciation of the Himalayan chain might reflect late uplift of high Asia. Subsequent events took place during MIS 8, 6 and 4–2, and continue today in the highest peaks.

As in Europe and North America, glaciation increased in intensity throughout the Andean chain from 800 Ka to the present day, but in the south, it was less extensive than during the Early Pleistocene events. In Australasia, following a 1 Ma break, the glacial record continues in MIS 12, followed by MIS 6, 4, and 3. In Tasmania, an early Middle Pleistocene event, possibly during MIS 16, is followed by glaciations during MIS 6 and 3. The glacial record during this time in Africa is restricted to the East African mountains Mount Kilimanjaro, Mount Kenya, and the High Atlas, where glaciations appear to be broadly equivalent to those elsewhere, i.e., during MIS 12, 6, and 2.

Last glaciation

The term Last Glacial Maximum or LGM is widely accepted as referring to the maximum global ice volume during the last glacial cycle corresponding to the trough in the marine isotope record centered on ca. 18 ^{14}C Ka BP (Martinson et al., 1987) and the associated global eustatic sea-level low also dated to 18 ^{14}C Ka BP (Yokoyama et al., 2000). It has also been assigned chronozone status (23–19 or 24–18 Ka cal BP dependent on the dating applied) by Mix et al. (2001) who consider the event should be centered on the calibrated date at 21 Ka cal BP (i.e., LGM sensu stricto). However, since the last maximum glaciation after MIS 5 occurred much earlier in some areas than in others, the term LGM should be used with care.

During the LGM, the extent of the glaciation of the Southern Hemisphere differed very little from that of the Pleistocene glacial maximum. Glaciers in Antarctica still reached to the shelf edge, and on New Zealand, Tasmania, and in South America, the glacier tongues were only slightly smaller than during earlier events (Andersen et al., 1999; Coronato et al., 2004a, b). On mainland Australia, local mountain glaciation occurred (Barrows et al., 2001, 2002). It seems that the LGM in the Southern Hemisphere began earlier than in the Northern Hemisphere, probably around 27 Ka (Suggate and Almond, 2005). The high mountains of East Africa were glaciated (Osmaston, 2004). There is no unequivocal evidence of glaciation in South Africa, although minor glaciers have been postulated by various authors (Borchert and Sänger, 1981; Hall, 1994). However, it must be borne in mind that South Africa is located relatively close to the equator to the North. Were it in the Northern Hemisphere, Cape Town would be situated at the same latitude as Atlanta in Georgia, USA or, if placed relative to the European ice sheet, it would be south of Tunis. Consequently, sea-ice cover did not reach the southern end of Africa (Figure 2b).



Quaternary Glaciation, Figure 2 Distribution of glaciers and sea ice in the Northern and Southern Hemispheres during the Last Glacial Maximum.

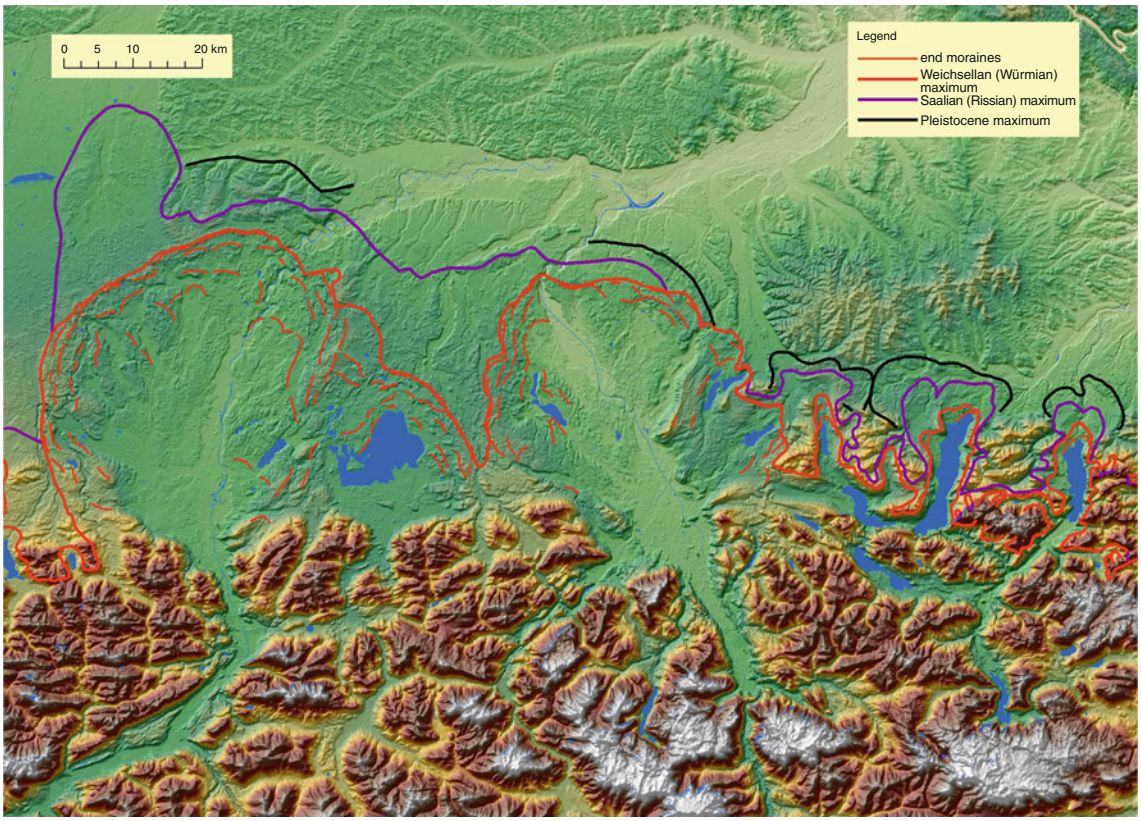
During the LGM, ice in many parts of the Northern Hemisphere reached an extent very similar to the Quaternary glacial maximum. In North America, the differences are very small. Again, most parts of Canada were ice covered, including the shelf areas (Dyke, 2004). It is the same in Greenland (Funder et al., 2004; Weidick et al., 2004). The map of global ice distribution (Figure 2a) shows that while sea-ice cover went very far south, most parts of the land areas of Beringia remained ice free.

In Europe, however, the situation was different. New evidence suggests that the North Sea was not fully glaciated during the Weichselian glacial maximum but slightly earlier (Sejrup et al., 1994, 2009; Carr, 2004). An ice sheet covered the Barents Sea and extended well into the Kara Sea but hardly touched the Russian mainland (Svendsen et al., 1999; Svendsen et al., 2004a, b). The ice sheet was markedly smaller than during the Quaternary glacial maximum. It seems that the northwards drainage of the Ob and Yenisei rivers was not impeded (Lambeck et al., 2006). Not only the glaciation of the Alps has been mapped in great detail (Figure 3), but also knowledge of the mountain glaciations has increased considerably. In glaciated mountain areas outside the major ice sheets, such as in Italy and Greece, the maximum Middle Pleistocene glaciations were much bigger than the local last glacial maxima (Giraudi, 2004; Woodward et al., 2004). This is attributed to a change in equilibrium-line altitude (ELA) because it has a much bigger impact on glacier size in areas characterized only by mountain glaciation than in areas where ice covered the lowlands during multiple glaciations.

There were major ice sheets or mountain glacier systems in the Siberian mountains further to the east. Because of the lack of detailed investigations to date, in most cases, it is not possible to differentiate between the extent of the LGM and earlier glaciations (Glushkova, 2001; Zamoruyev, 2004). Likewise, the age and extent of the glaciers in Iran and the mountain ranges and high plateaux further to the east, and especially the extent of glaciation on the Tibetan Plateau, are still matters of debate (Owen et al., 2003; Klinge and Lehmkuhl, 2004; Kuhle, 2004; Lehmkuhl and Owen, 2005; Abramowski et al., 2006). In contrast, the small mountain glaciers of Japan are well mapped and dated and, unlike those of the adjoining Asian mainland, the maximum ice advance of the last glaciation occurred in MIS 4 (Sawagaki et al., 2004). The same date for the maximum extent is found in New Zealand (Suggate, 1990; Preusser et al., 2005).

Summary

The Quaternary is synonymous with extensive glaciation of Earth's mid- and high-latitudes. Although there were



Quaternary Glaciation, Figure 3 Northern margin of the Alpine ice sheet draped on the SRTM terrain model.

local precursors, significant glaciation began in the Oligocene in eastern Antarctica. It was followed by glaciation in mountain areas through the Miocene (in Alaska, Greenland, Iceland, and Patagonia), later in the Pliocene (e.g., in the Alps, the Bolivian Andes, and possibly in Tasmania) and in the earliest Pleistocene (New Zealand, Iceland and Greenland). Today evidence from both the land and the ocean floors demonstrates that the major continental glaciations, outside the polar regions, rather than occurring throughout the 2.6 Ma of the Quaternary, were markedly restricted to the last 1 Ma to 800 Ka or less. Marine Isotope Stage (MIS) 22 (*c*. 870–880 Ma) included the first of the 'major' world-wide events with substantial ice volumes that typify the later Pleistocene glaciations (i.e., MIS 16, 12, 10, 6, 4–2).

Radar and glaciology

Definition

Radar. The term RADAR is an acronym for "RAdio Detection And Ranging." Radar is a system that uses electromagnetic waves to determine range, speed, direction, and physical properties of any target. Typically, a radar system has a transmitter and a receiver. The transmitter transmits the electromagnetic waves. The transmitted waves are reflected back by the target and are sensed using the receiver. The amplitude, phase, and the frequency shift of the received waves with respect to the transmitted waves give a measure of the properties of the target.
Snow. Dry snow is the mixture of ice and air whereas wet snow is the mixture of ice, air, and contents of free liquid water (wetness).
Ice. A mass of frozen water.
Glacier. A large mass of ice, which is moving very slowly through a valley or spreading outward from a center. Glaciers form over many years from packed snow in areas where snow accumulates faster than it melts.

Introduction

This entry elucidates the recent developments in the application of Microwave Remote Sensing techniques particularly space borne synthetic aperture RADAR (SAR) systems for snow, ice, and glacier studies. SAR is an active system imaging the earth's surface in day and night, in all weather, through cloud or haze, and their spatial resolution is compatible with the topographic variations in the Himalayan region. Currently space borne synthetic aperture RADAR data are widely used to map glacier-covered area in alpine and Himalayan regions and also to develop algorithms to infer geophysical parameters. Backscatter image of RADAR is extremely useful for the quantitative estimation of snowpack characteristics like snow wetness, snow grain size, snow density, and snow water equivalence, which are essential for hydrologic applications.

SAR data can also be useful to map snow cover and also identify different types of snow. Multi-temporal SAR data have great potential in mapping glacier facies which has distinct advantage in the glacier mass balance estimation. Various satellite SAR systems available in the past and present are presented in Table 1.

Radar data processing methodology

Calculation of backscattering coefficient
For any meaningful and quantitative analysis of Radar images, it is necessary to convert the DN values of these intensity images into their corresponding radar backscattering coefficient (σ^o) values. A variety of factors influence backscatter strength including satellite ground-track, incidence angle, radar polarization, surface roughness, and the dielectric properties of the surface. Different objects having same digital number are likely to correspond to different backscatter values. Hence, more accurate analysis on microwave remote sensing image can be done on backscatter value images. For example, Advanced Synthetic Aperture Radar data processing methodology is given in this entry.

As described in ESA document Rosich and Meadows (2004), the backscattering coefficient (σ^o) values of ASAR are obtained by combining the radar average pixel intensity and the incidence angle (I_j) at each pixel location, where the angle of incidence is obtained from the ASAR header data using interpolation method.

Radar average pixel intensity was then converted into backscatter coefficient (σ^0) using the following equation Rosich and Meadows (2004):

$$\sigma_j^{\,0} = \frac{< DN^2 >}{K} \times \left(\frac{R_{\mathrm{d}}}{R_{\mathrm{ref}}}\right)^4 \times \left(\frac{1}{G^2}\right) \times \mathrm{Sin}(\mathrm{I}_j) \qquad (1)$$

where I_j is the incidence angle at the j^{th} range pixel (the angle between radar line of sight and vertical when assuming a flat earth or it is equivalent to look angle), K is the absolute calibration constant, $<DN^2>$ is average pixel intensity, G^2 is two-way antenna gain at distributed target look angle, R_{d} is distributed target slant range distance, and R_{ref} is reference slant range distance. All images were multi-looked five times in azimuth and one time in range direction. Originally the image size is 24,886 lines by 6,033 pixels. After multi-looking and also removing nonoverlapping portion of the image, the size of the image is 4,997 lines by 6,033 pixels. The final spatial resolution is about 19.5 m in azimuth and 7.8 m in range. All the images were subjected to speckle suppression using Frost filter (Frost et al., 1982) with window size 3 × 3, and coefficient of variation and smoothing parameter using ERDAS Imagine radar module. The backscatter intensity images were converted into backscattering coefficient by taking $10.\mathrm{Log}_{10}\,(\sigma_{\mathrm{j}}^{\,0})$.

Slant-to-ground range correction

Using slant-to-ground range correction tool, the satellite data are projected into ground distance. Each pixel represents a specific area on the ground. Multi-look images are projected from slant-to-ground range. The input (slant range) pixel size 7.8 m is converted into given output (ground range) pixel size 19.5 m using satellite parameters like near range look angle, satellite height, slant range pixel size, and near slant range. After slant-to-ground range correction, finally spatial resolution of image is about 19.5 m in azimuth and 19.5 m in ground range and the size of the image is 4,983 lines by 3,685 pixels.

Due to the oblique incidence of SAR beam the terrain features become distorted in the image. This terrain distortion correction is performed by relating each pixel in the SAR image into cartographic reference system using high precision digital elevation model (DEM) and knowledge of the imaging and processing geometry. Among the above parameters geometric structure of the target plays an important role to correct the radar backscatter coefficient values. The topographic effect can be removed from the backscatter coefficient values by considering the local incidence angle. Finally, real-time snow parameters collected on these dates at different locations have been considered for calculating snow parameters, and

corresponding backscattering values were obtained from the corrected SAR backscattering images. The data processing steps are shown in Figure 1.

Radar applications in snow

Microwave interaction with snow

Microwave interaction with snow depends on dielectric and geometric properties of the object. Sensor properties also influence the target response to incident wave. In the case of snow-covered terrain, the total backscattered signal is the sum of scattering from air-snow, volume scattering in the snow layer, and scattering from the snow-ground attenuated by snow layer (Ulaby et al., 1986):

$$\sigma^0(\theta) = \sigma^0{}_{\mathrm{s}}(\theta) + \sigma^0{}_{\mathrm{v}}(\theta') + \frac{\gamma^2{}_{\mathrm{s}}(\theta')}{L^2(\theta')}\sigma^0{}_{\mathrm{g}}(\theta') \tag{2}$$

where $\sigma^0{}_{\mathrm{sa}}(\theta)$is surface scattering by the air/snow interface, $\sigma^0{}_{\mathrm{s}}(\theta')$is the volume backscattering by the snow layer, $\gamma_{\mathrm{s}}(\theta')$ is the power transmission coefficient for the air/snow boundary, $L^2(\theta')$is the one-way loss factor of the snow layer, $\sigma^0{}_{\mathrm{g}}(\theta')$is the scattering coefficient of the ground surface, and θ' is the transmission angle in the snow layer.

Information about the extension and the properties of snow-covered areas are very important for climatological and hydrological investigations. Because the physical mechanisms governing the backscattering from natural snow cover are complicated, unequivocal relationships between snowpack properties and SAR observations do not exist (Strozzi and Matzler, 1998). Hence, an intensive study is required for proper understanding of the interaction between microwaves and snow cover. These studies can proceed in two different ways.

For dry snow cover the backscattering from the snow surface may be neglected and the total backscattering is a combination of volume scattering from snow and surface scattering from the ground. In *wet snow*, the absorption loss is high and the scattering from the snow/ground interface may be neglected. The presence of liquid water content increases the absorption coefficient. Therefore, the volume scattering albedo is inversely correlated to snow wetness and snow density. At constant wetness and density, the volume scattering albedo increases as the size of the scatterers or their size variation increases, because, as Rayleigh scattering theory explains, the scattering coefficient is proportional to the third power of the scatterer's radii for a given volume fraction (Shi and Dozier, 1995).

Snowpack characteristics

Empirical relations

On the experimental side, in situ backscattering measurements of a homogeneous scene are made and the snow cover characteristics are collected simultaneously (Strozzi and Matzler, 1998). These measurements can be used in developing empirical models for snow parameters.

Backscattering from a snow-covered terrain depends on (1) sensor parameters, which include frequency, polarization, and viewing geometry, and (2) snowpack and ground parameters, which include snow density, liquid water content, ice particle size and shape, surface roughness parameters, and stratification also.

Inversion algorithms

Inversion model for dry snow density. Microwave interaction with snow depends on dielectric and geometric properties of the snow. Sensor properties also influence the target response to incident wave. In the case of snow-covered terrain, different processes contribute to the total backscattered signal: (1) scattering at the air/snow interface, (2) scattering inside the snow layer due to ice particles and at density boundaries, and (3) scattering at the snow/ground interface.

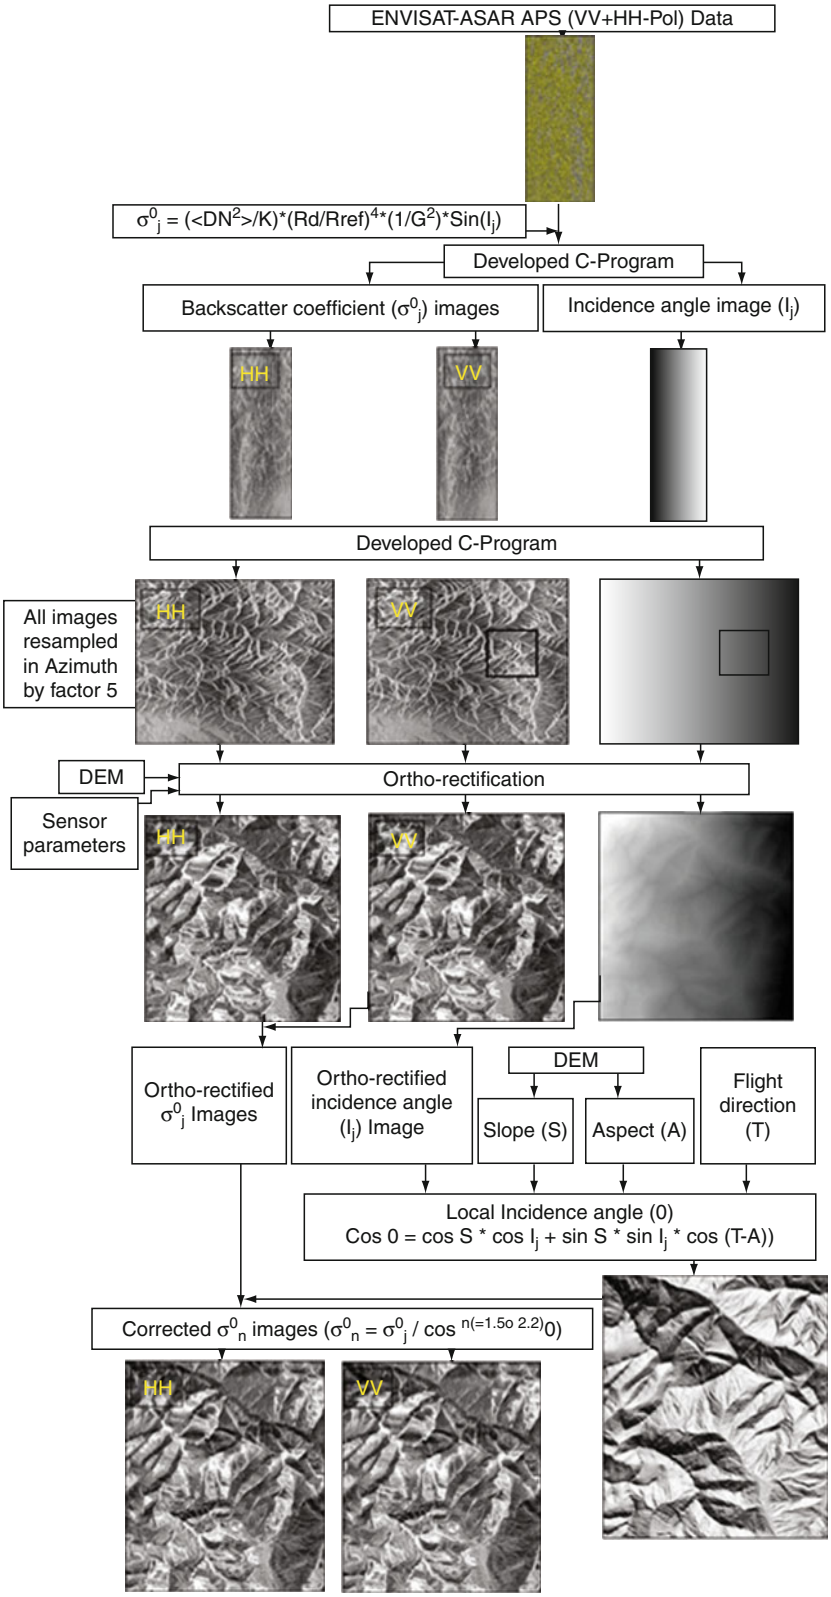
Total backscattering from the snow is sum of scattering from air-snow, volume scattering in the snow layer, and scattering from the snow-ground attenuated by snow layer (Ulaby et al., 1986). Due to large penetration (approximately 10 m at 200 kg/m^3 snow density) at C-band, in dry snow layer and small contribution of air/snow interface scattering in total backscattering from dry snow, we can neglect the air/snow interface scattering contribution from the total backscattering coefficient (Shi et al., 1990). Therefore total backscattering coefficient for dry snow is the sum of two main components, that is, snow volume backscattering and snow-ground backscattering.

Under an assumption that snow surface has no significant air/snow interface scattering and angle of refraction remains constant in dry snowpack, total backscattering from the dry snowpack can be defined as

$$\sigma_{\mathrm{t}}{}^{\mathrm{pp}}(k,\theta) = \sigma_{\mathrm{v}}{}^{\mathrm{pp}}(k_1,\theta_{\mathrm{r}}) + \sigma_{\mathrm{sg}}{}^{\mathrm{pp}}(k_1,\theta_{\mathrm{r}}) \tag{3}$$

In Equation 3, σ_{t}, σ_{v}, and σ_{sg} are total backscattering, volume backscattering, and snow/ground interface backscattering coefficients, respectively. pp is either VV or HH. k and k_1 are the incident wave numbers in the air and in snowpack, respectively. θ is incident angle and θ_{r} is angle of refraction.

The incident angle at air/snow interface and the angle of refraction in the snow layer and snow/ground interface can be related by the Snell's law. The observable change of wavelength at different densities in snow layers is found at L-band (Shi and Dozier, 2000) by comparing the difference between incident angle at air/snow interface and at snow/ground interface with different snow density (100–500 kg/m^3). For a given snow density, incident angle at the snow surface causes the change in the incident angle in the snow layer. These changes are observed at L-band propagation wavelength by Shi and Dozier (Shi and Dozier, 2000). Therefore, these changes can also be considered at C-band because C-band has lower penetration capability as compared to L-band. Hence C-band is more sensitive for above mentioned changes as compared to L-band. Since both the angle of refraction and wavelength



Radar Application in Snow, Ice, and Glaciers, Figure 1 Data processing steps in details.

shifts are only a function of the snow dielectric constant, which is mainly governed by the snow density, it is possible to estimate snow density by using C-band ASAR data.

For developing an algorithm for snow density estimation, the first order volume scattering model and the integral equation method with an exponential correlation function for the surface backscattering contribution from the snow/ground interface could be used. Both models depend on the four unknown functions, namely, dielectric constant, incident angle, volume scattering albedo, and root mean square height and surface correlation length. In case of snow/ground interface, using best pair of polarization, the unknown can be reduced to only dielectric constant and incident angle. In the case of volume backscattering, using volume backscattering ratios, the unknown can be reduced to only dielectric constant and incident angle. In the final term combining both volume backscatter and snow-ground scattering, only two functions, namely, incident angle and dielectric constant, remain (Singh and Venkataraman, 2009):

$$\sigma_t^{AP(vvhh)} = \frac{\sigma_t^{hh} \times \left(\frac{|T_{vv}|^2}{|T_{hh}|^2}\right) \times \left(\frac{|\alpha_{vv}|}{|\alpha_{hh}|}\right) + \sigma_t^{vv}}{\left(\frac{|T_{vv}|}{|T_{hh}|}\right) \times \left[\left(\frac{|\alpha_{vv}|}{|\alpha_{hh}|}\right) + 1\right]} \tag{4}$$

where

$$\begin{cases} \alpha_{hh} = \dfrac{\cos\theta - \sqrt{\varepsilon_s - \sin^2\theta}}{\cos\theta + \sqrt{\varepsilon_s - \sin^2\theta}} \\ \alpha_{vv} = (\varepsilon_s - 1)\dfrac{\sin^2\theta - \varepsilon_s(1 + \sin^2\theta)}{\left[\varepsilon_s \cos\theta + \sqrt{\varepsilon_s - \sin^2\theta}\right]^2} \end{cases} \tag{5}$$

T_{vv} and T_{hh} are Fresnel transmission coefficients, θ is incidence angle and it can be replaced by Snell's law, that is, $\sin^2\theta = \varepsilon_s \sin^2\theta_r$ in Equation 5. By knowing the incident angle, Equation 4 can be used to estimate the dielectric constant of the snow, which can be directly related to snow density using Looyenga's semiempirical formula given by (Looyenga, 1965)

$$\varepsilon_s = 1 + 1.5995\rho_s + 1.861\rho_s^3 \tag{6}$$

Integral equation method based algorithm is given which has been developed for retrieval of snow density from polarimetric data at C-band. An algorithm is also applied on radar backscattering coefficient for the estimation of snow permittivity and snow density in Himalayan region. ASAR estimated values for snow density have been validated by in situ measurements recorded concurrently with ENVISAT ASAR pass in the study region. The ground truth data are the average value from the top to bottom of snow layers of each snow pit. The field measured and estimated snow densities are given in Table 2. The comparison of snow density between field measured and ASAR estimated at seven snow pits has been done.

Radar Application in Snow, Ice, and Glaciers, Table 2 Measured and estimated snow density

Estimated ρ_s (kg/m^3)	Measured ρ_s (kg/m^3)	Absolute error $\|\Delta\|$ (kg/m^3)	Mean absolute error
204	242	38	21.2 kg/m^3
217	252	35	
240	247	7	
258	266	8	
280	268	12	
308	274	34	
321	306	15	

The absolute error was observed to be 21.2 kg/m^3. It indicates that the algorithm works well for the seasonal fresh snow cover. At higher elevation to moderate elevation, calculated snow density is observed to be 400–500 kg/m^3, increasing to <100–400 kg/m^3 at moderate to lower elevation (Figure 2).

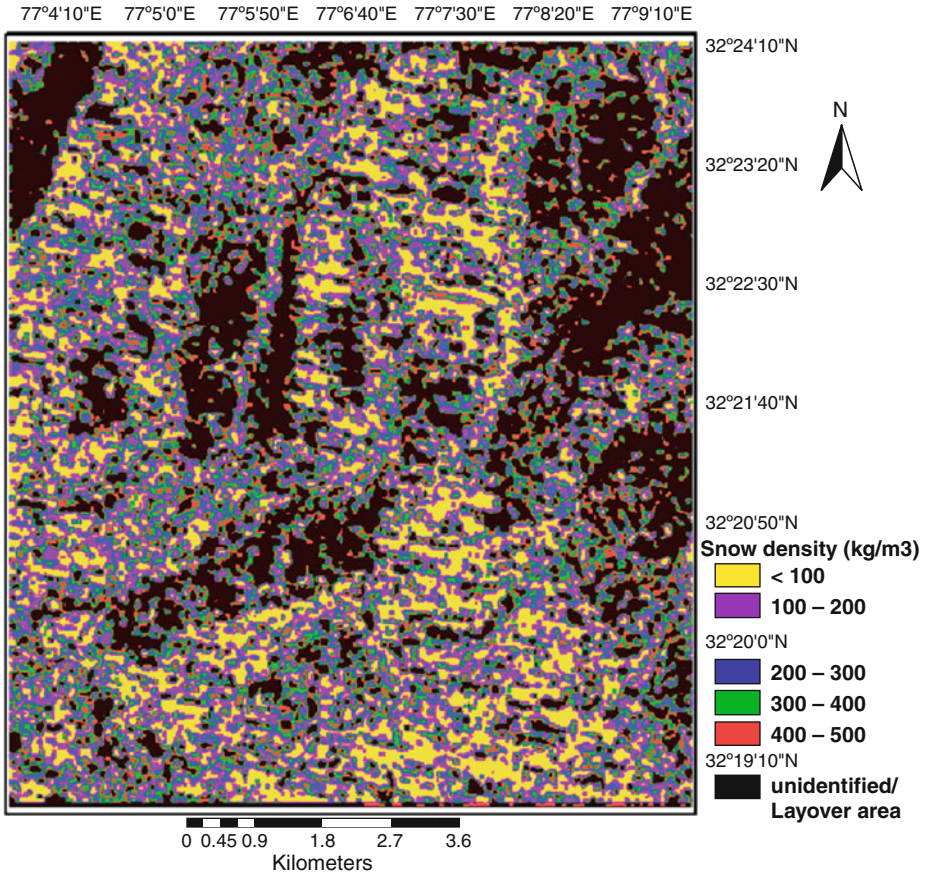
At the lower altitudes area, snow is fresh and thin. On the other hand, due to permanent snow cover at higher altitudes or over glaciers, there is a recrystallization process which results in the density increase. The spatial distribution of estimated snow density agrees well with regional condition.

The model does not require roughness properties. This investigation shows that this algorithm can be used for estimating dry snow density. The model can be applied to the seasonal snow cover when the snow is dry where the subsurface is soil or rock. The mean absolute error between measured and estimated snow density was found to be 21.2 kg/m^3 where subsurface is soil without vegetation cover but it may not be useful where the subsurface is dominated by volume scattering, for example, in snow-covered firn area.

Furthermore, effect of vegetation cover on snow density mapping may be included for accurate mapping of snow cover in vegetated area. Best range of incident angle will be found out for this model because this model is dependent on incident angle.

Inversion model for wetness estimation. For this entry, authors have demonstrated Integral Equation Method based inversion model, which has been developed (Shi and Dozier, 1995) for retrieval of snow wetness from polarimetric data at C-band. This model includes two main scattering components (snow volume backscatter and surface backscatter from air/snow interface) for wet snow.

The first order volume scattering and surface scattering models depend on the four unknown functions, namely, dielectric constant, incident angle, volume scattering albedo, and root mean square height and surface correlation length. In the case of surface backscattering through simplified nonlinear regression equations and also using best pair of polarization, the unknown can be reduced to only dielectric constant. In the case of volume backscattering, using volume backscattering ratios, the unknown can



Radar Application in Snow, Ice, and Glaciers, Figure 2 Snow density map of 24 Dec. 2007.

be reduced to only dielectric constant and incident angle. In the final term combining both surface and volume backscatter, only two functions, namely, incident angle and dielectric constant, will remain. Knowing the incident angle, one can solve snow permittivity which can be directly related to snow wetness.

Equation 7 can be used to estimate the permittivity of the snow:

$$M_1[a_{vx}\mathrm{Re}[\alpha_{vv}\alpha^*{}_{hh}](a_{vhx}D_{RS}-D_{TS})+b_{vx}M_2] = M_2\left[a_{vx}(\theta_i)\mathrm{Re}[\alpha_{vv}\alpha^*{}_{hh}] + \frac{b_{vx}M_2}{a_{vhx}D_{RS}-D_{TS}} - D_{Tv}|\alpha_{vv}|^2\right] \quad (7)$$

where

$$M_1 = \sigma_t{}^{vvhh} - D_{TV}\sigma_t{}^{vv} \quad (8)$$

$$M_2 = \sigma_t{}^{vv} + \sigma_t{}^{vv} - D_{TS}\sigma_t{}^{vvhh} \quad (9)$$

$$D_{TS} = \frac{D_{TV}+D_{TH}}{D_{TV}D_{TH}} \quad (10)$$

$$D_{RS} = \frac{|\alpha_{vv}|^2+|\alpha_{hh}|^2}{\mathrm{Re}[\alpha_{vv}\alpha^*{}_{hh}]^2} \quad (11)$$

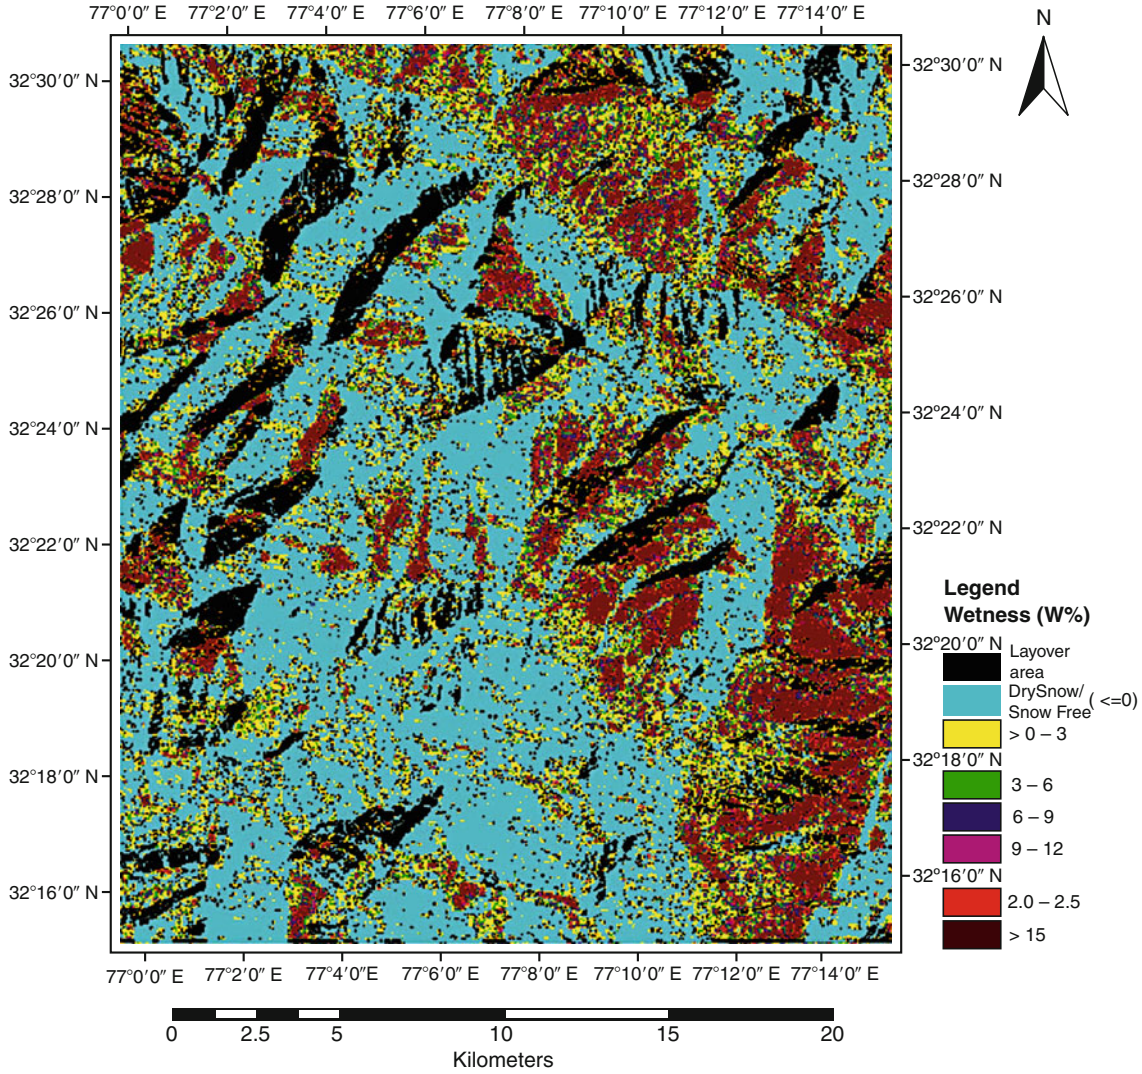
$$D_{TV} = \frac{\sigma_v{}^{vvhh}}{\sigma_v{}^{vv}} = \frac{\mathrm{Re}[T_{vvhh}]^2}{T^2{}_{vv}} \quad (12)$$

$$D_{TH} = \frac{\sigma_v{}^{vvhh}}{\sigma_v{}^{hh}} = \frac{\mathrm{Re}[T_{vvhh}]^2}{T^2{}_{vv}} \quad (13)$$

$$\sigma_v{}^{vvhh} = \mathrm{Re}\left[S_v{}^{vv}S_v{}^{hh*}\right] \quad (14)$$

and the coefficient $a_{vx}(\theta_i), b_{vx}(\theta_i)$ and $a_{vhx}(\theta_i)$ are provided in the appendix of Shi and Dozier (1995). Figure 3 shows ASAR estimated snow wetness image based on the modified Shi and Dozier (1995) inversion model.

Model for grain size estimation. A dry snow layer is a heterogeneous medium composed of ice particles with different size and microstructures. When snow is dry, the principle mechanism is volume scattering from the snowpack, and the most important variables are density and grain size. Backscattering increases as the snow grain size



Radar Application in Snow, Ice, and Glaciers, Figure 3 Snow wetness map of 27 Feb. 2006.

increases. Based on Rayleigh scattering, the backscattering coefficients for dry snow can be written as

$$\sigma^0{}_{\mathrm{ds}} = \frac{4\pi^3 r^3 \left|\frac{\varepsilon-1}{\varepsilon+2}\right|^2 \cos\theta'}{\lambda^3 \left|\mathrm{Im}\left\{\frac{\varepsilon-1}{\varepsilon+2}\right\}\right|} \tag{15}$$

For example, λ is C-band ASAR wavelength (λ= 0.056 m, and incidence angle varies from 15° to 45°) and measured average dielectric constant is 1.76–0.00029j. Grain size can be estimated using Equation 15.

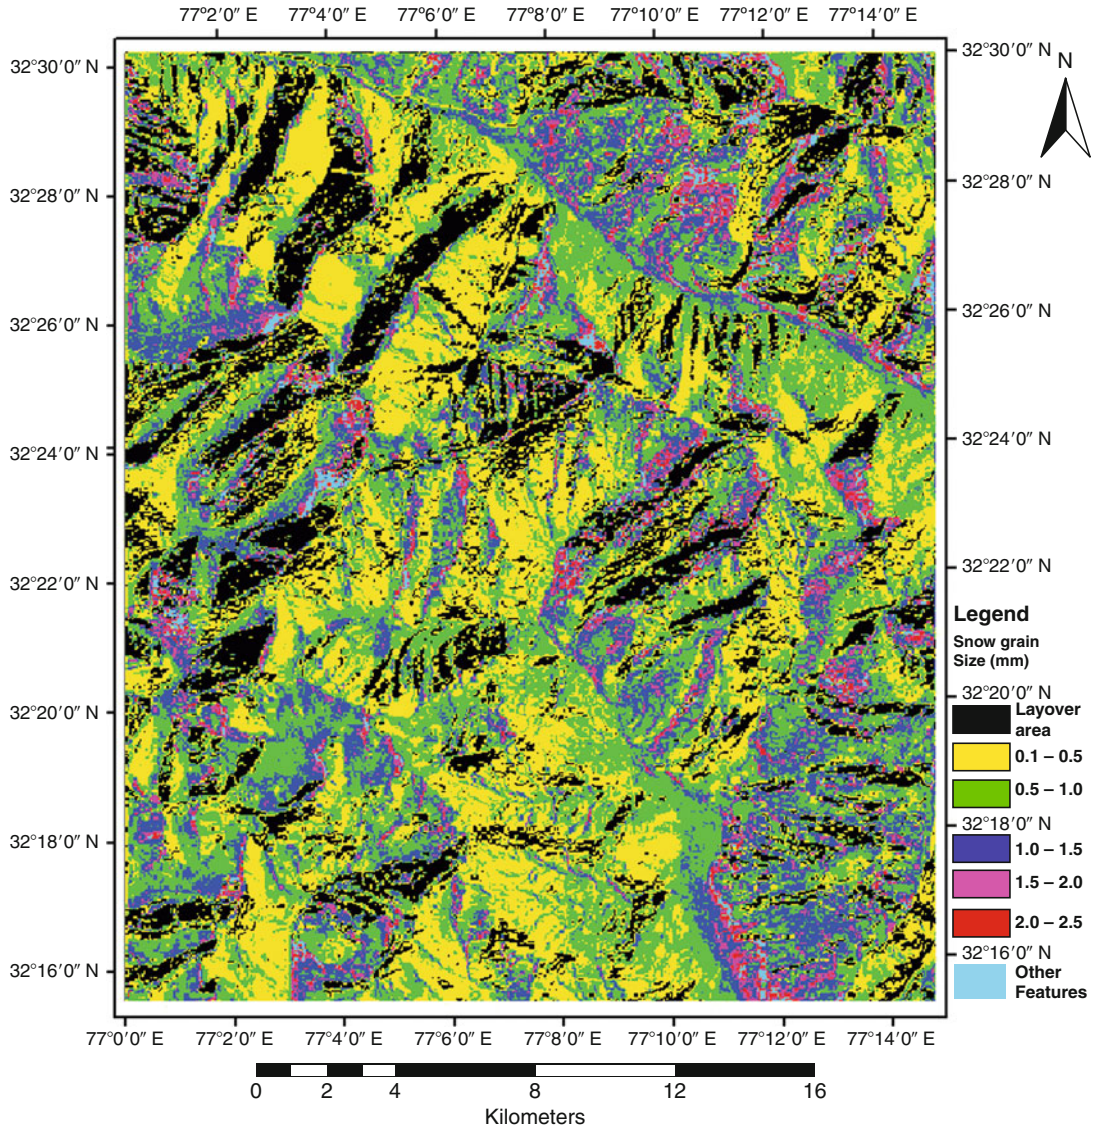
The color-coded grain size value image is shown in Figure 4. The ASAR estimated snow grain sizes agree well with the field measurements. The comparison of ASAR C-band estimated value with field grain size measurement shows an absolute error of 0.045 mm and relative error 9.6%. Backscattering coefficient increases as the grain size increases.

Seasonal snow cover mapping

Snow mapping using single polarization SAR images

Rott et al. (1988) developed a snow mapping procedure in which actual image and simulated image are used. The simulated image is generated using local incidence angle map of the area using DEM and some constant parameters which depends on surface type. Rott et al. (1988) used the following equation for the simulation of (σ^0):

$$\sigma^0(\theta_{\mathrm{i}}) = a\,\exp\left(\frac{\theta_{\mathrm{i}}}{\varphi}\right) + c\,\sqrt{\cos\theta_{\mathrm{i}}} \tag{16}$$



Radar Application in Snow, Ice, and Glaciers, Figure 4 Snow grain size map.

where σ^0 is the radar cross section in units per m^2, θ_i is the local incidence angle of the radar beam, and a, c, and φ are constant values for a particular surface type. For moraine and rock surfaces, the values $a = 0.35$, $c = 0.55$, and $\varphi = 10°$ were used by Rott et al. Rott et al. used C-HH polarized data and simulated data with the following conditions to map snow-covered area.

for	σ^0hh/σ^0sim	≤ 1.8	snow- and ice-free
for	$1.8 < \sigma^0$hh/σ^0sim	< 3.5	glacier ice
for	$3.5 \leq \sigma^0$hh/σ^0sim		snow

Rott et al., compared SAR classified results with that of TM and found that snow surface was underestimated in the SAR classification.

Shi and Dozier (1993) and Shi et al. (1994) used a different function for snow mapping using single polarized data. The normalized σ_n^0 is given by

$$\sigma^0{}_n = \sigma^0(\theta_i)/f(\theta_i) \tag{17}$$

where $f(\theta_i) = \cos^n(\theta_i)$, and n takes different values depending on frequency and polarization. The snow classification is performed by applying threshold of $\sigma^0{}_n$. The classification based on $\sigma^0{}_n$ at C-band VV gave an

overall agreement of 66% when compared with Landsat TM classification.

Snow mapping using multifrequency and polarimetric data

Rott et al. (1992) used polarimetric data for snow cover mapping. Based on the depolarization properties of the radar signal, they used the following equation for mapping snow cover. If the backscattering power satisfies the following condition,

$$P_{HV}/P_{VV} > m \quad \text{snow covered} \tag{18}$$

where $m = 0.04$ was used, P_{HV} is received power of cross-polarization, and P_{VV} is co-polarization data at C-band. Shi et al. (1994) also used the same procedure and their results are in agreement with Rott et al. (1992).

Snow mapping using repeat-pass SAR observations (single polarization)

This method was developed by Rott and Nagler (1992) and Rott and Nagler (1993) and used with ERS-1 SAR data. It is based on the fact that dry snow is not discriminated against snow-free ground during winter as the dry snow is transparent at C-band. Images acquired during snow-free conditions are usually taken as reference image. However, wet snow strongly reduced the backscattered signal. Images acquired during wet conditions are usually known as wet snow images. The change in σ^0 between snow and reference images leads to the detection of wet snow. By combining ascending and descending pass data, they could map snow cover even in layover and shadow areas.

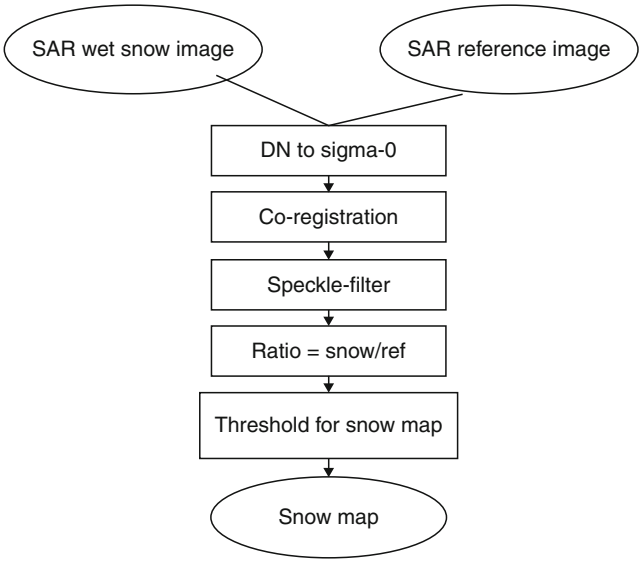
Nagler and Rott (2000) used threshold value -3 dB for wet snow mapping after comparing the results with snow classification using TM data. This procedure has been modified for snow cover mapping in our study and the modified procedure is shown in Figure 5.

Koskinen et al. (1997) suggested an algorithm which is optimized to detect snow in forested areas. By conducting a pixel-wise comparison between the two reference images and the current image, the equation for the relative fraction of snow-free ground is given by

$$F_g = 100\frac{\sigma_i^0 - \sigma_w^0}{\sigma_g^0 - \sigma_w^0}\% \tag{19}$$

where σ_i^0, σ_w^0, and $\sigma_g^0$are the backscattering during snow melt, and at the beginning of the snow melt period, and for snow-free ground, respectively.

Luojus et al. (2006) demonstrated a two-step technique for mapping wet snow cover over Boreal forest in Finland using ERS-2 multi-temporal data sets. The first step is the forest canopy compensation. This is done by nonlinearly fitting ERS-2 measured data with a semiempirical forest-backscattering model (Pulliainen et al., 2003) and information with forest stem volume to estimate



Radar Application in Snow, Ice, and Glaciers, Figure 5 Flow chart of wet snow cover mapping.

the backscattering signal at ground surface and the volume backscattering signals, the two-way transitivity of the forest canopy. In the second step, the fraction of wet snow-covered area (SCA) is calculated as

$$\text{SCA} = \frac{\sigma_{surf}^0 - \sigma_{ground-ref}^0}{\sigma_{snow-ref}^0 - \sigma_{ground-ref}^0}100\% \tag{20}$$

where σ_{surf}^0 is the estimated backscattering coefficient at ground surface, $\sigma_{ground-ref}^0$ is the reference signal from the snow-free ground, and $\sigma_{snow-ref}^0$ is the reference signal from the wet snow ground. One reference image describes the signal with fully wet snow cover situation and the other describes the snow-free at the end of the snow melting season. In addition to these two reference images, this method requires forest stem volume distribution.

Snow mapping using repeat-pass interferometric techniques

An Interferometry SAR technique for topographic mapping of surface does not only produce a high resolution DEM but also gives the information about changes on the surface during the repeat-pass cycle of satellite from the correlation properties of the radar echo. The measurement of interferometer correlation provides the information of changes during the timescale of the satellite repeativity and size scale on the order of a SAR wavelength. The coherence measurement between two repeat passes provides another useful measurement for snow cover mapping over large area. Strozzi et al. (1999) analyzed the ERS-1/2 tandem data and observed that coherence can help separate wet snow from other

surface where backscatters do not discriminate snow from other surface.

The basis of InSAR is phase comparison over many pixels. This means that the phase between scenes must be statistically similar. The coherence is a measure of the phase noise of the interferogram. The interferometric coherence is defined as the absolute value of the normalized complex cross-correlation between the two signals. The correlation will always be a number between 0 and 1. If the pixels are similar this will result in a high correlation and good results. If the pixels are not similar, that is, not correlated at a certain degree, then the phase will vary greatly and the result will be noise.

Theoretical and experimental studies have shown that coherence is determined by the spatial baseline of the interferometric pair, the time separation of the images, topographic effects, and noise sources. The change of backscattering characteristic at surface will cause the change of coherence degree at the separate time. Integrating the backscattering intensity, one can make classification using the difference of coherence degree for different surface type.

The technique is based on coherence between two images acquired at different dates. The coherence may vary depending on the melting of snow, forest growth, precipitation, soil moisture, and movement of the glaciers. Through this technique, wet snow-covered areas can be identified through coherence change. Rao et al. (2008) observed poor coherence in most of the areas if the interval between two dates is more than 30 days. Shi et al. (1997) processed SIR-C data at L-band for the analysis of interferometric coherence and thereby executed snow mapping. The limitation of this technique is that two images are to be acquired in a short interval with same viewing angle and swath mode. Presently, almost all satellites give data in the interval of 25–35 days.

Coherence measurement using repeat-pass SAR observations indicate low values for both wet and dry snow covers. The radar echoes get decorrelated for measurements between wet snow cover and bare ground. This happens mainly because radar signal can penetrate few centimeters in wet snow cover and hence the radar senses two different targets. In case of dry snow the dominant scattering is from the interface of snow and ground. Decorrelation occurs in dry snow mainly due to volume scattering from the snow layer and changes the local incidence angle.

The coherence was measured between several pairs repeat-pass ERS-1/2 and ENVISAT image data. Data analysis was performed using Gamma SAR and interferometric processing software. The coherence degrees of interferometric pair were calculated for different types of surface at different time interval. However, the amount of decorrelation is expected to be relatively smaller because radar senses same target with same scattering mechanism (only change in magnitude). The glacier has varied coherence degree according to the moving state. The correlation of snow is relatively lower due to the change of snow surface and roughness caused by snow and snow melting.

Coherence images of Gangotri glacier were obtained using ERS-1&2 tandem data of March 25 and 26, 1996, in ascending mode; ENVISAT ASAR 35-day interval data of July 9 and August 13, 2003, in descending pass; and ENVISAT ASAR 70-day interval data of May 19, 2004, and July 28, 2004. Authors acquired the nearest IRS – LISS III image to verify the classification accuracy.

Coherence images of Siachen glacier with April 1 and 2, 1996, ERS-1 and 2 tandem pair; May 2 and 3, 1996, tandem pair; and ASAR 70-day interval and ASAR 350-day interval data indicate that the coherence degrees of objects are high in the ERS SAR pairs due to short time interval and relatively short baseline. For snow and glacier region, snow melting and glacier movement will result in large decorrelation.

The wet snow cover over the glacier and non-glacier area can be discriminated from other targets using degree of coherence because wet snow metamorphism changes the scattering geometry, and therefore coherence is lost. But the decorrelation of time and baseline should be reasonable. Short time interval pair between snow and non-snow cover is better for separating snow from other targets.

Radar application in land ice and glacier studies

Glaciated terrain classification using full polarimetric SAR data

SAR Polarimetry is a very active area of research in Radar Remote Sensing and Classification using fully polarimetric SAR images (van Zyl et al., 1987; Novak and Burl, 1990; Ulaby and Elachi, 1990; Lee et al., 1991; Zebker et al., 1991; Rignot et al., 1992; van Zyl and Burnette, 1992; Novak et al., 1993; Boerner et al., 1998). SAR polarimetry can be important to snow study and to prepare the POLSAR data analysis and to develop methodology to snow parameters retrieval. Hence, an urgent need exists for establishing an approach for monitoring, modeling, and planning of snow parameters retrieval. However, such a systematic approach is still lacking. There is a need to explore the potential of Polarimetric SAR data, incorporating state-of-art scattering mechanism and polarimetric techniques based processing in formulating snow cover monitoring, snow wetness, snow density, etc. World over, there is no proven methodology/algorithms readily available, which can be directly applied for snow parameter studies in Himalayas. Hence, suitable methodology/algorithms are required to be developed for Himalayas for snow cover related studies. Hence, in this study, full polarimetric L-band ALOS-PALSAR data have been analyzed for snow cover classification of glaciated terrain in and around Badrinath region in Himalaya. ALOS-AVNIR-2 image was also used to provide assistance in the selection of different training classes. PALSAR data has been classified based on various components scattering mechanism models, namely, Entropy-Anistropy-Alpha by Cloude and

Pottier, Three components by Freeman and Durden (1998), and Four components by Yamaguchi et al. (2006). And all model results have been compared.

The Cloude–Pottier (1996) target decomposition is the most popular method used for snow cover classification. This method is based on eigenvalues of coherency matrix.

A three-component (surface, double bounce, and volume) scattering model based on the covariance matrix has been successfully applied by Freeman and Durden (1998) to decompose scattering mechanisms in POLSAR image analysis under the reflection symmetry condition. In this study, a four-component model (Yamaguchi et al., 2006; Yajima et al., 2008) has been used for snow cover study using ALOS-PALSAR data of May 12, 2007, over the Badrinath region in Himalaya. A four-component (surface, double bounce, volume and helix) scattering model is the extension of three-component scattering model, which deals with nonreflection symmetric scattering cases. There are problems in the implementation of the four-component algorithm on full polarimetric data because some negative powers occur in the decomposed image. This negative power occurrence problem is contradictory with physical conditions. In this entry, authors have demonstrated both old (Yamaguchi et al., 2006) and modified (Yajima et al., 2008) four-component decomposition procedures applied on PALSAR data, taking care of the negative powers occurrence problem and that the algorithm should be applicable to all areas in a general way.

In literature, both coherent and incoherent target decomposition theorems are available, namely, coherent decomposition: Pauli and Krogager decomposition and incoherent decomposition: decomposition of Freeman and Durden (1992, 1998), Cloude and Pottier (1996), and Yamaguchi et al. (2006).

The scattering matrix [S] is only able to characterize the coherent or pure scatterers. On the contrary, this matrix cannot be employed to characterize the distributed scatterers. This type of scatterers can only be characterized statistically, due to the presence of speckle noise.

The coherency matrix is given as

$$[T] = k.k^{*T} \tag{21}$$

where *T denotes complex conjugation and transposition and **k** denotes the target vector.

Target vector is obtained by vectorization V (.) of the scattering matrix **S** in each pixel:

$$k = V(s) = (1/2)\mathrm{Trace}\{S[\Psi]\} \tag{22}$$

Ψ is a set of 2 by 2 complex basis matrices.

Using Pauli basis matrix, target vector is defined as

$$k = (1/\sqrt{2})\begin{bmatrix} S_{\mathrm{hh}} + S_{\mathrm{vv}} \\ S_{\mathrm{hh}} - S_{\mathrm{vv}} \\ 2S_{\mathrm{hv}} \end{bmatrix} \tag{23}$$

where S_{hh}, S_{vv}, and S_{hv} are the elements of scattering matrix **S**.

The incoherent decomposition theorems can be expressed as

$$[T] = q_1[T_1] + q_2[T_2] + q_3[T_3] + \cdots + q_k[T_k] \tag{24}$$

In this work, *H/A/Alpha* (Cloude and Pottier, 1996), three-component scattering power decomposition (3-CSPD) model (Freeman and Durden, 1998), and 3-CSPD model extension a four component scattering power decomposition model (Yamaguchi et al., 2006) have been studied.

The $H/A/\alpha$ decomposition technique is based on the three eigenvalues (λ_1, λ_2, and λ_3 with decreasing magnitude) of the coherence matrix $<T>$, and defines the entropy H, the anisotropy A, and the α angle.

The degree of randomness of each target or the degree of statistical disorder of each target is known as the entropy. The entropy (H) can be defined in the Von Neumann sense from the logarithm sum of the eigenvalues of $[T]$:

$$H = -P_1\log_3 P_1 - P_2\log_3 P_2 - P_3\log_3 P_3 \tag{25}$$

$$0 \le P_i = \frac{\lambda_i}{\sum_{i=1}^{3}\lambda_i} \le 1 \tag{26}$$

The entropy indicates depolarization of the target. If entropy is low then target is weakly depolarized; when entropy is high then the target is depolarized.

The anisotropy A is the linear combination ratio of the second and third eigenvalues of $[T]$. Thus anisotropy can be defined as

$$A = \frac{\lambda_2 - \lambda_3}{\lambda_2 + \lambda_3}; \quad 0 \le A \le 1 \tag{27}$$

The mean scattering angle (α) is an angle between incident and return radar beam. It varies from 0° to 90°.

$$\bar{\alpha} = P_1\alpha_1 + P_2\alpha_2 + P_3\alpha_3 \tag{28}$$

With the three-component scattering mechanism model based decomposition theorem, presented by Freeman and Durden (1998), the coherency matrix can be decomposed into

$$[T] = f_{\mathrm{s}}[T_{\mathrm{s}}] + f_{\mathrm{d}}[T_{\mathrm{d}}] + f_{\mathrm{v}}[T_{\mathrm{v}}] \tag{29}$$

With the four-component scattering mechanism model based decomposition theorem, presented by Yamaguchi et al. (2006), similarly the coherency matrix can be decomposed into

$$[T] = f_s[T_s] + f_d[T_d] + f_v[T_v] + f_c[T_h] \tag{30}$$

where f_s, f_d, f_v, and f_c are surface, double bounce, volume, and helix scattering coefficients, respectively.

For supervised classification Wishart complex distribution (Lee and others, 1994) has been applied for snow cover classification. The Wishart distribution is expressed as

$$P(\langle T\rangle/T_m) = \frac{L^{Lp}|\langle T\rangle|^{L-P}e^{-LTr\left([T_m]^{-1}\langle T\rangle\right)}}{\pi^{\frac{p(p-1)}{2}}\Gamma(L)...\Gamma(L-p+1)[T_m]} \quad (31)$$

where L is number of looks and p is polarimetric dimension. Using the complex Wishart distribution of the coherency matrix **T**, an appropriate distance measure, d, can then be calculated according to Bayes maximum likelihood classification as

$$d_m(\langle T\rangle) = LTr\left([T_m]^{-1}\langle T\rangle\right) + L\ln([T_m]) - \ln(P([T_m])) + K \quad (32)$$

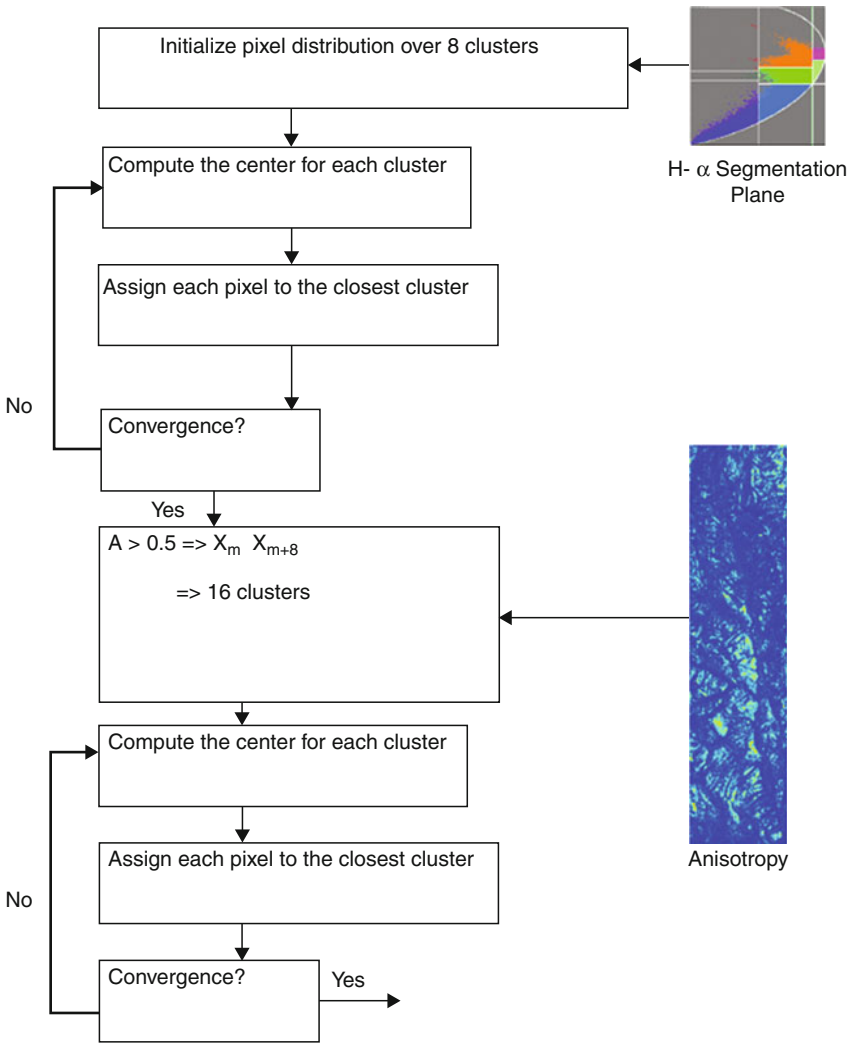
thus leading to a minimum distance classification independent of the number of looks used to form the multilooked coherency matrix $<\mathbf{T}>$:

$$\langle[T]\rangle \in [T_m] if d_m(\langle[T]\rangle) < d_j(\langle[T]\rangle)\forall j \neq m \quad (33)$$

In this investigation, H/Alpha Wishart and H/A/Alpha Wishart approaches have been attempted for the classification of PALSAR images. The flowchart of the H/A/Alpha Wishart unsupervised classification scheme is shown in Figure 6.

The decomposition schemes were applied on L-band PALSAR data set over the Badrinath region, which includes snow, forest, glacier, rocks, etc.

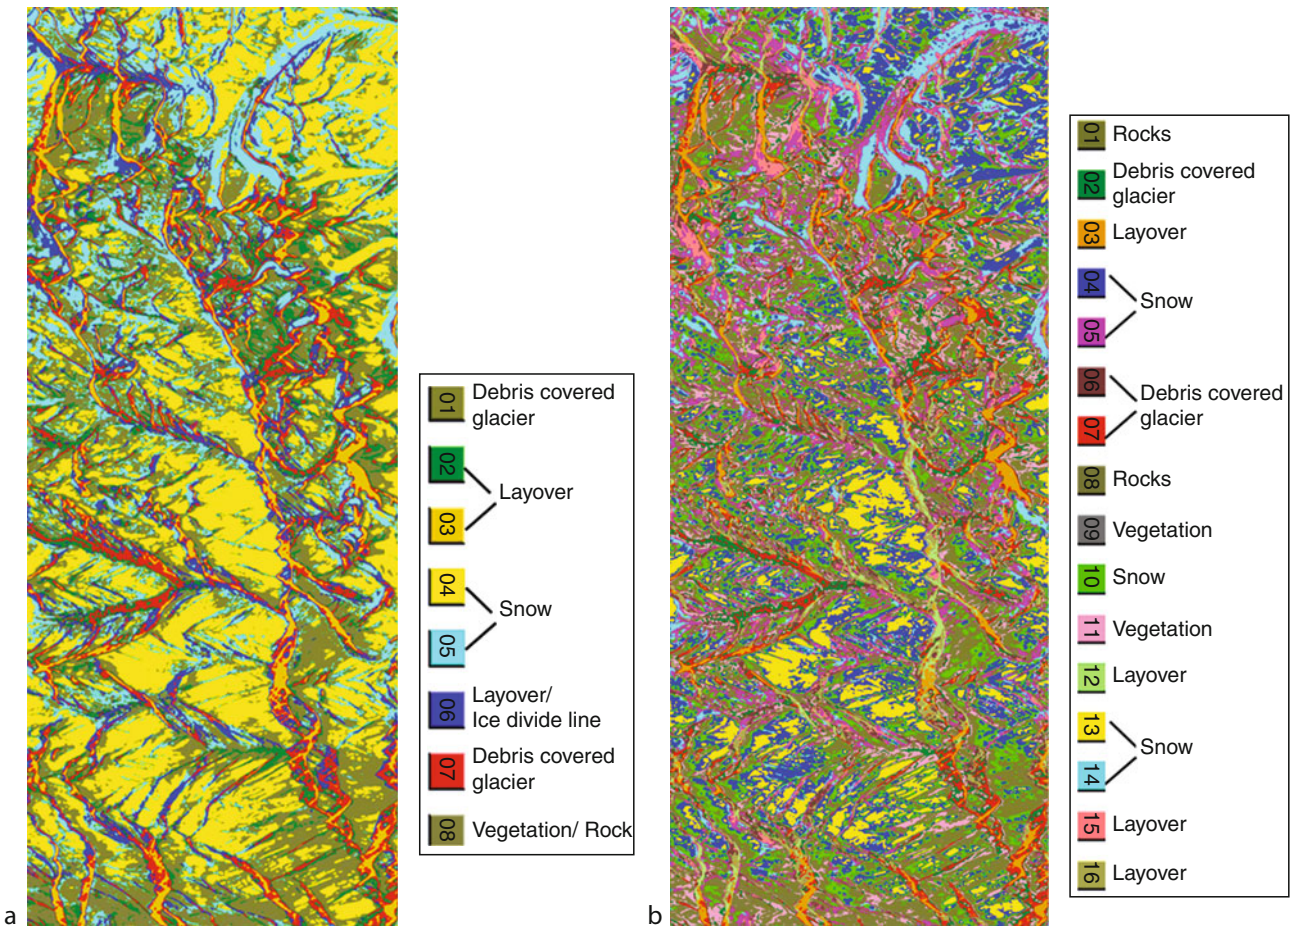
AVNIR-2 image of May 6, 2007, is used for analysis. Some part of this image covered by cloud and in other part, snow cover and non-snow cover area can be easily visually interpreted. Pauli RGB was made using diagonal element of coherency matrix which gives the clear information about single scattering (Snow cover area over glacier and non-glacier), double bounce (dihedral features) and volume scattering (Vegetation) in the study area. The H, A, and α parameters are decomposed from polarimetric PALSAR data over Badrinath area using H/A/Alpha



Radar Application in Snow, Ice, and Glaciers, Figure 6 Flow chart of the H/A/Alpha Wishart unsupervised classification scheme.

decomposition technique. The images were classified using H/A/Alpha Wishart unsupervised classifier (Entropy, anisotropy, and alpha angle corresponding to scattering mechanism). Results show that most of the pixels fall in single scattering and roughness scattering regions of the Entropy (H)/Alpha plane. The area has some small villages and forest and hence, the corresponding pixels have the content of multiple (dihedral and double bounce) scattering. The H/Alpha Wishart classifier classified the total image into eight different classes and after introducing anisotropy (A), number of different classes becomes 16. The classified images show that H/A/Alpha Wishart unsupervised classified images (Figure 7b) are better than those obtained using H/Alpha Wishart unsupervised classifier (Figure 7a). With the help of AVNIR-2 images, field information and Survey of India topography map, legend has been given to classified images and it was also identified that the H/A/Alpha Wishart unsupervised classifier has classified snow cover area into five classes whereas H/Alpha Wishart combination classified into two classes. After that, all snow classes have been merged and made one class for total snow cover mapping. H/A/Alpha Wishart classifier classified more pixels under snow classes as compared to H/Alpha-Wishart classifier.

Entropy-Anistropy-Alpha-Wishart classifier for training the samples provides better classification results according to region of interest. Classification technique was applied on Entropy-Anistropy-Alpha combination images, which are generated by speckle filtered data. Speckle filter (Sheng and Xia, 1996) for reducing the noise from the polarimetric data provides better accuracy. Also previous work shows that classification accuracy increases as refined Lee filter window size increases (Singh et al., 2008). Speckle is suppressed by refined Lee filter with window size 7×7. Using H/A/Alpha Wishart classifier, ALOS-PALSAR data was classified into six major classes (e.g., snow, non-snow, and unidentified/layover). Snow cover area was classified into one single class. When two training samples for snow-covered area (snow Class 1 and Class 2) were used, then classified image gives information about seven distinct classes. And user accuracy for snow class is higher as compared to single snow class



Radar Application in Snow, Ice, and Glaciers, Figure 7 (**a**) H/Alpha Wishart classified image (**b**) H/A/Alpha Wishart classified image.

classified image. Similarly, three different training samples for snow class were assigned, and it provides better user accuracy for snow classes as compared to classified image with one and two snow training samples for classification (the confusion matrix of the classified classes based on given training sample are shown in Tables 3a, 3b, and 3c). Classified image with eight (three snow and five non-snow) classes shows that more pixels were classified as snow compared to classified image with six and seven classes.

For this entry, authors also compared the visual interpretation of all decomposed FCC with the Pauli RGB and AVNIR-2 image. It was found that updated four-components scattering decomposition FCC seems better compared to three-components and old four-components FCC. Figure 8a, b shows the classified PALSAR image using 4- scattering component model and Wishart distribution.

Using old four-component and Wishart classifier, ALOS-PALSAR data was classified into major classes (e.g., snow, non-snow, and unidentified/layover, Figure 8a and b). Snow cover area was classified as one single class (Figure 8a) and as two classes (snow Class 1 and Class 2, Figure 8b). Supervised Wishart classification technique was applied on coherency matrix, and training samples were taken from four-component color composite image with the help of visual interpretation of ALOS AVNIR-2 image and field information. Four-scattering component model Wishart supervised classified images are shown in Figure 8a and Figure 8b. With the help of 4-component scattering component decomposition, snow can be easily classified into two classes using supervised methods but with the help of H/A/Alpha decomposition it can be classified into three classes. Tables 3a, 3b, 3c, 3d, and 3e reveal higher user accuracy for snow classes. This means that L-band PALSAR data are good for snow mapping.

In addition, the higher user accuracy snow class was found for 4-scattering component model Wishart supervised classified image (Table 3e). Based on the quantitative comparison and other analysis it seems that H/A/Alpha Wishart unsupervised classified images are better than the images obtained using H/Alpha Wishart unsupervised classifier.

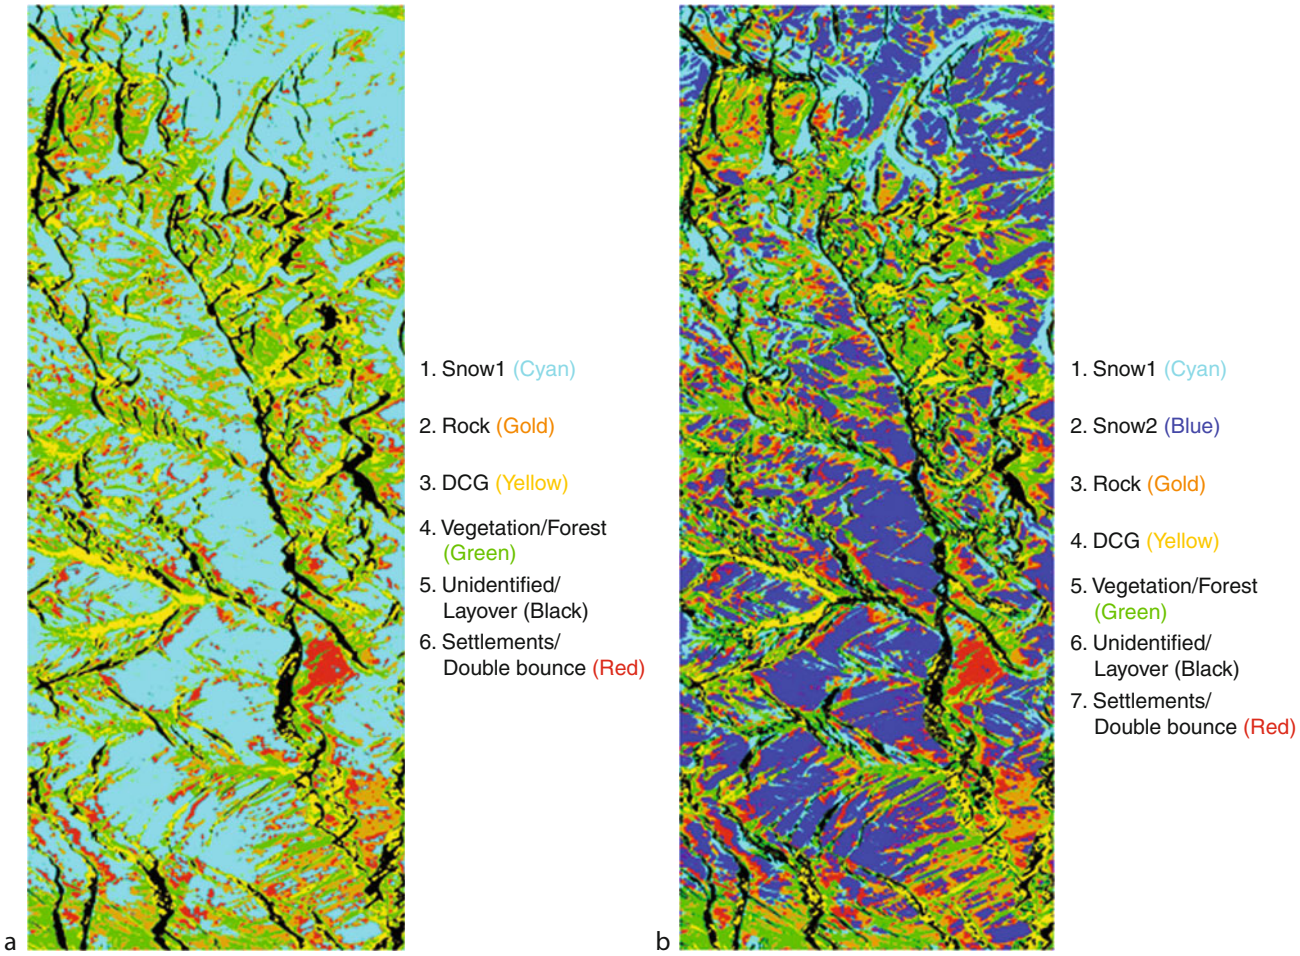
Glacier facies mapping

Glacier facies are distinct zones in the surface layer of an ice sheet or glacier. The concept of glacier facies developed as a result of physical measurements made in Greenland on repeated traverses that went inland from the west coast at two latitudes and north to south along the crest of the ice sheet. Snow pits and shallow cores showed discontinuities in physical characteristics that defined the facies boundaries (Partington, 1998).

The dry-snow zone, where there is no surface melt, is located at the highest elevations of the ice sheet. The percolation zone, where some melt occurs but meltwater percolates into the snowpack and refreezes, is immediately below the dry-snow zone in elevation. It is not easily distinguished from the wet-snow zone, where the complete annual accumulation of snow may experience meltwater percolation and refreezing. However, at the lower elevations of the wet-snow zone numerous melt ponds form and there are large areas of slush. Lower still is the superimposed ice zone, where meltwater has refrozen onto the colder glacier ice surface. Because superimposed ice is created by melting and refreezing of the current year's snow, this zone is still considered part of the ice sheet accumulation area. The lowest elevation zone is the bare ice zone, which represents the ablation region. The equilibrium line is defined as the boundary between the regions of net accumulation and net ablation, that is, the lower boundary of the superimposed ice zone. The snow (or firn) line is the lowermost elevation where, at the end of the ablation season, snow (or firn) remains on the glacier surface, that is, the upper boundary of the superimposed ice zone. Firn is densified snow that survives at least one melt season.

Radar glacier facies and zones can be identified on glaciers and ice fields on the basis of backscatter variations in multi-temporal SAR images (Partington, 1998). These glacier zones have backscatter signatures related to the structure of the snowpack, which varies, with the balance of accumulation and melt at various elevations (Fahnestock et al., 1993). It has been observed that (1) backscatter is sensitive to the near-surface temperature in the dry-snow zone, (2) backscatter coefficient is totally dominated by the ice structure in the percolation zone, and (3) the presence of thick ice layer leads to different spectral responses in the wet snow zone and a higher backscatter value is observed at higher frequencies.

Terrain corrected backscatter coefficient (σ_i^0) images of winter, late summer, and early summer have been obtained using the aforesaid processing procedure. These three multi-temporal images were merged together through layer stack program of ERDAS. Imagine by assigning winter image as Layer 1, late summer image as Layer 2, and early summer image as Layer 3. DEM was also merged with the SAR composite. This combination helps to obtain the elevation value as well as backscatter coefficient values for any particular pixel to carry out quantitative analysis.



Radar Application in Snow, Ice, and Glaciers, Figure 8 (**a**) 4- scattering component model -Wishart supervised classified image with 1 snow classes (**b**) 4- scattering component model - Wishart supervised classified image with 2 snow classes.

From this combined image, the study area has been extracted displaying Layer 1 in Blue channel, Layer 2 in Green channel, and Layer 3 in Red channel. This color combination SAR image is useful to identify different glacier zones due to tonal variations based on SAR composite image interpretation key (Table 4).

Further, for quantitative analysis the difference image showing the difference in backscatter coefficient values between September and January season was also generated. Generally, the winter image defines maximum freeze conditions and the late summer image defines maximum melt conditions. In addition to the generation of combined SAR images as composite, the backscatter coefficient value along with corresponding elevation data have been extracted along a profile cutting across various glacier zones separately for all these three SAR images. The analysis and plotting of these values and the interpretation of the combined SAR composite help in delineation of various glacier zones and this is discussed in the following.

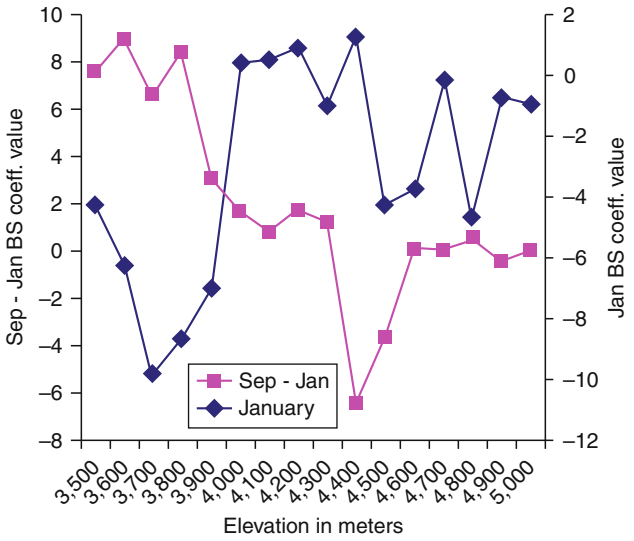
Two parameters considered in combination to give the best positioning for the snow line and dry snow line are winter backscatter coefficient and the difference between the end of ablation and winter backscatter coefficient (Partington, 1998). Figure 9 shows the plot of January backscatter and September minus January backscatter vs. elevation data extracted along a profile (Figure 10) for Beaskund glacier. This plot shows very clearly the delineation of Percolation/Wet snow facies and Ice facies and thus helps to clearly define the snow line. However, the separation between percolation facies and wet snow facies is not distinct. From this figure, it is clear that ice facies goes below 4,000 m. Above the altitude of 4,000 m lies the percolation facies together with wet snow facies. Dry snow facies is absent in Beaskund glacier. These findings need confirmation through field observations.

Further, for quantitative analysis of the difference image showing the difference in backscatter coefficient values between September and January season was also generated. Generally, the winter image defines maximum freeze

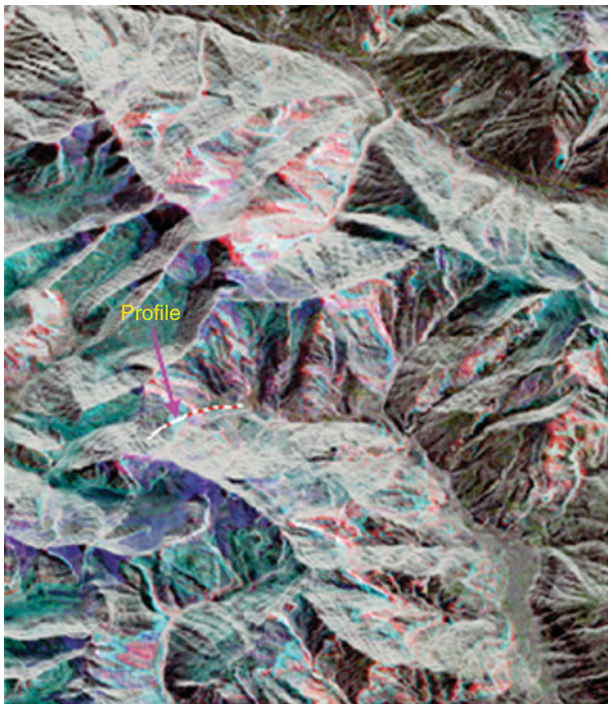
Radar Application in Snow, Ice, and Glaciers, Table 4 Key for SAR composite image interpretation

Satellite data from seasons	Assigned in channel
Winter	Blue
Late summer	Green
Early summer	Red

Glacier Facies		Winter	Late summer	Early summer	Final appearance
Dry snow facies		Low	Low	Low	Dark grey
Percolation/	Highest	Moderate	High	Moderate	Green
Wet snow	Upper	High	High	High	White
Facies	Middle	High	Moderate	High	Purple/Pink
	Lower/wet snow	High	Low	Low	Green
Ice facies		Low	High	Low	Green



Radar Application in Snow, Ice, and Glaciers, Figure 9 September Minus January and January Backscatter Vs. Elevation.



Radar Application in Snow, Ice, and Glaciers, Figure 10 Multitemporal Radarsat Image combining winter, late summer and Early Summer Images.

conditions and the late summer image defines maximum melt conditions. In addition to the generation of combined SAR images as composite, the backscatter coefficient value along with corresponding elevation data have been extracted along a profile cutting across various glacier zones separately for all these three SAR images. The analysis and plotting of these values and the interpretation of the combined SAR composite help in delineation of various glacier zones and this is discussed in the following.

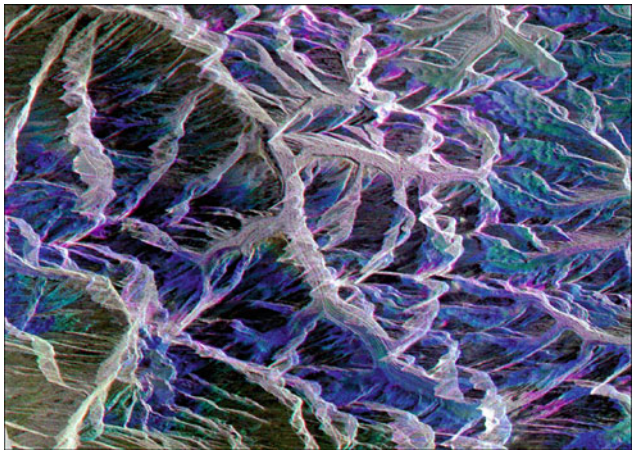
The region beyond the elevation of 4,000 m is the region with comparatively bright returns. This region has been identified as percolation zone together with wet snow zone. In percolation zone backscatter increases due to scattering from ice lenses and vertical ice pipes formed due to the freezing of percolating meltwater. According to Baumgartner et al. (1999), in the percolation zone, the backscatter coefficient is independent of the frequency, and the angular response is controlled by the ice structures such as surface roughness, lenses, and pipes. In wet snow zone the snow has reached the melting point as a result of latent heat released by extensive refreezing of meltwater (Fahnestock et al., 1993). In this zone backscatter is of intermediate intensity. In the wet snow zone the backscatter coefficient is temporally dependent as the temperature variations affect the moisture content and modifies the spectral backscatter energy. The snow and ice surface roughness determine the angular response (Baumgartner et al., 1999). In the present study it was not possible to clearly distinguish between percolation zone and wet

snow zone. Hence, it is grouped as a single unit called percolation/wet snow zone. This zone extends from altitude 4,000 up to > 5,000 m. This zone shows generally higher backscatter coefficient value and the values range between 10.667 and 2.590 dB. Further, this zone can be subdivided into four small zones as seen in the multi-temporal color image. At higher levels of percolation facies white zone is observed in the multi-temporal SAR image. White color zone is quite natural as the percolation facies has higher backscatter values in all three seasons. This is because there is no melt in any of the three seasons. At some higher altitude also green color is found somewhere in the multi-temporal color image. However, the appearance of green color in the higher altitude of percolation facies is somewhat anomalous and unusual. This indicates higher backscatter in September than in January or May. As there is no ground truth to validate an interpretation, Partington (1998) has suggested three possible explanations for future investigations. These include summer depth hoar development, rime-frost development, and high winter accumulation over percolation facies. Further down, the zone appears purple, as the backscatter will be uniformly high during winter and early summer and low in late summer. In this region melt is present in the late summer image but not in the early summer or winter image. Finally, toward the lowest altitude in the percolation/wet snow facies, the zone appears blue, as the backscatter would be high in the winter data and low in both summer images. In this region melt is associated with both early and late summer images. This blue color zone is a narrow zone of intermediate brightness.

The lowest zone is the bare ice zone which is a combination of glacier ice produced by compaction of snow at higher elevations and superimposed ice that forms by freezing of meltwater at the base of the firn (Fahnestock et al., 1993). This zone extends from terminus of the glacier to firn line, which is the highest elevation to which the annual snow cover recedes during the melt season. Compared to wet snow zone, the bare ice zone appears smooth with low backscatter in winter image. However, in late summer image this is inverted (Fahnestock et al., 1993). The ice facies lies below the equilibrium line, which is at 4,000 m altitude. The ablation region can be seen to lie below the "blue" lower zone of the percolation/wet snow facies (Figure 11). The backscatter coefficient values of the ice facies vary from 15.068 to 3.219 dB. It has been observed that the late summer backscatter values are higher than winter and early summer backscatter values. Because of this, it appears as having a green tint in the multi-temporal image (Figure 11). Bare ice exists at the end of the ablation season but earlier in the season there remains snow cover.

Glacier mass balance

Mass balance can be defined as the algebraic sum of the accumulation and ablation at any time. Accumulation includes all processes by which material is added to the glaciers, whereas ablation includes all processes by which snow and ice are lost from the glaciers. The measurement of the net balance can be determined using direct glaciological measurements. However, in terrains where the field measurements are impossible, indirect photogrammetric methods are useful to estimate net balance (Paterson, 1994).



Radar Application in Snow, Ice, and Glaciers, Figure 11 SAR FCC image over Gangotri glacier combining Winter (Blue), Late summer (Green) and Early summer (Red).

Radar application in mass balance estimation

SAR interferometry DEM

Volume change estimation of mountain glaciers can be done using high resolution multi-temporal digital elevation model (DEM) and extent measurement of glacier. Shuttle Radar Topography Mission (SRTM) C-band data and a digital elevation model (DEM) generated from topographic maps have been used for measuring the change in height. ERS-1/2 data TanDEM is very useful for generation of DEM of the glaciated terrain. Multi-temporal DEM derived from ERS-1/2 TanDEM data can be used for estimating the volume change in glacier or ice. High resolution InSAR DEM can be generated using spotlight mode SAR interferometric pairs of TerraSAR-X. Change in glacier height can be deciphered using differencing two DEMs after resampling them on the same spatial resolution. Change in area of the glacier and change in height generally give the information of change in total volume of glacier/ice.

Cryosat-2 elevation

In near future, Cryosat-2 Elevation can be used to obtain variation in the glacier elevations and relate these variations to gain or loss in mass balance. The study of the mass balance of glaciers can be estimated using data sets of SAR Interferometric mode of SAR Interferometric Radar Altimeter (SIRAL) onboard CryoSat-2, which is intended to provide improved elevation estimates over ice sheets with variable topography. The change in the elevation

can be related to mass balance study. The details about Cryosat-2 can be obtained from the following link: http://www.esa.int/esaLP/LPcryosat.html

TanDEM-X

TanDEM-X (*T*erraSAR-X *a*dd-o*n* for *D*igital *E*levation *M*easurement) opens a new era in space borne radar remote sensing. The first bistatic SAR mission is formed by adding a second, almost identical spacecraft, to TerraSAR-X and flying the two satellites in a closely controlled formation with typical distances between 250 and 500 m. Primary mission objective is the generation of a consistent global digital elevation model. The scientific use of the data can be divided into three areas: new quality Digital Elevation Models, along-track interferometry, and new bistatic applications. The mission has been approved for full implementation by the German Space Agency with a planned launch in fall 2009 (for more details see this link: http://www.dlr.de/hr/desktopdefault.aspx/tabid-2317/3669_read-5488). This mission will be very useful for glacier mass balance study.

ELA method based on SAR FCC

Glaciers often lie in remote areas that are difficult to access, and they can have vast surface areas. This makes it difficult and costly to collect in situ data at regular time intervals, be it for direct measurements of the mass balance or for meteorological measurements. Satellite based remote sensing with its characteristics such as synoptic view, repetitive coverage, and uniformity over large areas is an important tool for glacier monitoring and mapping. Here the use of satellite instruments for measuring only the mass balance related glaciological parameters are discussed. The mass balance cannot be presently established using remote sensing alone. In case of small and medium sized alpine glaciers there are possibilities to determine the equilibrium line altitude (ELA) by analyzing the multi-temporal high resolution satellite data. The ELA is assumed to coincide with the snow line altitude at the end of ablation season (Kulkarni et al., 2004).

Since several obstacles like presence of cloud cover for optical remote sensing techniques and difficulties in field work for mass balance change detection using ground based measurement method. Hence synthetic aperture radar (SAR) can be used to detect the changes in mass balance and glacier facies using SAR FCC. The annual position of the equilibrium line can be retrieved from backscatter observation due to composite contribution to the backscatter variation in the equilibrium zone.

Once the theoretical snowline is obtained the same snowline can be used in the existing algorithm to estimate the mass balance and the difference can be studied. One such algorithm is developed by Rabatel et al. (2005) which can be used to find the mass balance calculation.

Summary

In this entry, application of synthetic aperture radar (SAR) for snow, ice, and glacier are discussed. Empirical as well as inversion models for estimation snowpack characteristics are described with case study. Various algorithms and techniques involving single pass SAR data with fixed polarization, repeat-pass InSAR coherence technique, and polarimetric SAR techniques are elucidated for mapping snow cover. Multi-temporal SAR data have great potential for identification and delineation of glacier facies, which helps to map equilibrium line. New emerging radar satellite for development of high precision DEM are also included which have direct application for glacier mass balance study. In the beginning of the entry a comprehensive methodology for SAR data processing is enclosed specially for glacier application scientists.

RADIATIVE TRANSFER MODELING

Jie Cheng[1], Shunlin Liang[2]
[1]College of Global Change and Earth System Science, Beijing Normal University, Beijing, China
[2]Department of Geography, University of Maryland, College Park, MD, USA

Definition

Albedo. The total fraction of light scattered into the upward hemisphere by a surface.
Emissivity. Emissivity is defined as the ratio of the actual radiance emitted by a given surface to that emitted by a blackbody at the same temperature. It is a measure of surface radiation ability.

Introduction

Radiative transfer (RT) is the radiant energy transported through a medium in the form of an electromagnetic wave. The interactions between electromagnetic waves and media are complex physical processes that include absorption, scattering, and emission. These interactions can be described mathematically with the radiative transfer equation, in which energy is always represented by the spectral radiance or intensity:

$$\frac{\mathrm{d}I(s)}{\mathrm{d}s} = -K(I - J),$$

where $I(s)$ represents the spectral radiance (I) at a specific direction (S), K is the volume extinction coefficient, and J is the source function.

The radiative transfer equation has been widely used in astronomy, atmospheric science, and remote sensing. However, the radiative transfer equation is a differential integral equation (Liang, 2004), and it is preferable to use the radiation at fixed locations in a medium in actual applications. Thus, we should determine the solution to the radiative transfer equation, given the optical properties of the medium and their boundary conditions. Generally, there are two types of solutions: approximate solutions (also called *analytical solutions*) and numerical solutions. Both of these solution types characterize the behavior of radiation in the medium.

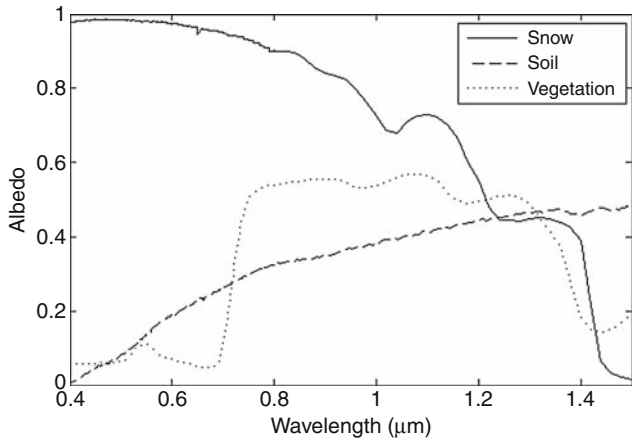
In remote sensing, satellite sensors measure the radiation signal attenuated by the intervening atmosphere between the satellites and the surface. The measured radiation signal and the surface parameters are primarily linked by surface and atmospheric radiative transfer models. Therefore, radiative transfer models are essential for satellite radiation signal interpretation and the inversion of surface parameters.

Importance of RT modeling

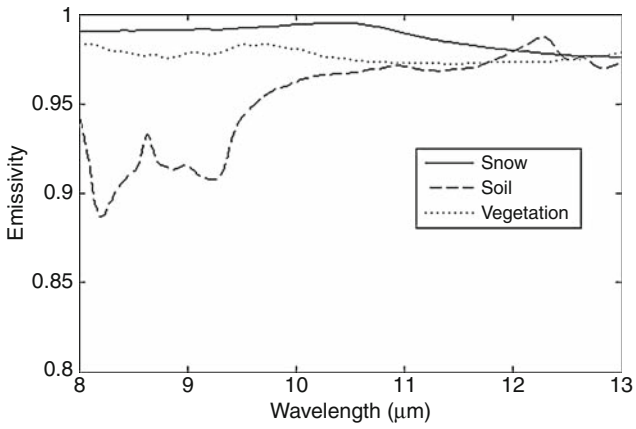
Snow, ice, and glaciers are important land surface types. They have high albedos in the visible and near-infrared

spectrum (Figure 1), and substantially reflect solar radiation. They also have high emissivities in the thermal infrared spectral region (Figure 2). Furthermore, these land surface types have pronounced effects on the energy budget of the Earth-atmosphere system. They determine the amount of water that will be released during spring runoff, and are the primary water sources for almost all of the major river systems across the world. Therefore, snow, ice, and glaciers are very important for hydrological applications and water resource management.

In situ measurements of the physical properties of snow, ice, and glaciers are extremely difficult, due to spatial and temporal representations and expenses, and can even be dangerous. Remote sensing has the advantage of global coverage at high temporal frequencies, and is an ideal tool for studying these land surface types at the regional and global scales. Additionally, the satellite remote sensing of snow, ice, and glaciers often requires a radiative transfer model to simulate and invert their radiation properties.



Radiative Transfer Modeling, Figure 1 Spectral albedo values of snow, soil, and vegetation in the visible and near-infrared spectral region.



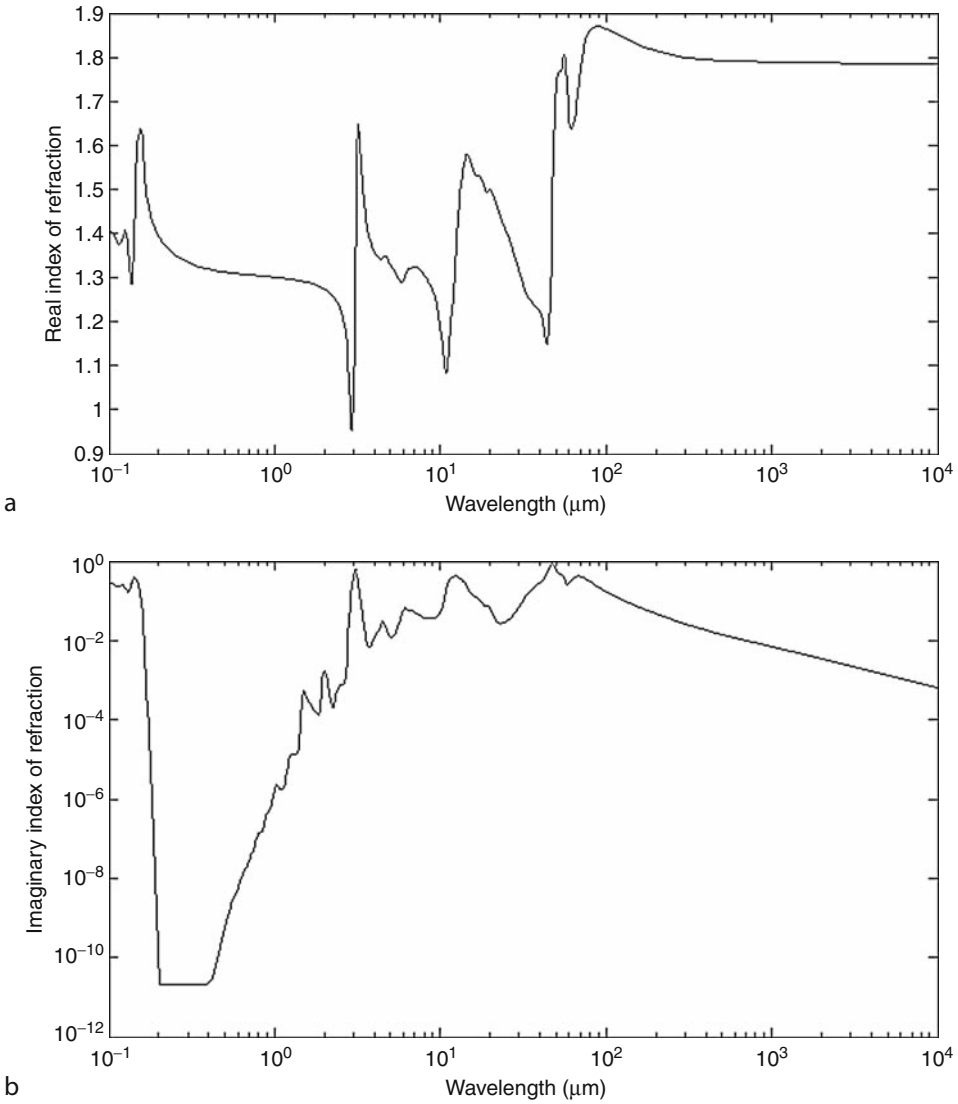
Radiative Transfer Modeling, Figure 2 Spectral emissivities of snow, soil, and vegetation in the thermal infrared spectral region.

The basic physical components of snow, ice, and glaciers are irregular ice crystals, air in porosity, liquid water production when melting, and impurities when contaminated by aerosols and other pollutants. The ice crystal is the basic scattering, absorbing, and emitting agent in snow, ice, and glacial media. In the optical region, the factors of greatest concern are the albedos and emissivities of these land surfaces types. The former determines how much incident solar radiation is reflected back into the sky by snow, ice, and glacier surfaces, and the latter determines how much radiation is emitted; both influence the radiation budgets of these surface types. Microwave remote sensing can be used to determine the snow cover, snow depth, and snow water equivalent (SWE), which are indicators of global climate change, particularly the glacial ablation resulting from global warming.

Surface albedo and emissivity modeling

Snow can be considered a layered particulate medium. To model the albedo and emissivity of a snow surface cover, it is necessary to begin with the known single-scattering properties of snow particles, which govern the ensemble properties of the snow medium (Nolin and Liang, 2000). The single-scattering properties needed as inputs for radiative transfer models are the extinction cross section, single-scattering albedo (ratio of scattering to extinction cross section), particle scattering phase function, and asymmetry factor (the cosine of the average of the particle scattering phase function). Calculating the scattering properties of a snow particle requires the optical constants, $m = n + ik$ (also referred to as the *complex refractive index*), where n is the usual refractive index that determines the phase speed and k is related to the absorption coefficient, as well as the size parameter, $x = 2\pi r/\lambda$, where r is the sphere radius and λ is the wavelength. A compilation of the optical constants of ice, from the ultraviolet to the microwave spectrum, is now available (Warren and Brandt, 2008). Figure 3 shows the complex refractive index of ice.

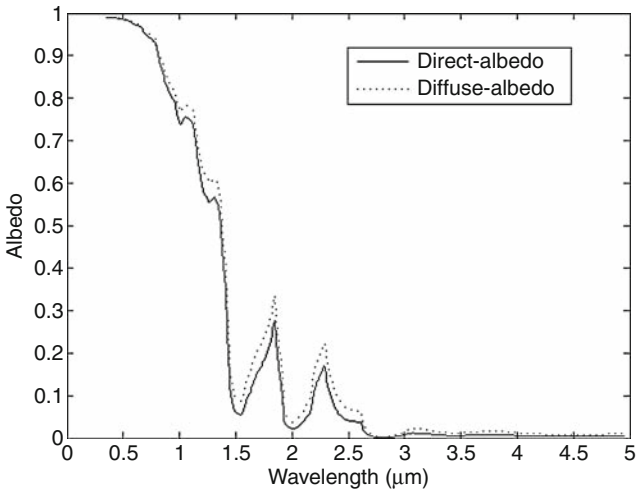
There are numerous light scattering theories and computational codes available to calculate the single-scattering parameters for a single particle (Wriedt, 2009). One of the most popular theories is the Mie theory (Mie, 1908) for optically homogeneous spherical particles. Although realistic snow particles are nonspherical and tend to be spheroidal, randomly oriented "equivalent spheres" with the same volume-to-surface ratios are commonly used to represent snow grains. These "equivalent spheres" allow the Mie theory to be used for the computation of the single-scattering parameters of snow particles. Previous studies have shown that the "equivalent spheres" assumption is a feasible surrogate. For example, Mugnai and Wiscombe (1987) demonstrated that their scattering results were the same as those for ensembles of nonspherical



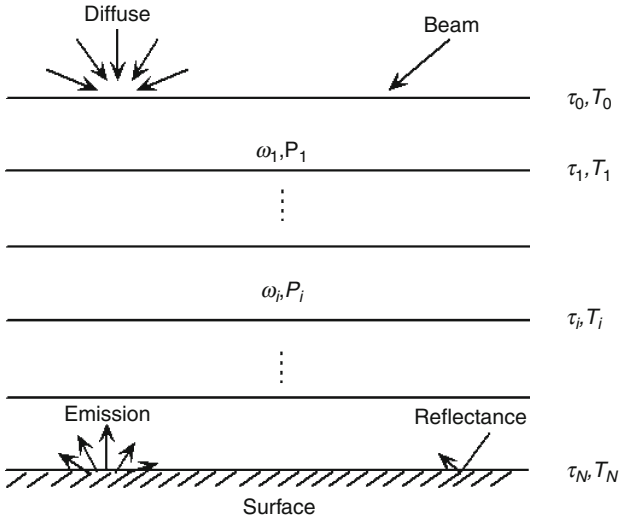
Radiative Transfer Modeling, Figure 3 Complex refractive index of ice: (**a**) Real part, (**b**) Imaginary part.

particles. Other studies (Dozier, 1989; Grenfell and Warren, 1999) have shown that the volume-to-surface area ratio of an ice particle can be used to represent an optically equivalent grain size for ensembles of nonspherical ice particles. Thus, snow particles are often represented by "equivalent spheres" in radiative transfer models.

In the past, there were several limited snow albedo models (Dunkle and Bevans, 1956; Giddings and La Chapelle, 1961; Barkstrom, 1972; Bohren and Barkstrom, 1974) available to the scientific community. Unfortunately, these models are now obsolete due to their obvious shortcomings, because no single model is valid for all wavelengths in the solar spectrum, or for an arbitrary combination of diffuse and direct incidence. To address this issue, a practical snow spectral albedo analytical model was put forward by Wiscombe and Warren (1980). In the Wiscombe and Warren model, the extinction cross section, single-scattering albedo, and asymmetry factor are calculated by the Mie theory using known snow optical constants and size parameters. The δ-Eddington approximation is used for multiple scattering (Joseph et al., 1976). The formulations of direct-beam and diffuse albedos are presented. Figure 4 depicts semi-infinite direct-beam and diffuse albedos calculated by the Wiscombe and Warren formulation. The snow effective radius is 50 μm and the solar zenith angle is 30°. Snow is always contaminated by desert dust and carbon soot aerosols, which absorb in the visible and near-infrared spectral regions, and have pronounced effects on snow albedo modeling in the visible spectral region. Warren and Wiscombe (1980) extended their previous snow albedo model to incorporate the optical constant of these impurities into the snow optical constant to allow for aerosol contamination.



Radiative Transfer Modeling, Figure 4 Semi-infinite direct-beam and diffuse albedo values calculated by Wiscombe and Warren model. Snow effective radius is 50 μm and solar zenith angle is 30°.



Radiative Transfer Modeling, Figure 5 Schematic illustration of optical medium stratification for numerical calculation of radiative transfer. Each layer has single-scattering albedo ω, phase function P, and temperature T. They are defined as layer averages.

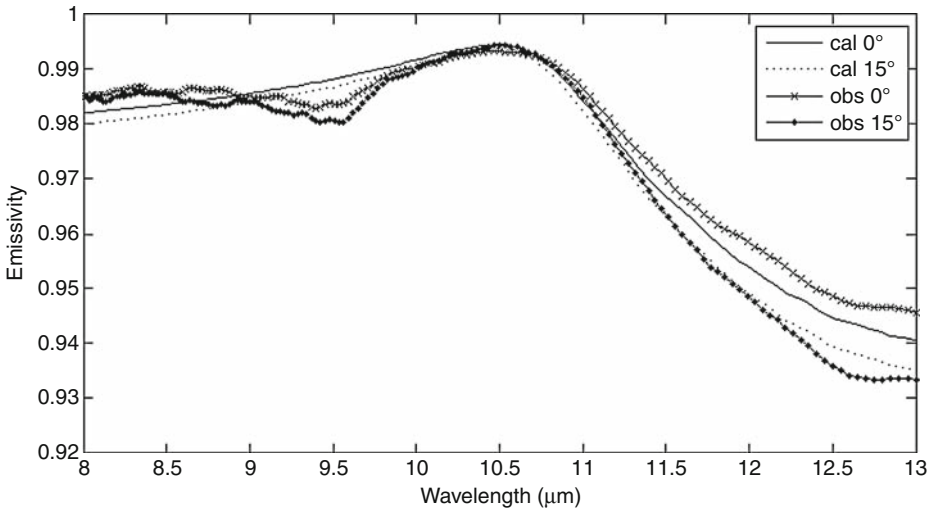
Several analytical radiative transfer models were originally designed for other semi-infinite media such as quartz, soil, and the planetary surface. These models can also be used for snow. Conel (1969) developed a cloudy atmosphere model of the condensed powder emission spectrum in which the Mie theory is used to calculate single-scattering parameters, and multiple scattering is modeled with a two-stream approximation. Hapke (1981, 1993) developed a series of analytical bidirectional reflectance models for a semi-infinite particulate medium. In Hapke's reflectance models, the single-scattering properties of a particle are calculated with the geometric optical method, and multiple scattering is approximated with the two-stream method. In Hapke's emittance model, the directional emissivity of a semi-infinite medium is derived through the embedded invariance theory (Hapke, 1993). Moersch and Christensen (1995) used the Mie theory to replace the geometric optical method for single-scattering parameters, and evaluated the Mie/Hapke hybrid model using laboratory-measured quartz emissivity spectra. Liang and Townshen (1996) developed a modified Hapke model for a soil bidirectional reflectance simulation by dividing the original multiple-scattering parameters into those for double scattering and higher-order scattering. The modified Hapke model demonstrates higher accuracy than the original. In these models, particles are treated as independent and do not impact each other. In actuality, particles in semi-infinite media, like snow and soil, touch each other and are sometimes densely packed. As pointed out by Van de Hulst, the neighboring particles must be separated by three particle radii for the independent scattering approximation to be valid (Hulst, 1957). Thus, the independent scattering approximation is not valid for such media. Wald (1994) questioned the rationality of an independent scattering approximation and put forward a diffraction subtraction method to correct the Mie theory in relation to the single-scattering albedo and asymmetry factor. Mishchenko also developed a method to correct the Mie theory (Mishchenko and Macke, 1997). He used a static structure factor based on the filling factor – an index to characterize packing conditions. The static structure factor has a strong physical foundation, and is based on solving Maxwell's equation for light scattering and the statistical mechanics for dense packing. Pitman et al. (2005) used these two correction methods to modify the Mie single-scattering parameters and drive several radiative transfer models of silicate surface emissivity. Comparisons using measured silicate surface emissivities show that radiative transfer models cannot replicate observations, even if the Mie single-scattering parameters are modified using these correction methods.

In addition to analytical radiative transfer models, numerical models are also widely used in snow albedo modeling, including the discrete ordinates radiative transfer (DISORT) model, adding-doubling model, and spherical-harmonic model. The DISORT model was introduced by Wick (1943) and further developed by Chandrasekhar to model the radiative transfer of planetary atmospheres (Chandrasekhar, 1960). Liou (1973) extended the DISORT model for aerosols and cloudy atmosphere conditions, and demonstrated that it is an effective and powerful tool. A numerical DISORT computational code was introduced by Stamnes et al. (1988). DISORT assumes that the medium consists of multiple adjacent homogeneous layers. For each layer, the single-scattering albedo and phase function are assumed to be constant, but these can vary from layer to layer (Figure 5). Given the single-scattering properties, DISORT can be used to calculate the reflective characteristics (e.g., surface albedo and

bidirectional reflectance) of snow. Because it is a highly accurate model, DISORT is often used as a benchmark to evaluate the performance of other analytical radiative transfer models. The adding-doubling model was introduced by Hansen for the interpretation of the intensity and polarization of sunlight reflected from clouds (Hansen, 1971). It starts with a thin cloud layer with a known single-scattering albedo and phase matrix, and then adds a layer with a double optical depth. This process is repeated until the total optical depth is achieved. The reflectance and transmittance of the layered medium can be calculated by adding the values of each individual thin layer. Leroux et al. (1999) used the adding-doubling model to develop the polarized bidirectional reflection distribution function (BRDF). Aoki et al. (2000) used this model to simulate the spectral albedo and bidirectional reflectance of the snow surface. The spherical-harmonic model was developed by Mishchenko et al. (1999), and is an efficient model for calculating the bidirectional reflectance of a semi-infinite homogeneous particulate medium.

Based on Kirchhoff's law, the directional emissivity can be calculated by subtracting the directional-hemispherical reflectance. Thus, the radiative transfer models used to calculate snow albedo can also be used for calculating the directional emissivity of snow. Dozier and Warren (1982) derived a formulation of the directional emissivity of snow based on Kirchhoff's law and the Wiscombe and Warren snow spectral albedo analytical model, with the assumption that snow is a semi-infinite scattering medium. Their studies showed that the directional emissivity of snow can result in a 3 K difference between the thermodynamic temperature and brightness temperature in the 12–14 μm spectral region. Wald used the single-scattering parameters corrected by diffraction subtraction as inputs for the Wiscombe and Warren model (Wiscombe and Warren, 1980), Hapke emittance model (Hapke, 1993) and doubling model (Wiscombe, 1976) to investigate their feasibility for snow emissivity modeling. This method quantitatively predicts the directional hemispheric reflectance of disaggregated snow samples with particle radii greater than 50 μm. Cheng et al. (2010) investigated the abilities of three analytical radiative transfer models (Conel model, Dozier and Warren model, and Hapke emittance model) and one numerical (DISORT) radiative transfer model to determine the directional emissivity of snow, and compared the simulation results with actual in situ measurements of the directional emissivity of snow. The most suitable hybrid RT model was identified. For modeling the directional emissivity of snow, the Mie-corrected/Hapke model is the best choice. The root mean square error (RMSE) of the Mie-Mishchenko/Hapke model is less than 0.005 for r = 35 μm in the 8–11 μm spectra region; the RMSE of the Mie-Wald/Hapke model is less than 0.009 for r = 400 μm in the 8–11 μm spectra region; the RMSE is less than 0.006 for r = 300 in the 8–13 μm spectra region; and the RMSE is less than 0.006 for r = 550 μm in the 8–11 μm spectra region – except for the 60 and 75° view angles.

Ice can be treated as a smooth surface. Its bidirectional reflectance can be calculated with the Fresnel reflectance theory given the relative refractive index and emittance angle. The directional emissivity of ice can be derived with the Fresnel reflectance theory and Kirchhoff's Law. Hori et al. (2006) calculated the directional emissivity of bare ice using the Fresnel reflectance theory and compared the result with field and laboratory measured values. They obtained consistent results with absolute differences on the order of 0.01, which is the desired accuracy for remote emissivity sensing devices. Figure 6 shows the measured nadir and 15° emissivities of ice, as well as the values calculated by the Fresnel reflectance theory.



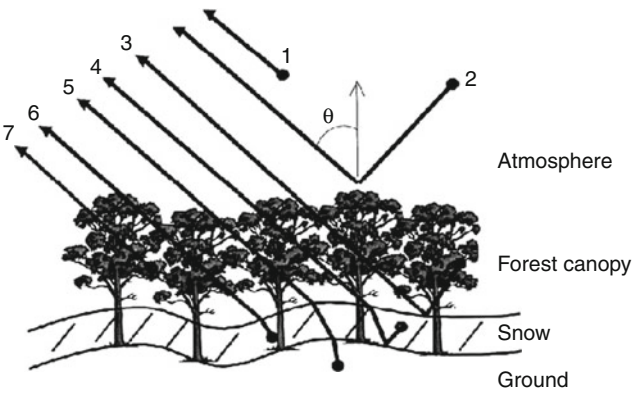
Radiative Transfer Modeling, Figure 6 Comparison of measured directional emissivity of ice with that calculated by the Fresnel reflectance theory.

Microwave emission modeling

In the microwave spectral region, snow is a dense particulate medium, and the interactions between microwave signals and snow include surface and volume scatterings. Snow volume scattering is composed of coherent and incoherent multiple scatterings. Microwaves can penetrate the snow surface and interact with the underlying ground. The microwave emissions from a snowpack come from the snow itself and from the underlying ground. These two emissions are governed by the extinction and emission properties of the snow layer, and by the transmission and reflection properties of the air-snow and snow-ground interfaces. The ground emission, and the interactions at the snow-ground boundary, must be considered in a snow-microwave emission model.

There are many models for surface scattering, including the small perturbation method (SPM), Kirchhoff approximation (KA) (Ulaby et al., 1982; Fung, 1994), small slope approximation (SSA) (Broschat, 1993), and integral equation model (IEM) (Fung et al., 1992). These models have individual applicabilities and are similar under specific conditions. For example, the SPM is valid for slightly rough surfaces, while the KA can be used for surfaces with greater roughness. SSA and SPM produce the same simulation results for emissivity. The IEM has demonstrated its applicability for a wide range of surface roughness parameters through comparisons with Monte Carlo simulations and laboratory-controlled measurements. However, it cannot achieve satisfactory emissivity simulation results for very rough surfaces because of several weak assumptions adopted by the model. Chen et al. (2003) extended the original IEM model by removing these weak assumptions, and subsequent comparisons of the surface emission simulation results of AIEM with those of three-dimensional Monte Carlo simulations for Gaussian rough surfaces indicate that AIEM is accurate and applicable for a wide range of surface dielectrics, roughness values, and sensor frequencies. These achievements have produced a fundamentally improved understanding of the measured microwave signals for snow.

In recent years, significant progress has been made in the theoretical modeling of microwave emissions from snow. Several microwave snow emission models have been published to describe the relationships between snow parameters and electromagnetic quantities (e.g., brightness temperature). These include the microwave emission model of layered snowpacks (MEMLS) model (Wiesmann and Matzler, 1999), the model developed by the Helsinki University of Technology (HUT) (Pulliainen et al., 1999), the dense medium radiative transfer (DMRT) model (Chuah et al., 1996; Tsang and Kong, 2001), and the slab multiple-scattering microwave emission model (also referred to as the DRRT-AIEM-MD model, Jiang et al., 2007). Microwave emission models can be classified as empirical, semiempirical, and theoretical. The DMRT model is one of the theoretical models, which are based solely on physical theory, without the use of any experimental data. The MEMLS, HUT, and DRRT-AIEM-MD are semiempirical models, which are developed by combining theory with measured results. For example, the HUT model was developed from the radiative transfer theory, and the extinction coefficient in the model was derived from experimentation. Because of the different approaches used to model physical processes, characterize the electromagnetic properties of snow, and solve the radiative transfer equations, each kind of model has its own application limitations. The DMRT model can be used to validate semiempirical models, and as a forward simulation tool to provide the data used to establish the empirical relationships in empirical models. However, it cannot be included in an operational inversion methodology due to its complexity. The MEMLS model is a multilayer and multi-scattering snow emission radiative transfer model, and although it is not suitable for the direct retrieval of snow variables, it can be used to validate a retrieval algorithm. The HUT model only considers one homogeneous snow layer, which includes the soil, vegetation, and atmosphere, and is widely used to determine the SWE or snow depth from remote sensing data because of its simplicity (Figure 7). The influence of internal layering in a snowpack is not considered in the HUT model. Such internal layering will increase the scattering in the snowpack and change the spectral gradient. It should be pointed out that there is no single algorithm that yields good estimates for the SWE at the global scale.



Radiative Transfer Modeling, Figure 7 Major contributions to spaceborne observed scene brightness temperature. All of these contributions are included in the Helsinki University of Technology (HUT) snow emission model: (1) upward emitted atmospheric radiation; (2) downward emitted reflected atmospheric radiation; (3) downward emitted reflected forest canopy emission contribution; (4) downward emitted reflected snowpack emission contribution; (5) upward emitted reflected emission contribution; (6) upward emitted snowpack emission contribution; (7) upward emitted forest canopy emission contribution [From Pulliainen and Hallikainen (2001), Remote Sensing of Environment. Complementary modeling techniques

In addition to the analytical and numerical radiative transfer models, geometrical optical models and Monte Carlo methods can also be used to simulate the radiation properties of snow, ice, and glaciers. These are complementary to the analytical and numerical radiative transfer models, and can be treated as a part of radiative transfer modeling. When the particles are very large relative to the wavelength of the incident light, the geometrical optics approach can be used to model the surface reflectance. Leroux et al. (1998) used a photometric roughness model based on a model developed by Roujean et al. (1992) that used vertical protrusions arranged on a flat scattering surface to investigate the snow surface roughness effects on the albedo. They found that the sastrugi caused by wind erosion have a darkening effect that can reduce the albedo by as much as 10%. Leroux and Fily (1998) modified the model by orienting the regularly spaced identical protrusions along the same direction, ignoring the inter-facet multiple scattering, and assigning an appropriate bidirectional reflectance to the underlying flat snow surface. They found that there was still a quantitative disagreement between the simulations and measurements. Two factors are thought to be responsible for this disagreement: the imperfections of the roughness model and uncertainties in the experimental data. Clearly, more measurements and model refinements should be carried out in the future.

In the analytical or numerical radiative transfer models, a basic scattering unit is assumed to be homogeneous and have the same properties, such as the commonly used plane-parallel assumption. The scatters in each optical thin plane are assumed to have the same properties, even though these are miscellaneous. When considering the radiation distribution calculation for a complex dense medium, these approaches sometimes have limited domains of validity.

The Monte Carlo method is effective at solving mathematical problems by random sampling (Kim et al., 2004). It consists of simulating the behavior of each individual photon using probabilistic methods. In order to get satisfactory results, it is essential to produce a large number of photons in the simulations. The wave scattering problem has been a hot topic of continued study for many years because of its broad applications (Li et al., 1999). Fortunately, the advent of modern computers and more efficient computation methods makes it possible to model microwave scattering with the Monte Carlo method (Chan et al., 1998). Two kinds of microwave scattering problems can be solved with the Monte Carlo method – the rough surface and discrete scatter problems (Zurk et al., 1996). In the rough surface scattering problem, the bi-static scattering coefficients can be derived by directly solving Maxwell's equation using the Monte Carlo method. For a dense medium problem, a large number of photons are needed to perform Monte Carlo simulations of the extinction, phase matrix, and absorption coefficients. These parameters are then used in either analytical or numerical radiative transfer models to calculate the bi-static scattering properties of a dense medium.

Nieto-Vesperinas and Soto-Crespo (1987) simulated the scattered intensities of a one-dimensional perfectly conductive random surface with the Monte Carlo method. Tsang et al. (1992) iteratively solved Maxwell's equation in multiple scattering form, and used the Monte Carlo method to compute the extinction rates for fractional volumes of up to 25%. Zurk et al. (1995) used the Monte Carlo method to simulate the extinction rates for densely packed spheres with clustered and non-clustered geometries. Zurk et al. (1996) used the Monte Carlo method to derive the phase matrix, effective permittivity, and scattering coefficients for a densely packed medium composed of up to 5,000 spheres. The simulated parameters were used as inputs to a second-order radiative transfer model to predict the backscattering of a layer of snow. These results were compared with those calculated using DMRT and the independent scattering assumption. Different results were obtained due to the assumption used in the calculation of the extinction coefficient, phase matrix, and effective permittivity. Three-dimensional method-of-moment Monte Carlo simulations of microwave emissions from lossy dielectric random rough surfaces were made possible by fast computation methods (Li et al., 2000). Chen et al. (2003) used Monte Carlo simulations of the three-dimensional solutions of Maxwell's equations to study the frequency dependence of the scattering by dense media.

Primary applications

Radiative transfer models have been used (Liang, 2004, 2008): (1) to directly calculate surface albedo and emissivity given the basic surface physical parameters, and (2) to invert the surface physical parameters from remote sensing data.

Surface albedo and emissivity calculation

The albedo of a snow, ice, or glacier surface determines how much incident solar energy is absorbed and reflected by the surface. The emissivity of a snow, ice, or glacier surface characterizes its ability to emit radiation, and can be used to estimate the surface temperature. The albedo and emissivity are two critical parameters in estimating the surface energy budget, which is highly related to the physical state of the surface, such as one involving snowmelt and runoff. The Wiscombe and Warren (1980) snow spectral albedo model has been embedded in land surface and global circulation models to calculate the snow surface albedo (Dai et al., 2003; Schmidt et al., 2006). Dozier and Warren (1982) derived a formulation for the directional emissivity of snow from the Wiscombe and Warren (1980) directional-hemispherical reflectance equation using Kirchhoff's law. They used this formulation to study the directionality of snow emissivity from its brightness temperature. The formulation of Dozier and Warren (1982) was used to calculate the directional emissivity of

a snow-covered surface, and the calculated directional emissivity was used to determine the surface temperature from satellite data (Key and Haefliger, 1992; Key et al., 1997). Snyder et al. (1998) used the formulation of Dozier and Warren (1982) to consider the angular effect of snow surface emissivity. Even though the formulation of Dozier and Warren (1982) has been widely used in calculating snow surface emissivity because of its reliable temperature determination, it cannot reflect the radial dependence of snow emissivity (i.e., the decrease in snow emissivity with an increase in particle radius). Cheng et al. (2010) investigated the ability of radiative transfer models to determine the directional emissivity in snow modeling, and compared the simulation results with in situ measurements of the directional emissivity of snow. They found that the hybrid Mie-corrected/Hapke model is the best choice for determining the directional emissivity in snow modeling.

Surface physical parameters retrieval

The surface physical parameters derived from remote sensing data can be used in many applications such as forecasting avalanches, validating metamorphism models, and obtaining snow data in remote areas (Brun et al., 1989; Bourdelles and Fily, 1993; Nolin and Stroeve, 1997). Therefore, many studies have focused on determining the snow grain size, emissivity, SWE, or snow depth from remote sensing data. While the previous discussion focused on the details of the spectral albedo and emissivity calculations, we will now focus primarily on estimating: (1) the snow grain size, and (2) the SWE or snow depth.

Snow grain size retrieval

Dozier et al. (1981) investigated the effects of the snow grain size on the visible and near-infrared reflectance using the Advanced Very High Resolution Radiometer (AVHRR) data. Their results indicate the dependence of the snow reflectance on the snow grain size and snow water equivalent. Dozier and Marks (1987) showed that it was possible to retrieve the snow grain size by combining the Wiscombe and Warren (1980) model and AVHRR data. Nolin and Dozier (1993) estimated the snow grain size from the Airborne Visible/Infrared Imaging Spectrometer (AVIRIS) data, using an exponential relationship between the snow grain size and 1.04-μm reflectance derived with the DISORT model. Fily et al. (1997) retrieved the snow grain size from the Landsat data for highly mountainous terrain in the French Alps based on the forward radiative transfer DISORT model. Nolin and Dozier (2000) discovered that, in spectral snow reflectance, the scaled band area of absorption by ice centered at 1.03 μm depends on the snow grain size, and developed a new algorithm for grain size retrieval. Their retrieval experiments indicated that this new algorithm is both robust and accurate. In their algorithm, the relationship between the snow grain size and scaled band area is derived with DISORT. Li et al. (2001) compared the snow grain sizes retrieved from four AVIRIS channels using a logarithmic expression derived from DISORT simulations, obtaining different snow grain sizes from the same pixel. The different penetration depths for different wavelengths are thought to be responsible for this phenomenon. It could be used to retrieve the average snow grain size for different snow layers. Painter et al. (2003) used a bidirectional reflectance model based on the Mie theory and DISORT model, in conjunction with a spectral mixture analysis based on the endmember reflectances for different snow grain sizes, to simultaneously retrieve the snow grain size and snow cover. Stamnes et al. (2007) developed an algorithm to determine the snow grain size and impurity concentration from the Advanced Earth Observing Satellite II (ADEOS-II) Global Imager (GLI) data utilizing the Mie theory and DISORT model. Aoki et al. (2007) validated the algorithm using the GLI and Moderate Resolution Imaging Spectrometer (MODIS) data.

SWE or snow depth retrieval

The penetration depth of the visible, near-infrared, and thermal-infrared wavelengths is very limited, while microwaves can always penetrate the snow surface and reach the underlying ground. Microwave remote sensor data are always used for determining the SWE or snow depth, especially passive microwave remote sensing data. Pulliainen and Hallikainen (2001) explored the use of the HUT snow emission model to retrieve the SWE of dry snow cover from spaceborne Special Sensor Microwave/Imager (SSM/I) observations. The derived SWE values were compared with those derived with an empirical regression algorithm. The comparison results showed that the overall accuracy of the algorithm based on the HUT snow emission model was substantially better than that of the empirical regression algorithm. The algorithm based on the HUT snow emission model could estimate the regional SWE under dry snow conditions with an overall RMSE of about 30 mm, without using any training reference data on the SWE. Roy et al. (2004) investigated the feasibility of using the HUT snow emission model for the estimation of the SWE in a Canadian boreal forest environment. They first compared the snow-covered ground brightness temperatures modeled with the HUT snow emission model to those measured by an airborne radiometer. Large biases were discerned, which they ascribed to the extinction coefficient modeling in the HUT snow emission model. They proposed a new semiempirical function for the extinction coefficient. The modified HUT snow emission model can now obtain a more accurate brightness temperature in a boreal forest environment. The modified HUT snow emission model was used to retrieve the SWE based on an iterative inversion technique. The retrieval results showed that a mean error of ± 10 mm could be achieved,

with a negligible bias. Pulliainen (2006) proposed a novel assimilation technique based on the modeling of observed brightness temperatures as a function of snowpack characteristics. They mapped the SWE and snow depth in boreal and subarctic zones by assimilating spaceborne microwave radiometer (SSM/I and AMSR-E) data and ground-based observations. Their results show that assimilation techniques can substantially improve the SWE and snow depth retrieval accuracy. Parde et al. (2007) used the HUT snow emission model to estimate the SWE from airborne and satellite data, and validated their retrieval results with ground-based SWE measurements. These validation results showed that the accuracy of the retrieved SWE could meet the requirements of seasonal snow pack evolution, interannual variation, and hydrological applications. Vachon et al. (2010) developed a method to monitor the SWE using a modified HUT model. In their method, the model was first calibrated by incorporating in situ measurements (snow depth and density) to find optimized initial assumptions for the model parameters, including the extinction coefficients. The SWE was then retrieved from the satellite observations. The validation results showed that model calibration before SWE retrieval could improve the accuracy of the SWE estimation.

Nuclear fallout

Definition

Fallout is the residual radiation hazard from a nuclear explosion, so named because it "falls out" of the atmosphere into which it is spread during the explosion. It commonly refers to the radioactive dust created when a nuclear weapon explodes. This radioactive dust, consisting of hot particles, is a kind of radioactive contamination. It can lead to contamination of the food chain (Simon et al., 2006).

Effects

A wide range of biological changes may follow the irradiation of animals. These vary from rapid death following high doses of penetrating whole-body radiation, to essentially normal lives for a variable period of time until the development of delayed radiation effects, in a portion of the exposed population, following low dose exposures.

Unit

The unit of actual exposure is the Roentgen which is defined in ionizations per unit volume of air, and all ionization-based instruments (including Geiger counters and ionization chambers) measure exposure. However, effects depend on the energy per unit mass, not the exposure measured in air. A deposit of 1 J/kg has the unit of 1 gray. For 1 MeV energy gamma rays, an exposure of 1 Roentgen in air will produce a dose of about 0.01 gray (1 centigray, cGy) in water or surface tissue. Because of shielding by the tissue surrounding the bones, the bone marrow will only receive about 0.67 cGy when the air exposure is 1 Roentgen and the surface skin dose is 1 cGy. Some of the lower values reported for the amount of radiation which would kill 50% of Population (the "LD_{50}") refer to bone marrow dose, which is only 67% of the air dose.

Definition

Radioactive isotopes are the atoms with unstable nucleus which decay with time by emitting different types of particles or radiations such as neutrons, electrons (beta particles), etc. or gamma radiations (see *Radioactivity*).

Origin

Naturally occurring radionuclides fall into three categories: primordial radionuclides, secondary radionuclides, and cosmogenic radionuclides. Primordial radionuclides originate mainly from the interiors of stars and, like uranium and thorium, are still present because their half-lives are so long that they have not yet completely decayed. Secondary radionuclides are radiogenic isotopes derived from the decay of primordial radionuclides. They have shorter half-lives than primordial radionuclides. Cosmogenic isotopes, such as carbon-14, are present because they are continually being formed in the atmosphere due to cosmic rays. Artificially produced radionuclides can be produced by nuclear reactors, particle accelerators, or radionuclide generators. The details of various radioisotopes with their half-lives, decay mode, principle sources, etc. are given in Table 1.

Uses

The radioisotope of hydrogen (tritium) in the form of water molecule (^3H_2O) and denoted by symbol ^3H or T is still widely used for various hydrological studies. There are other variety of artificially produced radioisotopes like ^{60}Co, ^{82}Br, ^{131}I, ^{137}Cs, ^{198}Au, ^{226}Ra, ^{241}Am, etc. that are used for various hydrological investigations. Radioisotopes are used to study the movement of surface water, and to measure water runoffs from rain and snow, as well as the flow rates of streams and rivers. Natural radionuclides are used in geology, archaeology, and paleontology to measure ages of rocks, minerals, and fossil materials.

Dangers

If radioisotopes are released into the environment, through accident, poor disposal, or other means, they can potentially cause harmful effects of radioactive contamination.

RADIOACTIVITY

Bhishm Kumar
Hydrological Investigation Division, National Institute of Hydrology, Roorkee, Uttarakhand, India

Definition

The process of decay of an unstable atom in order to attain a stable nuclear configuration by giving out α, β particles and γ or x rays is known as radioactivity (See *Radioactive Isotopes*).

The process of radioactivity may complete in a fraction of second or it may continue for millions of years depending upon the type of decaying atom. During the process of radioactivity, an unstable atom may be converted into a different type of stable atom in one stroke or there may be a series of chain of daughter nuclei before finally stable nuclide is formed. The decaying atom is called the parent nuclide, while the intermediate transformations and finally stable nuclide are called daughter and granddaughter nuclides, respectively.

Radioactive decay

The rate of decay of any radioisotope obeys the following exponential law:

$$N = N_o * \exp(-\lambda t),$$

where N is the number of radioactive atoms present at time t, N_o is the number of radioactive atoms present t = 0, and λ is the decay constant, which is a unique property for each isotope. Usually, the rate of decay is defined by the half-life ($T_{1/2}$), where

$$T_{1/2} = \ln(2)/\lambda$$

which is the time required for half of the radioactive nuclei to disintegrate. Half-life values for radioisotopes vary from fractions to a second to millions of years.

Unit

The unit of radioactivity is the Becquerel (Bq), which is defined as the quantity of any radioisotope that decays at the rate of one disintegration per second (dps). Earlier the unit was the curie (Ci), which is equal to 3.7×10^{10} Bq. Specific activity is defined as the amount of radioactivity of a given radioisotope per gram of a compound or element (Payne, 1983).

Synonyms

Rain-on-snow event

Definition

Rain-induced snowmelt. Liquid water generated within a melting snowpack by rain heat flux and turbulent atmospheric fluxes.
Rain-on-snow. A hydrometeorological event occurring when rain infiltrates an existing snowpack.

Introduction

Net radiative and sensible, latent, and rain heat fluxes constitute the major energy sources that result in snowmelt. The importance of each of these fluxes to the generation of snowmelt depends on the local context and varies with time and space. Rain-induced snowmelt contributes to meltwater movement in forests (Levia and Underwood, 2004), runoff (Ishii and Fukushima, 1994), and streamflow (Ikebuchi et al., 1986). Rain-induced snowmelt is, however, of greatest importance with regard to rain-on-snow events. Rain-on-snow events are not uncommon in alpine and temperate regions of the world (Gray and Male, 1981; Singh et al., 1997). In the western United States, for example, over 380 cooperative weather station sites reported > 100 rain-on-snow events and another 86 cooperative weather stations reported >200 rain-on-snow events in a 55-year period from 1949 to 2003 (McCabe et al., 2007). Early season rain-on-snow events are of societal importance as they have been reported to create persistent weak layers (i.e., facet–crust combinations) in seasonal snowpacks that can lead to avalanches (Hägeli and McClung, 2003). Rain-on-snow events also have been documented to lead to catastrophic flooding (Leathers et al., 1998; Marks et al., 2001) and slushflows (Tomasson and Hestnes, 2000; Hestnes and Bakkehoi, 2004) that result in widespread property damage and loss of life.

Snowmelt energetics

Rain-induced snowmelt is an important component of the hydroclimatology of regions with ephemeral seasonal snow cover. The prevailing meteorological situation and the condition of the snowpack are two major factors in determining the intensity of rain-induced melt and the energy fluxes responsible for snowpack ablation. The total energy gained by a snowpack during a rain-induced melt event can be expressed using the formula:

$$Q = Q_n + Q_h + Q_e + Q_r + Q_g$$

where Q is the total energy gained by the snowpack, Q_n is the net radiation, Q_h is the sensible heat flux, Q_e is the latent heat flux, Q_r is the rain heat flux, and Q_g is the ground heat flux (Singh et al., 1997). The net radiation (Q_n) can be broken into its components and expressed as:

$$Q_n = S_n + L_n = S\downarrow(1-\alpha) + (L\downarrow - L\uparrow)$$

where S_n is the net shortwave radiative flux, L_n the net longwave radiative flux, $S\downarrow$ the incoming shortwave radiation, α albedo, $L\downarrow$ the incoming longwave radiation, and $L\uparrow$ the outgoing longwave radiation (King et al., 2008).

Meteorological effects on rain-induced snowmelt

During rain-induced melt events, the most important energy fluxes to the pack are generally the sensible (Q_h), latent (Q_e), and rain heat (Q_r) fluxes. By definition, the meteorological situations that result in significant rainfall occur in association with thick cloud cover. Thus, net radiation is commonly small during rain events as is the ground heat flux, at least in comparison to the turbulent fluxes and energy transfer by the rain itself. Sensible and latent heat fluxes can be estimated in diverse ways (King et al., 2008). Sensible heat flux is dependent upon the temperature difference between the snowpack and the atmosphere, and the wind speed, and can be expressed as:

$$Q_h = \rho C_a C_H w(T_a - T_o)$$

where ρ is the density of the atmosphere, C_a is the specific heat of the atmosphere at constant pressure, C_H is the bulk

transfer coefficient for sensible heat, w is the wind speed, and T_a and T_o are the air and snow surface temperatures, respectively. From this equation, it is obvious that greater differences in temperature between the snowpack and the atmosphere lead to larger sensible heat fluxes. Moreover, an increase in the wind speed also increases the magnitude of the sensible heat flux into the snowpack.Similarly, the flux of latent heat can be expressed as:

$$Q_e = L_v C_E w(q_a - q_s)$$

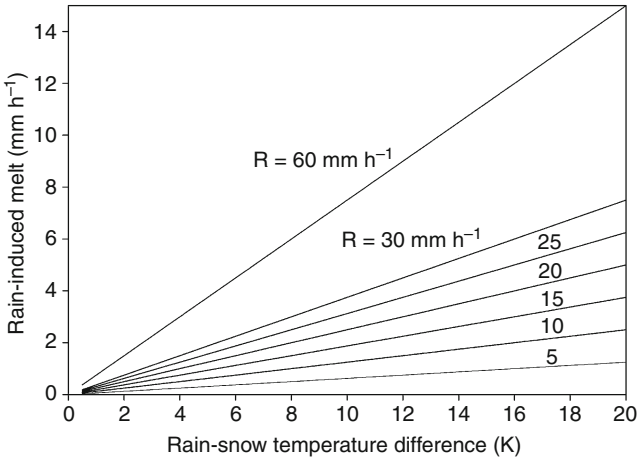
where L_v is the latent heat of vaporization, C_E is the bulk transfer coefficient for latent heat, w is the wind speed, and q_a and q_s are the water vapor densities of the atmosphere and snow surface, respectively. This equation suggests that the value of the latent heat flux is primarily dependent upon the water vapor density difference between the atmosphere and the snow surface, and the wind speed. The vapor density difference over a melting snowpack is a function of the atmospheric dew point temperature, and hence a characteristic of the overlying atmosphere (higher dew point temperatures lead to larger vapor density differences).

Consideration of the equations for both sensible and latent heat fluxes indicates that the magnitude of the turbulent fluxes is dependent on the meteorological conditions. The snow surface/atmosphere temperature differences that drive the sensible heat flux depend upon the characteristics of the air mass in contact with the ablating snowpack, as do the water vapor density differences that drive the latent heat flux. Both equations are also highly sensitive to the wind speed. Thus, the temperature and dew point temperature of the overlying air mass and the wind speed associated with the meteorological situation drive the magnitude of the turbulent energy fluxes. Because most rainfall situations are accompanied by temperature and dew points above 0°C, and often high wind speeds, these atmospheric characteristics generally lead to large fluxes of energy into the snowpack.

Energy transfer from rainfall to the snowpack can also be important in the ablation of snow cover. The flux of energy from liquid precipitation to the pack can be expressed as:

$$Q_r = 0.001 \times \rho_w \times C_{pw} \times (T_r - T_s) \times R$$

where ρ_w is the density of water (1,000 kg m^{-3}), C_{pw} is the specific heat of water (4.2 kJ kg^{-1} °C^{-1}), T_r is the temperature of the rain, T_s is the temperature of the snow surface, and R is the rainfall rate (Singh et al., 1997). Thus, the amount of energy transferred to the pack by rainfall depends upon the temperature difference between the liquid precipitation and the snow surface, and the rate at which the precipitation is falling (Figure 1). Therefore, in most rain-induced snowmelt events, the meteorological situation is of primary importance. As an air mass with temperatures and dew point temperatures above 0°C overspreads a snow-covered region, large sensible and latent heat fluxes are directed into the pack. It is important to note that the dew point temperature of the air mass is critically important in the melt process. Condensation of water vapor will occur on the snowpack whenever the dew point temperature of the air mass is above 0°C. The condensation releases latent heat directly into the pack, either warming the pack or supplying energy for melt. The rain heat flux is governed by the temperature of the liquid precipitation and rainfall rate, which is also dependent on the specific meteorological context. The combination of these three energy fluxes (sensible, latent, and rain heat) can cause very rapid melt of a snowpack, resulting in flash floods and slushflows.



Rain-Induced Snowmelt, Figure 1 Rain-induced snowmelt (mm h^{-1}) for various rainfall rates (R, mm h^{-1}) and rainfall/snowpack temperature differences (K).

It should be clear that rain-induced snowmelt will differ both spatially and temporally as a function of land cover type. The precipitation partitioning of incident rainfall by a forest canopy would exhibit marked spatial and temporal variability of snowmelt as a result of interception and the channeling of throughfall and stemflow at localized points on the forest floor. Thus, the routing of snowmelt (rain-induced or otherwise) in the subcanopy would be spatially heterogeneous (Bründl et al., 1999). The complex three-dimensional geometry of a forest canopy also would lead to pronounced temporal heterogeneity of melt of intercepted snow due (partly) to shading by neighboring trees and the lower albedo of intercepted snow compared to fresh snow on the earth's surface (Leonard and Eschner, 1968). As such, a prairie would be expected to have a more homogeneous melt signature as it lacks the tall vegetation of a forest canopy and its coincident geometric irregularities that complicates energy balances, heat fluxes, and snowmelt patterns.

Snowpack characteristics and rain-induced snowmelt

The condition of the snowpack also affects the timing and intensity of melt during a rainfall event (Gray and Male, 1981). Snowpacks can fall into one of two very

general categories. In many cases, the snowpack may have temperatures below 0°C throughout. In this case, liquid precipitation will freeze as it enters the pack, releasing its latent heat of fusion, helping to warm the snowpack temperature. This process will continue until the pack has warmed enough for melt to begin. Rain that falls on a melting snowpack will add energy to the pack proportional to its temperature and the rainfall rate. In this case, the energy can go directly into the melt process. Thus, a cold snowpack (pack temperature <0°C) will delay the onset of melt as energy from liquid precipitation and turbulent fluxes warm the pack to a temperature of 0°C.

Rain-on-snow events and severe flooding

An excellent example of the potential for destruction associated with rain-induced snowmelt can be seen by consideration of the January 1996 event that occurred in the mid-Atlantic region of the United States (Leathers et al., 1998). During this event, the rapid ablation of a snowpack of nearly 1-m depth and heavy rainfall combined to cause catastrophic flooding across north-central Pennsylvania. This event resulted in as many as 30 fatalities, many injuries, and approximately $1.5 billion in damages. A strong meteorological disturbance moved across the region on January 18th and 19th with temperatures and dew point temperatures that, in many cases, rose above 15°C. Rainfall in excess of 7.0 cm fell in many locations over a 24-h period with corresponding wind speeds reaching 12 m s^{-1}. The meteorological conditions resulted in large values of sensible, latent, and rain energy fluxes into the pack, with total flux values greater than 500 W m^{-2} during much of the event. In this case, the combination of the fluxes described above led to maximum melt rates of greater than 12 cm h^{-1}.

Summary

Rain-induced snowmelt engendered by rain-on-snow events is of hydrologic importance in many areas of the world. The primary energy fluxes accounting for rain-induced snowmelt include turbulent (sensible and latent heat) and rain heat fluxes. The magnitude of these fluxes is dependent upon meteorological conditions particular to a specific event. Antecedent snowpack conditions also affect the timing and intensity of rain-induced snowmelt. A comprehensive understanding of rain-induced snowmelt fluxes is critical to the hydroclimatology of regions with frequent rain-on-snow events that can cause flooding and slushflows.

RAM RESISTANCE

Prem Datt
Research and Design Center (RDC), Snow and Avalanche Study Establishment, Himparishar, Chandigarh, India

Ram resistance is the resistance offered by snow while driving a ram penetrometer (ramsonde) vertically within it. The ram resistance is an index of the relative hardness. A graphical profile that exhibits ram resistance with depth is called a Ram profile. The ram is a tube or rod with a centimeter scale for depth and a standard cone-shaped tip (diameter 40 mm, apex angle 60°). Ram index $R = T + H + nHf/p$, where n is the number of blows, f is the vertical fall height of the hammer, T is the weight of

tube, H is the weight of the hammer and guide rod, and p is the penetration depth.

RATING CURVE

Ian C. Willis
Department of Geography, Scott Polar Research Institute, University of Cambridge, Cambridge, UK

Definition

A *rating curve* is a relationship between two stream or river variables, usually its Discharge (m^3 s^{-1}) and a related variable such as water stage (depth of water above a local datum, m). A suspended sediment rating curve is a relationship between Suspended Sediment Concentration (kg m^{-3} or g l^{-1}) and discharge. A solute rating curve is a relationship between solute concentration (typically in mg l^{-1}) and discharge. If more than one solute (Solute in Glacial Meltwaters) is considered at a time, concentrations are usually expressed in equivalent units (meq l^{-1}). Rating curves are usually constructed using linear or nonlinear (log–normal or log–log) regression, where parameters are fitted by the least squares method. Rating curves are used to calculate or predict a variable that is difficult to measure continuously, from another variable that is easier to determine. The aim is to produce a continuous time-series of discharge, or suspended sediment or solute concentration.

Generating a rating curve

Rating curves are needed, as water discharge is the fundamental unit of measurement in most hydrological studies or for water resource planning purposes, and yet it is difficult to measure continuously. Since discharge is the product of mean channel width, depth, and velocity, it may be determined at a weir or other gauging device where velocity variations are kept to a minimum, as water builds up behind the weir, so that discharge varies mostly with cross-section area (width × depth). If the weir geometry is known, the head of water above the weir crest can be converted directly to discharge via a mathematically defined rating curve. Often a V-notch weir is used, where an arithmetic change in stage produces a geometric change in discharge defined by a logarithmic rating relation between the two variables. Weir construction is costly, requires maintenance, and is potentially environmentally damaging. Therefore in places where this is not possible or desirable, for example, for a short-term study in an upland mountain catchment, an alternative method of determining discharge is required.

An empirically defined rating curve may be constructed at a natural stable river cross section, preferably where the channel depth to width ratio is high. Stage may be measured continuously at a point in a channel (see below). Several instantaneous discharge measurements are made over the range of stage values recorded and used together with the associated stage measurements to define the rating curve. The curve is then used together with the stage records to synthesize a continuous discharge Hydrographs for the catchment.

Measuring variables needed to construct a rating curve

Constructing a rating curve requires various attributes of a stream or river to be measured (Hubbard and Glasser, 2005). Continuous measurements of stage can be made using an analogue chart recorder. The simplest method involves a float and counterweight housed within a stilling well. The float moves up and down with the water level and activates a pen, which draws a line on a rotating drum. The drum rotates via a mechanically or electrically driven clockwork device. A complete revolution of the drum can take a week or a month or even a year, depending on the data resolution required and the resources available for changing the chart paper. Digital data loggers, which record calibrated electronic voltage or current inputs from a pressure transducer or transmitter, have now largely replaced chart recorders as a means of obtaining continuous stage measurements.

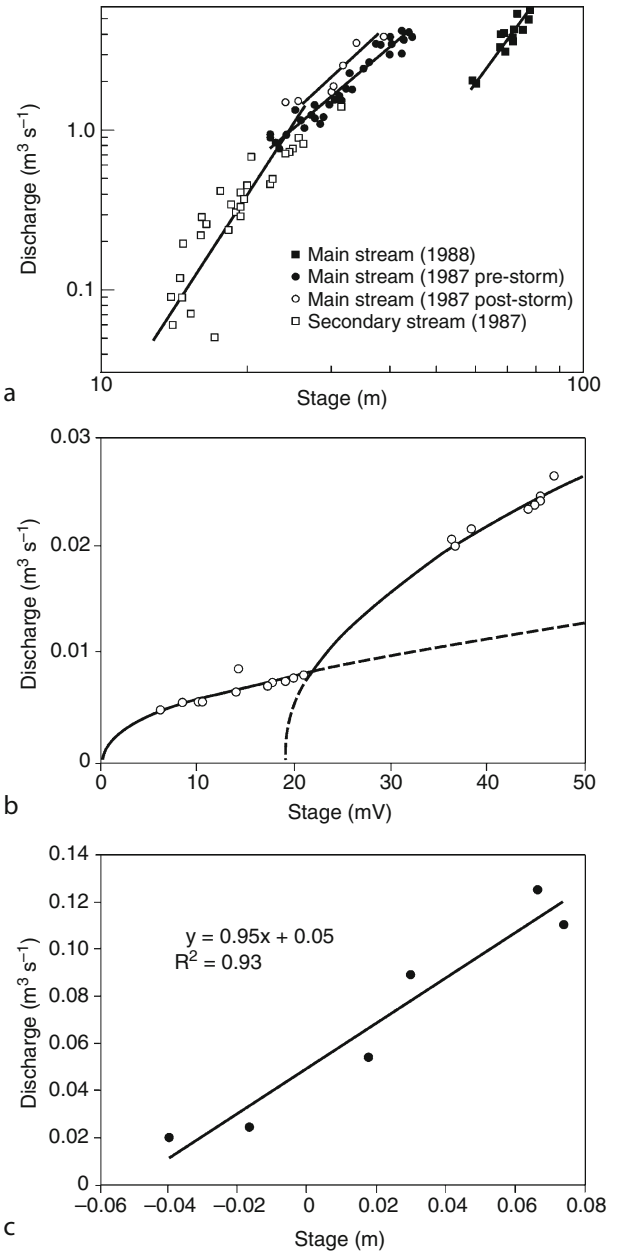
Instantaneous measurements of discharge are typically made using either the "velocity-area technique" or by dilution gauging (Hubbard and Glasser, 2005). The former involves measuring average cross-section area and velocity and multiplying these together to produce discharge. Often, the cross section is divided into smaller segments of known width. The depths marking the ends of each segment are measured and averaged. Similarly, the depth-averaged velocities at the ends of each segment are measured and averaged to give the average velocity of the segment. Velocity is measured using a flow (current) meter (sometimes called a velocimeter). This may be a mechanical propeller device, where the number of revolutions per unit time is recorded and converted to velocity using a calibration equation. Alternatively, an ultrasonic flow meter may be used of which there are two main types: transit-time flow meters or Acoustic Doppler Velocimeters (ADVs). Since the velocity measured at 40% of the distance up from the bed is typically representative of the depth-averaged velocity, a single measurement using a flow meter at this depth is often sufficient. Having determined the average depth and velocity of each segment, they can be multiplied together with the segment width to give the discharge for each segment. Cumulating across all segments gives the total discharge for the channel.

Dilution gauging involves the injection into the stream of a known quantity of salt or dye solution, of known concentration, and the monitoring of salt or dye concentrations at high temporal resolution some distance downstream as the salt or dye cloud passes. The distance between the injection and monitoring sites (the mixing length) must be of the order of 10 channel widths for turbulent streams, and up to 100 channel widths for more gently flowing streams. This is so that the distance is great enough to ensure that the initial solution is completely mixed in the water as it passes the monitoring site but not too great for concentrations to fall below the detection level as the cloud passes. The product of the initial solution concentration and volume (kg m^{-3} m^3) divided by the integral of the monitored breakthrough curve concentration, with respect to time (kg m^{-3} s), gives the total discharge of the stream.

Uses of rating curves

Rating curves have been constructed in many snow- and ice-covered catchments in order to generate continuous catchment outlet hydrographs that can be used to investigate snow/ice Melting Processes and Catchment Routing. For example, Willis et al. (1990) constructed rating curves on two streams draining Midtdalsbreen, Norway and were able to construct continuous discharge hydrographs for the streams over two summer melt seasons (Figure 1a). This then enabled them to interpret the results of dye tracing experiments and infer the characteristics of the glacier drainage system (Willis et al., 1990) to calculate water storage variations within the catchment (Willis et al., 1993) and to explain sediment dynamics in the proglacial stream and identify the influence of glacier movement on sediment evacuation from the catchment (Willis et al., 1996).

Rating curves are not only useful for generating hydrographs from catchment outlets but have also been used to generate hydrographs at specific points within catchments. For example, Kohler (1995) and Willis et al. (2002) produced stage discharge curves for supraglacial streams feeding Moulins. Kohler (1995) used a "moulin bag," a large fabric funnel connected to a section of open pipe at its lower end. The bag was suspended in a moulin and as the flow of water into the moulin varied, the water level in the bag rose and fell and was recorded continuously using a pressure transducer and logger. Seventeen discharge measurements were made in the supraglacial stream feeding the moulin (Figure 1b). A comparison of moulin input discharges and proglacial stream outflow discharges enabled Kohler (1995) to model the proportion of pressurized and non-pressurized flow in the englacial/subglacial drainage system (Englacial Conduit). Willis et al. (2002) used a pressure transducer at the base of a hole drilled into a supraglacial stream and six measurements of discharge from which to construct a stage discharge curve (Figure 1c). The resultant hydrograph enabled the testing of a glacier surface melt and routing model.

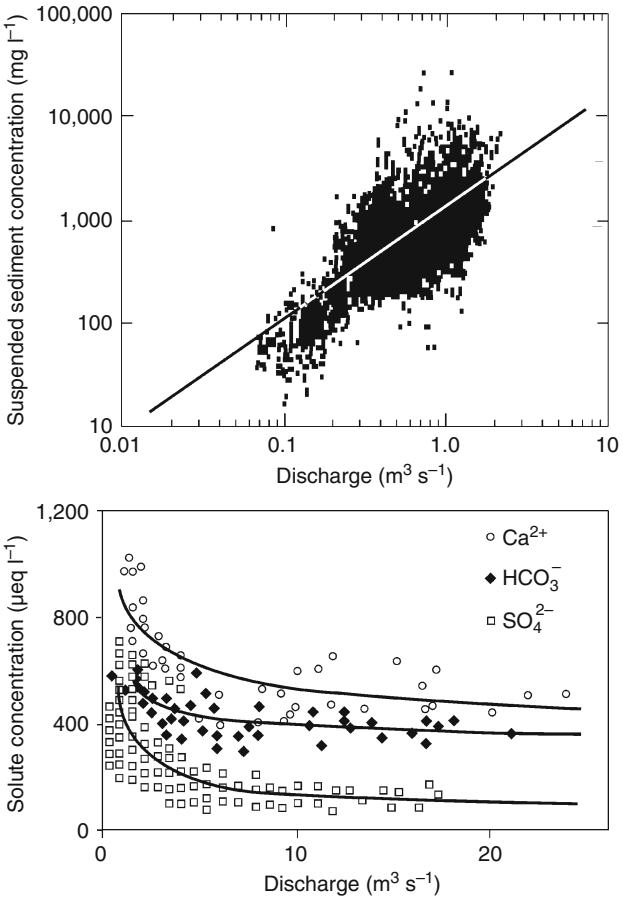


Rating Curve, Figure 1 Stage discharge rating curves developed for: (**a**) Proglacial streams at Midtdalsbreen, Norway (Willis et al., 1990); and supraglacial streams feeding moulins at (**b**) Storglaciären, Sweden (Kohler, 1995) and (**c**) Haut Glacier d'Arolla, Switzerland (Willis et al., 2002). Note that for (**a**), there are separate rating curves for a main stream and a secondary stream, for the main stream for two different years, and for the main stream in one year but before and after a flood, which dislodged the stage recorder. For (**b**), two rating curves are defined, one for low flows and one for high flows as the "moulin bag" contained a main outlet, which operated all the time but a secondary outlet that operated only at high flows. Also note that the stage units are in pressure transducer raw millivolt output. For (**c**), the stage records have been de-trended to remove the effects of surface melt on the pressure transducer records, so units are deviations from this trend.

Suspended sediment rating curve

Suspended sediment rating curves are often constructed in order to calculate catchment Sediment Yield (weight or volume of sediment transported in a given time period, kg a^{-1} or m^3 a^{-1}) or Erosion Rate (sediment yield divided by catchment area, m a^{-1}). This is of interest from a scientific and practical standpoint. Scientifically it is of interest for understanding short- medium- and long-term erosion, transport and depositional processes within a catchment (Sediment Entrainment, Transport, and Deposition; Sediment Routing). It is of practical interest for the design of hydroelectric power or for water supply or irrigation purposes since sediment will fill reservoirs, abrade turbines and silt up artificial channels and tunnels. Suspended sediment yield can be calculated by integrating instantaneous calculations of Suspended Sediment Load over time, where load (in units of kg s^{-1}) is the product of sediment concentration (kg m^{-3}) and discharge (m^3 s^{-1}). If hourly measurements of suspended sediment concentration (SSC) and discharge are known, their product will give hourly values of instantaneous suspended sediment load. Multiplying this by 3,600 (the number of seconds in an hour) will give hourly values of yield, and cumulating these over, say, a year will give the annual catchment suspended sediment yield. Unfortunately, with very few exceptions, continuous long-term measurements of suspended sediment concentrations are rarely made in snow- or ice-covered catchments, and so alternative methods must be adopted to calculate yields.

The usual method is to monitor discharge continuously (or generate a continuous hydrograph using a rating curve approach described above), obtain several measurements of suspended sediment concentration over the range of discharges observed, define an empirical relationship between the measurements of SSC and the contemporaneous measures of discharge – the suspended sediment rating curve – and use this relationship to estimate SSC from discharge, thereby producing a continuous SSC time-series. Often there is a logarithmic relationship between the two variables. If this is the case, SSCs and therefore suspended sediment yields will be underestimated due to statistical bias and a correction factor may be used to improve the estimates (Ferguson, 1986). The bias increases with the degree of scatter on the bivariate rating plot. Scatter exists due to: (1) seasonal variations in sediment availability, (2) Hysteresis effects associated with variations in sediment supply on the rising and falling limbs of diurnal hydrographs and with a downstream kinematic wave effect, (3) transient flushes of sediment in the absence of discharge variations due to snow bridge or bank collapse or glacier movement (Basal Sediment Evacuation by Subglacial Drainage System), and (4) sediment supply processes associated with rainstorms (Fenn et al., 1985). For these reasons, multiple regression and time-series techniques may be used in favor of a simple rating curve to improve the accuracy of estimating SSC and load in nival and glacial streams (Gurnell and Fenn, 1984; Willis et al., 1996). Figure 2a shows a suspended sediment rating curve constructed for 6 years of summer data for a glacierized (Glacierization) catchment in Switzerland.



Rating Curve, Figure 2 (**a**) Suspended sediment rating curve for 6 years of data collected in the catchment draining Glacier de Tsidiore Nouve, Switzerland (Fenn, 1988). (**b**) Solute rating curves for three of the major ions in a meltwater stream draining Finsterwalderbreen, Svalbard (Wadham et al., 1997).

A recent study has used continuous stage records together with empirically derived stage–discharge rating curves and suspended sediment rating curves to calculate discharges and suspended sediment loads in ten remote catchments in Nepal (Gabet et al., 2008). The catchments range in size from 7 km^2 to 3,217 km^2 and are between 0% and 21% glacierized. Instantaneous sediment loads varied over four orders of magnitude (10^1–10^4 kg s^{-1}), mostly due to large variations in discharge and rainfall. Accounting also for solute and Bed Load contributions enabled the calculation of total yields and erosion rates across Nepal. Erosion rates varied between ~0.1 and ~2.0 mm a^{-1} and were higher in the wetter southern catchments than in the drier northern ones. These fall within the range found in a large review of erosion rates in glacierized catchments, which vary over four orders of magnitude

from 0.01 mm a^{-1} for polar glaciers and thin temperate plateau glaciers on crystalline bedrock to 0.1 mm a^{-1} for temperate valley glaciers on crystalline bedrock in Norway, to 1.0 mm a^{-1} for temperate glaciers on a variety of rock types in Switzerland to 10–100 mm a^{-1} for large fast-flowing temperate glaciers in the tectonically active southeast Alaska (Hallet et al., 1996).

Solute rating curve

A few studies have attempted to construct solute rating curves for snow or ice fed catchments in an attempt to determine catchment solute yields (weight or volume of dissolved material transported in a given time period). As with suspended sediment yields described above, this is of interest scientifically for determining catchment denudation rates. Ideally, separate regression-based rating curves should be constructed for each major chemical species (Figure 2b), although many studies concentrate solely on the main cations. Additionally, most studies fail to account for solutes derived from sea salt and the snowpack, and attribute all dissolved material to crustal weathering. Typically, due to dilution effects, strong negative correlations exist between stream discharge and individual solute species. Exceptions may occur for Cl^- and NO_3^- due to particularly high concentrations at low discharges associated with solute flushing from the snowpack in spring, and so corrections may need to be made to account for this (Sharp et al., 1995). As with suspended sediment rating curves, bias will occur if the timing of solute sampling is not representative of the range of discharges measured. For example, a 15-year study in the Swiss Alps showed that the weekly bulked discharge-proportional sampling was vastly preferable to grab (instantaneous) samples taken every 2 weeks at reproducing unbiased yields of major cations and anions (Schleppi et al., 2006).

A comparison of a few studies in snow- and ice-covered catchments shows that cationic weathering rates are of the order 500–1,000 meq m^{-2} a^{-1}, significantly higher than estimates for continents as a whole, and that the total solute denudation rate measured in a Swiss Alps catchment is about three times higher than a global average estimate (Sharp et al., 1995). Comparisons between catchments suggest that those with higher discharges also have the highest solute fluxes. However, comparisons within an individual catchment between years with contrasting climatic conditions suggest that the increased discharge is offset by decreased solute concentrations (due to reduced residence time between rock/sediment and water), so that solute flux remains fairly constant from year to year (Collins et al., 2002).

Summary

Rating curves are widely used in catchment hydrology studies and for water resource planning and management. Stage–discharge rating curves (Stage–Discharge Relationship) are used to produce continuous records of stream or river discharge, i.e., catchment or sub-catchment Hydrographs. Suspended sediment and solute rating curves are used to generate continuous time-series of suspended sediment or solute concentration from a discharge series, which are often used, together with the discharge series, to estimate catchment sediment and solute yields and thereby denudation rates. Such studies suggest that snow- and ice-covered catchments generally have higher denudation rates than their snow- and ice-free counterparts. As most rating curves are empirically derived using statistical regression, they have errors associated with them and they can only be used within the catchment for which they were designed and within the range of stage or discharge values that were used to define them.

RECESSION COEFFICIENT

Manmohan Kumar Goel
Water Resources System, National Institute of Hydrology, Roorkee, Uttarakhand, India

A hydrograph has three major components: direct surface runoff, interflow, and groundwater flow. The rising limb extends from the time of beginning of surface runoff to the first inflection point on the hydrograph and represents the increase in discharge due to increase in storage in the basin. The crest segment of a hydrograph is in-between the inflection point on the rising limb to a corresponding point on the recession limb and represents the arrival of flow from that portion of the basin which receives the highest concentration of runoff volume. The point of inflection on the falling side of a hydrograph marks the beginning of recession limb which represents the withdrawal of water from various storages built up in the basin. The shape of recession curve depends entirely on the basin characteristics and it is mathematically represented as:

$$q_t = q_0 K^t \tag{1}$$

where "q_o" is specific initial discharge, "q_t" is discharge after time "t" (both "q_o" and "q_t" are within the same straight segment), and "K" is the recession coefficient. Taking $t = 1$, we get:

$$K = q_1/q_0 \tag{2}$$

In the recession limb of a hydrograph, the recession coefficient represents the ratio of the discharge after a unit time step of some specific initial discharge to the specific initial discharge, provided both the discharges are along the same straight segment.

Recession coefficient increases as the discharge hydrograph stabilizes. After the cessation of precipitation, various basin storages that contribute to the recession curve include surface storage (surface detention and channel storage), interflow storage, and groundwater storage. Recession coefficient is considered to be made up of three components (K_s for surface storage, K_i for interflow storage, and K_g for groundwater storage) to take care of the three types of storages as:

$$K = K_s.K_i.K_g \tag{3}$$

Different recession coefficients can be determined by analyzing the recession curve for a long time. When Equation 1 is plotted on a semi-log paper with discharge on the log-scale, its plots as a straight line and recession coefficients for different flow components can be found. Initial rough estimates of these coefficients (when t is in days) could be: K_s (0.05–0.50), K_i (0.50–0.85), and K_g (0.85–0.99).

Recession coefficients depend on the units of time and the area of catchment. Smaller time units tend to increase the values of K. Similarly, larger basins may also indicate higher values of K.

RECESSION OF DISCHARGE

Synonyms

Streamflow recession

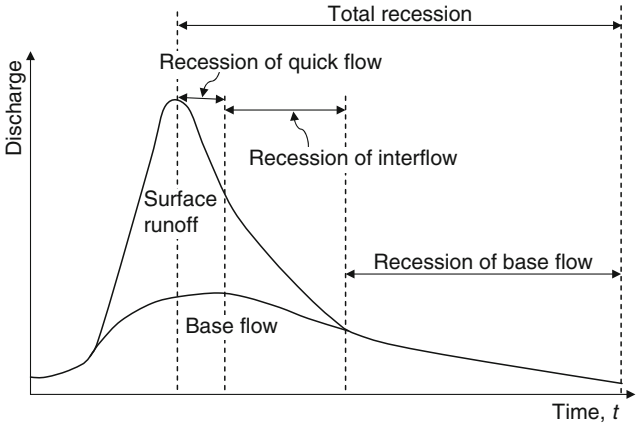
Definition

Recession of discharge. The gradual depletion of discharge during periods with little or no precipitation constitutes the recession of discharge. A recession period lasts until streamflow begins to increase again due to subsequent precipitation. Depending on the source of flow in the recession period, the recession is further classified as recession of quick flow, recession of interflow, and recession of baseflow.

Recession curve. The specific part of discharge hydrograph after the crest (and the precipitation event), where streamflow diminishes during a rainless or dry period is called the flow recession curve, at a specific river cross section of the basin. Hence, recession curves are the part of the hydrograph that are dominated by the release of water from natural storages.

Introduction

Streamflow recession represents withdrawal of water from natural storages with no inflow (Singh, 1989). Therefore, it is more or less independent of time variation in rainfall and infiltration; it may be slightly dependent, however,



Recession of Discharge, Figure 1 Typical hydrograph showing recession of individual components of runoff.

on rainfall distribution and heavily dependent on ground conditions (Chow, 1964). It constitutes the falling limb of a hydrograph to the right after the crest where streamflow diminishes during a dry period. Its analysis yields information on retention characteristics of the basin and of groundwater storage and depletion. Streamflow recession rates and consequently, the shape of recession curves depend primarily on catchment topography and geology. Individual components of runoff: quick flow, interflow, and baseflow have their own distinct recession characteristics and rates (Barnes, 1939). The ranges of these rates may overlap, which reflect the fact that the distinctions between surface flow and interflow and between interflow and baseflow are not always clear (Klaassen and Pilgrim, 1975; Nathan and McMohan, 1990). A typical hydrograph showing recession of individual components of runoff is shown in Figure 1. As can be seen from Figure 1, initially the recession curve is steep as quick flow leaves the basin. It flattens out with delayed flow supply from deeper subsurface stores and may eventually become nearly constant if sustained by outflow from a glacier or from groundwater storage.

Analysis of recession

Analysis of recession of discharge has long been a subject of considerable interest (Barnes, 1939; Knisel, 1963; Hall, 1968, 1982; Nathan and McMohan, 1990; Tallaksen, 1995; Chapman, 1999; Wittenberg, 1999; Singh et al., 2000; Sujono et al., 2004; Hammond and Han, 2006). It has many practical applications in many areas of hydrological research, water resources assessment, planning, and management. Analysis of recession of discharge is also important in snowmelt runoff studies (Garstka et al., 1958; Martinec, 1965; Singh et al., 2000), glacier runoff studies (Meier, 1964), mass balance, and melt water delay characteristics of different parts of the glacier (Singh, 1994; Singh et al., 1995). The recession characteristics of a snowmelt hydrograph contain substantial information about snow water storage and can be considered as an index of snow water storage (Singh et al., 2000). A comprehensive review of streamflow recession analysis and its various applications have been compiled by Hall (1968), Anderson and Burt (1980), Singh (1989), and Tallaksen (1995).

Many methods are available in literature to model recession. These include methods based on use of basic flow equations, reservoir outflow, autoregressive processes, empirical relations, wavelet transform analysis, etc. (Singh, 1989; Wittenberg, 1994, 1999; Tallaksen, 1995; Chapman, 1999; Sujono et al., 2004). The most commonly used method for modeling recession is to use linear and nonlinear stores. Use of linear stores for recession analysis can be traced back in literature to studies by Boussinesq in 1877 and Millet in 1905. The method however became popular after Barnes (1939) analyzed the structure of discharge recession curves. In linear store method, the flow during recession is linearly related to storage, S.

$$S = kQ \tag{1}$$

This leads to relation between flow at time t, Q_t to flow at time $t = 0$, Q_0 as

$$Q_t = Q_0 e^{-kt} \tag{2}$$

where, Q_0 = initial discharge at start of recession, Q_t = discharge after time t and k = a constant known as recession constant or depletion factor. A plot of $\log(Q_t)$ against time should show a straight line if the storage–outflow relation is linear. A best-fit line is drawn through the plotted points and the slope is determined. This slope represents the value of the recession coefficient, k. A higher value of k results in faster draining of water from the basin, whereas a lower value of k represents slower drainage from the basin. The typical ranges of daily recession constants for streamflow components, namely quick flow (0.2–0.8), interflow (0.7–0.94), and groundwater flow (0.93–0.995) do overlap (Nathan and McMohan, 1990). However, high recession constants (e.g., >0.9) tend to indicate dominance of baseflow in streamflow. A curved semi-logarithmic plot for recessions means that the storage–outflow relationship is nonlinear and may be analyzed using appropriate nonlinear relations (e.g., Wittenberg, 1999).

Time variability of recession

A considerable variability is observed in recession behavior of a stream for most catchments with time. This is reflected in variations, in the shape of the recession segments found in a stream hydrograph. Variations in recession rates are caused by difference in climate during the time of recession; variability in areal distribution of rainfall, residual storage in connected surface water bodies, catchment wetness, and conditions prevailing prior to the start of recession. In large catchments, spatial variability in storm patterns cause differences in the distribution of flow paths in the catchment, which in turn may influence

the drainage pattern (Laurenson, 1961). Climate influences the recession rate during the time of recession by recharge from precipitation or snow melt, or by loss from evapotranspiration (Tallaksen, 1995). High evaporation rates during warm weather of active growing season can significantly influence low flows and recession dynamics particularly in shallow water table regions.

Conclusion

The recession segment of streamflow hydrograph contains information on retention characteristics of the basin and of groundwater storage and depletion. Analysis of recession can provide valuable information needed for hydrological research, water resources assessment, planning and management, snow melt, glacier melt, glacier mass balance, etc. Many models of varying complexities have been developed in the past to understand dynamism in recession characteristics of a stream. Further research, however, is required to understand better physical processes governing recession of discharge and its variability with time.

RECONSTRUCTION OF THE LAST GLACIATIONS IN THE WHOLE OF ASIA

Matthias Kuhle
Department of Geography and High Mountain Geomorphology, University of Göttingen, Göttingen, Germany

Synonyms

Pleistocene glaciation of Asia during the last Ice Age (Würm, Weichsel); Quaternary glaciation of Asia during the MIS 4-2

Definition

Reconstruction of the maximum former extent of the ice cover in Asia.

Introduction

The current state of ice age research suggests to confine this overview of the reconstruction of the past glaciation in High Asia to the Last Ice Age, the Würm-Ice Age (Weichsel-Ice Age MIS 4-2), i.e., to the last maximum ice extent and at most to a somewhat earlier ice extent during the early to middle Würm-Ice Age – if at all there is a reliable possibility to differentiate these two advances regionally, considering the data obtained so far. With regard to the method this restriction suggests itself because of the chronological nearness of the LGM-advance, so that naturally the indicators might be best

preserved. The former extents of the ice – as far as they have not been overthrust by the last advance and thus underwent a Quaternary-geological reshaping, i.e., destruction – could only be preserved by still more extended glacier traces beyond those of the LGM. However, due to the several times higher age, this ought to have led to much clearer solifluidal and erosive traces of modification, i.e., blurrings. The resulting uncertainties as to the diagnosis of the older glaciations lead to this restriction to the youngest maximum extent of the ice.

Detailed explanations with regard to the Weichsel-(Würm Ice Age) glaciation in Asia

N-Asia, Siberia

According to the climate zones the largest LGM-glacier faces can be assumed to be in the Siberian Arctic region. Indeed, there exist relevant investigations showing an eastward continuation of the European ice sheet with its center in Scandinavia up to beyond the Urals, i.e., up to the area of the Kara Sea (Grosswald, 1998; Astakhov, 1998; Arkhipov, 1998). However, the interpretations as to the extent of the LGM-Kara-ice sheet are different: Grosswald (ibid. pp. 16–17) assumes a continuous N-Siberian ice sheet that has dammed up the rivers discharging interglacially and currently to the N. This led to the development of large proglacial lakes which were integrated into a transcontinental system of meltwater drainage. Here, the existence of these ice-dammed lakes – evidenced by correlating lake sediments, lake terraces, overflow channels and spillways – is put forward as independent finding of a continuous ice sheet in the Siberian Arctis. So, in the Turgay Valley of SW-Siberia, Grosswald recognizes the Quaternary-geologically provable function of a Late-Würm spillway that led the Siberian ice sheet meltwater into the Aralo-Caspian basin. This interpretation is contradictory to that of Astakhov (1992). The later analysis of space images with strong resolution by V.R. Baker (Grosswald, 1998) supports the opinion that geomorphologically young features of erosion are concerned here as they can only derive from the turbulent and powerful streamflow of a W-Siberian ice-dammed lake. A confirmation is seen in a second valley, the Manych valley, as a major spillway which connected the Khvalyn meltwater basin, i.e., the ancient Caspian Sea, with the Black Sea (V.R. Baker; personal communication after Grosswald, 1998, p. 16). Obviously this is also a geomorphologically young form.

As far as the Kara ice sheet is concerned, Astakhov (1998, p. 26) follows the reconstruction of Grosswald (1980) especially with regard to the extent of the S-ice margin, which similar to Scandinavia, is supposed to have been located 500–1,000 km away from the ice divide. Later comments with regard to a Kara ice sheet reaching even further southward (Grosswald and Goncharov, 1991; Grosswald, 1994), however, are not in agreement with Astakhov (1998). The maximum ice thickness is estimated at 2–3 km, whereby the great Pleistocene thickness of permafrost is considered to be an indication of very cold ice and, accordingly, a rather greater ice thickness. The soft underground of Cretaceous, Palaeogene, and Quaternary very clayey sediments, however, rather might have flattened the ice dome (ibid.). According to Arkhipov et al. (1980) the reconstructed ice thickness of still 400–500 m very close to the ice margin in the Polar Urals is a further indication of very cold and therefore thick glacier ice. Anyway, due to a thick ice like this and the very cold conditions, the possibility of mountainous ice dispersal centers has to be ruled out, particularly since the Urals are only 50–80 km wide. Dibner (1970) mapped a submerged hummocky relief and the ice directional features and erratics prove an advance of the Kara ice sheet from the W-Kara Sea basin not only to the S and W (see above), but also to the E up to the Yamal Peninsula (Astakhov, 1979; Gataullin, 1988). The sparse 14C-datings limit the corresponding ice advance in the area of Novaya Zemlya to older than 15 Ka. This chronological classification, which has to be understood as minimum age, is confirmed by loess-like silts with syngenetic wedges, lying on youngest tills, that in the area of the Yamal peninsula are dated to 13–14 Ka (Bolikhovskaya and Bolikhovsky, 1992). Because the uppermost till contains large fields of fossil glacial ice (isolated masses of dead ice are still buried in the drift: Astakhov and Isayeva, 1988) that would not have survived the very warm Eemian transgression, the oldest time-period of the Kara ice sheet that has been proposed is MIS 4 (110–50 Ka) (Astakhov, 1998).

As for the eastern continuation of the proposed connected N-Siberian ice sheets the reports of the Pole Star-Expedition 1993 (Fütterer, 1994) are important. Here the opinion is expressed, that the observed erosive incision into the shelf of the Laptev Sea E of the Taimyr Peninsula gives evidence of the Ice Age existence of the Lena River which eroded the glacially dewatered shelf. Thus, the synchronous existence of an E-Siberian ice sheet was also refuted. Grosswald and Spektor (1993) and Grosswald and Hughes (1995), however, think that this erosion form is the result of one or several floods of a Lena paleo-lake dammed up by the E-Siberian ice sheet and broken out during the Late Glacial.

According to the comments above, also a northern continuation of the terrestrial Pleistocene Siberian ice sheet in the shape of a marine ice sheet in the Arctic Ocean is presented (Vogt et al., 1994). To this point findings at a depth of the ocean of 500–850 m and perhaps up to 2,000 m in the form of detected plowmarks on the Yermak Plateau. These speak at least for huge icebergs and thus thick calving ice fronts, if not for a crushed ice shelf. The existence of this marine ice sheet on the N-margin of Siberia is also supported by investigations of box core sediments for evidence of biological life in the Arctic Ocean which did not show any traces of life between 13 and 26 Ka. This suggests the covering of the area by an ice shelf with a thickness of several hundreds of meters, so that in the water underneath an abiotic zone had developed, as shown by Travis (1994). These findings are in

contradiction to those of Zubakov and Borzenkova (1990) who plead for an uninterrupted, continuous evolution of organic life in the Arctic Ocean against the existence of a whole Arctic ice sheet and also an ice shelf.

Again further to the E the mapping of oriented tundra landforms and oriented lakes shows a radial structure of outline. They run from the environment of the New Siberian Island to the S diverging in a fan-like pattern up to the Yana-Indigirka Lowland and adjacent areas including the ridge- and lake complex. These forms – taken from space images and air photographs – that received their shape from drumlinization as well as large-scale fluting produced by a marine ice sheet are also interpreted as indicators of the Late Weichsel continuation of the inland ice in excess of 145°E (Grosswald, 1998, Figures 9 and 19). For Grosswald and Hughes (1995) these flowlines, derived from both the ice-shoved features and oriented tundra forms, at the same time were the basis for the reconstruction of another great ice sheet connected to the E, the so-called "Beringian ice sheet." Corresponding indicators, but also push moraines, are stated by those authors for the lower Kolyma basin, Karchyk Peninsula, and the adjacent Ayon Island. The accompanying ice-spreading center was situated NE of the Kolyma Delta. Furthermore, appropriate evidences of till sheets and accumulations of glacial erratics or "Lapland-style" geomorphology are stated for the Chukchi Peninsula, Cap Serdtse Kamen, and the Wrangel Island (Laukhin et al., 1989; Grosswald, 1998). With regard to a connected S- to SE-ice extent as far as into the Bering Strait and across the Chukchi Range evidences are given by, e.g., truncated spurs and huge masses of coarse debris accumulated on the lee (southern) side of the 700-m-high steep flank of the mountains up to high up to Cape Dezhnev, as well as numerous U-shaped valleys oriented in a N–S-direction up to down to the S at 60°N at Cape Oljutorskij (Grosswald, 1998, Figure 12). The extent of the Bering ice sheet along meridian 167°E to the S up to 55°N is supported by findings as, e.g., glacial troughs and striations on the Bering Island (Erlich and Melekestsev, 1974).

Last the recently discussed question with regard to a possible ice sheet in the Sea of Ochotsk as an additional center of the Siberian ice sheet has to be approached. The area is surrounded by mountain ranges (Kolymsky, Suntar Khayata, and Koryak Ranges) that due to ELA-depressions up to near to sea level of the – according to the Kara Sea – cold Sea of Ochotsk were heavily glaciated (Grosswald, 1998). Geomorphological investigations of Udintsev (1957) show that the Ice Age margins of the mountain glaciers in a seaward direction have reached up to the sea. Terrestrial outlet glaciers like these enter the Penzhina- and Gizhiga inlets and have filled the Shelikhov Bay at least up to 59°N. Accompanying chains of parallel end moraines, eskers, and drainage channels are described by Grosswald (1998, p. 15) for the W-coast of the Kamchatka Peninsula. As for forms of the U-shaped basin bottom of the Sea of Ochotsk, situated at a water depth about 1,000 m, a variety of explanations have advanced (Udintsev, 1957; Volnev, 1983), so, e.g., tectonic faulting and folding of the crust. Grosswald (1998) tends to the opinion that these are glacigenic forms, and further to the S, at 47°–49°N, he postulates a geomorphologically diagnosable area of an ice shelf break. This can be supported by coarse sediments, including boulders (Bezrukov, 1960), found at several places of the sea floor, so, e.g., off the coast of SW Kamtchatka, where a 3–8-m-thick lodgement till was cored (Kuzmina and Yeremeeva, 1990). Up to now it is unexplored how far this still hypothetical Ochotsk ice sheet, as an additional center of the Siberian glaciation, has reached the SE. Possibly in the SE the ice sheet changed into an ice shelf that was buttressed by the submarine ridge of the Kuril (Grosswald, 1998).

The Siberian mountains

Zamoruyev (2004) thinks that in NE-Asia no large ice sheets have existed like in Europe or North America, but that the glaciation was restricted to the mountains N of the Stanowoi mountains up to the Werchojansk mountains in the N and up to the Korjaken mountains in the E. Thereby cirque and hanging glaciers up to large dendritic glaciers with piedmont glacier tongues were concerned. A mountain ice cap of a few 100 km in diameter developed as largest glacier type in the S-Werchojansk mountains (ibid. p. 321). According to this opinion only glaciers from the Chukotka Peninsula reached the ocean and covered the modern shelf. While the extent of the recent glacier surface in the NE-Asian mountains is not much greater than 560 km², that of the Pleistocene glaciation was still 500,000 km². After Kind et al. (1971), Velichko (1973), Svitoch (1978) and Degtyarenko (1984) the period of the Late Pleistocene (Weichsel, LGM) was that of the greatest extent. Among others this has been proved by 14C-data about 33–35 Ka and by means of glacial deposits which in the W-slope of the Werchojansk mountains reached down up to the Lena River. According to Zamoruyev (2004) the Ice Age glaciation of the Werchojansk mountains and its chronology is representative for the other mountain regions in NE-Asia. But also the ice cover – as far as it derives from the mountains – is still seen controversially. So, e.g., Svitoch et al. (1980) even are of the opinion that the inner lowland of Chukotka has never been reached by the mountain glaciers.

Sheinkman (2004) in principle agrees with the summarized vergency of Zamoruyev (2004) as to a mountain climate for Central- and NE-Asia that during the Pleistocene ice age was colder, but with respect to the precipipitation similar to the current climate. Compared with Europe – he explains – the LGM-glaciation was rather insignificant. As well directly as indirectly this contradicts the findings as to an extended N-Siberian inland glaciation summarized above (see Section N-Asia, Siberia). Indirectly, because the very large proglacial

lakes, dammed up by the inland ice, and their transcontinental meltwater drainage system must have brought an enormous humidity in the currently rather semiarid continental areas. Thus, much greater ELA-depressions as suggested by the last-mentioned authors would become probable for the local mountain glaciations.

As for the Altai mountains Sheinkman (2004) found out a maximum length of the valley glaciers of 70 km during the Late Pleistocene, while for the NE-Siberian glaciers (see above) he supposes extents of twice this size (about 150 km in length) in the past, though the current glaciers in the Altai are the greater ones. An Ice sheet glaciation is ruled out. However, local piedmont glaciations, i.e., ice fields at the foot of the mountains are stated as maximum advances (ibid. p. 334).

The mountains to the S and E outside of Siberia

Not only the large past ice surfaces are paleoclimatically important, but also the comparatively minor high mountain glaciations. These make possible to reconstruct the Ice Age increase of the ELA (uplift of the snowline) from the Siberian Arctis via the temperate latitudes and the high-continental- semiarid subtropics as far as to the monsoon-humid tropics of S-Asia. Therefore, exemplary findings of glaciation are to be described from several further high mountains of Asia.

In the Japanese Alps, altogether five glacier advances occurred during the Last Glaciation, i.e., here since MIS 4; to these belong advances just before 24 Ka, 20–18 Ka, 11–10 Ka, and in the early Holocene (Sawagaki et al., 2004); in the Hidaka Mountains this has also taken place during MIS 3 and 2, here stated by tephrochronological investigations. The whole glacier surface is determined to be c. 800 km² large and the glaciated areas decrease from 2,500 m asl at 35°N to 1,000 m asl at 45°N (ibid. p. 217). However, for the Japanese Alps between 34° and 37°N and at c. 137–139°E, Iozawa (1979) describes besides cirques between 2,400 and 2,700 m asl, also U-shaped valleys extending to below of 1,000 m asl. This speaks in favor of a clearly minor sea-level of the corresponding lowest ice margins than 1,000 m asl, also in the Japanese Alps. For the Northern and Central Japanese Alps, Sawagaki et al. (2004, Figure 2) settle the lowest ice margins about 1,100 m asl. Information as to the S-Alps is lacking, so that obviously the lowest positions of the ice margins are situated noticeably below 1,000 m. In general, however, the N-Japanese Alps are supposed to have been heavier glaciated than the Central and S-Alps (ibid.). Due to the lack of current glaciers, a minimum depression of the ELA of 1,200 m has to be considered according to these data. In the Hidaka mountains (42°–43°N) with heights of 1,500–2,000 m asl, which are seen as second key-area of the past Japanese glaciation, the lowest, c. 40 Ka old positions of the glacier termini reached down to c. 800 m asl (Sawagaki et al., 2004, Figure 2). This proves an LGP (Last Glacial Period) height of the snowline at a maximum of c. 1,400 m asl and corresponds to an ELA-depression of at least 1,000–1,200 m.

The Würm-glaciation of Taiwan (22°–25°N) with its highest elevation, the 3,952 m-high Yu Shan, reconstructed since 1934 (Tanaka and Kano, 1934; Panzer 1935), has been described by youngest papers of Böse and Hebenstreit (2001) as a still provisional interim report; (Böse, 2004,"studies are in progress", p. 351). This much is certain: there existed a cirque- and hanging valley glaciation during MIS 2 that, e.g., has led to concave longitudinal valley profiles as far as down to 3,350 m asl. From these and further findings an ELA-depression of at least 3,300 m asl (Yu Shan) has been extracted according to an ELA-depression of at least 600–700 m asl (ibid.).

In Malaysia we find the highest mountain between the monsoon-tropical Himalaya and the equatorial peaks of New Guinea: Mt. Kinabalu (4,101 m asl, 6°05′N 116°33′E) on the N-tip of Kalimantan. For the LGM Koopmans and Stauffer (1967) reconstructed a 5.5 km² large ice cap on the highest E-plateau and a thicker one on the lower W-plateau. The plateau-ice was at least 80 m thick. In addition, small valley glaciers had developed. In the main valley one of them has created a U-shaped cross-profile inset up to 1,000 m deep; at 2,900 m asl moraines are left behind. A further moraine is described from the N-slope near Paka Cave at 3,100 m asl (Hope, 2004). Accordingly, snowline altitudes about 3,500 m asl are verified. Smith and Lowry (1968) describe several cirques at different positions. In any case, the ELA must have run below 3,600 m, i.e., below the glaciated summit plateau. Hope (2004), however, raises objections, because the rock forms led back to a past glaciation, as, e.g., stripping of the summit plateau, smoothing and plucking, etc., might also be a result of the rock structure of the granite and its weathering, like exfoliation which creates smooth slabs. However, on the basis of his knowledge of literature, i.e., without knowing the field himself, he supposes the glaciation to be the probable cause of the forms concerned. As test area in Indonesia, Mount Leseur in N-Sumatera (3°45′N) is approached. For this massif van Beek (1982) indicates a glaciated surface of about 100 km² and a Pleistocene ELA at 3,100 m asl. As for the highest summit of Sumatera, the centrally situated 3,805 m-high Mount Kerinci, Hope (2004) quotes an ELA at 3,450 m and an Ice Age glacier nourishing area of 2.4 km² situated above. To sum up, one may assume a height of the snowline of c. 3,500 m for Malaysia and Indonesia during the LGP.

As an example from the arid SW of Asia a reconstruction of the glaciation in the Iraq mountains is approached by Wright (2004). Among others he describes for the Algurd Dag in the NW Zagros, the ridges of which reach 3,000–3,500 m asl, that "extensive Pleistocene glaciers formed on the N-slopes and flowed through gaps southward down-valley tributary to the greater Zab River to elevations as low as 1,100 m" (ibid., p. 215). On subsidiary ridges also exposed to the N, cirques with bottoms about 1,500 m asl have been met; they were also classified as belonging to the Late Pleistocene. This corresponds with an ELA-depression in excess of 1,700 m against today (ibid., p. 215). Evidence has also been provided of

a mountain glaciation in the 4,135 m-high, currently non-glaciated Kuh-i-Jupar massif in the semiarid SE-Zagros (S of Kerman) during the LGP (Würm glaciation, MIS 4-2:60-18 Ka) (Kuhle, 1974, 2007a). During the LGP glaciation, the glaciers reached a maximum of 10–12 km in length. They flowed down into the mountain foreland as far as 2,160 m. The thickness of the valley glaciers reached 350 m. The glacier termini mostly remained separated in the mountain foreland. The climatic ELA ran at c. 3,050 m asl, that is 1,500 m below the current theoretical snowline. Thus, a temperature depression of c. 10–15°C must be assumed for the SE-Iranian highland. The recessional moraines, which are preserved in the high valleys, document a Late Glacial glacier retreat in four stages (I–IV). These four Late Glacial stages can be identified at many places in the mountains of High and Central Asia. Additional evidence of a Late Pleistocene glaciation was found on the adjacent massifs of the Kuh-i-Lalezar and Kuh-i-Hezar (ibid.).

High Asia

Between Siberia and High Asia, i.e., from Central- to S-Asia, Last Ice Age mountain glaciers mediated, e.g., in the E-Sayan mountains, the Transbaikalian mountains, the Altai (see above The Siberian mountains) as well as the Tianshan with their in part relatively large high plateau glacier areas, so on the Tienshan plateau, up to the Tibetan inland ice area and the high mountains surrounding Tibet with their icestream networks (Kuhle, 2004; Sheinkman, 2004 and others).

Published up to 1973, but also even later, the synopsis of older results and views on the Pleistocene glacier cover in High Asia provided by Wissmann's 1959 compilation, was considered as being accepted. This concept of a very insignificant glacier cover of Tibet and its mountains was also pursued in the recent Chinese literature by Shi and Wang (1979); it has also been reproduced by CLIMAP (Cline, 1981, entitled "Last Glacial Maximum"). These authors speak of a 10% to a maximum of 20% ice cover of the mountains and plateaus of Tibet. Since 1973 new data were obtained on the maximum extent of glaciation in High Asia. Evidence for an ice sheet covering Tibet during the Last Glacial period means a radical rethinking about glaciation in the Northern Hemisphere. The ice sheet's subtropical latitude, vast size (2.4 million km²), and high elevation (6,000 m asl) are supposed to have resulted in a substantial albedo-induced cooling of the Earth's atmosphere and the disruption of summer monsoon circulation. Moraines were found to reach down to 460 m asl on the S-flank of the Himalayas and to 2,300 m asl on the N-slope of the Tibetan plateau, in the Qilian Shan region. On the N-slopes of the Karakoram, Aghil, and Kuen-Lun mountains moraines occur as far down as 1,900 m asl. According to the arrangement of the positions of their morphological and sedimentological elements they were classified. Samples have been analyzed as to their grain size distribution, lime- and humus content, as well as sorting coefficient. Additionally, petrographical and morphoscopical analyses of quartz grains were carried out. Thus, ground-, lateral-, and end moraines could be differentiated and subglacial or subaerial fluvial reshaping was diagnosed. Radiographic analyses of erratics suggest a former ice thickness of at least 1,200 m. Glacial polish and roches moutonnées in the Himalayas and Karakoram suggest former glaciers as thick as 1,200–2,700 m. On the basis of this evidence, a 1,100–1,600 m lower equilibrium line altitude (ELA) has been reconstructed, resulting in an ice sheet of 2.4 million km², covering almost all of Tibet. 14C-ages classify this glaciation as MIS 4-2 in age (Würmian = LGP, c. 60,000–18,000 years ago) (Kuhle, 1998, 2004).

As for the reconstruction of the Ice Age glaciation of the mountains, evidences have to be quoted of a farthest and lowest glacier extension from the Karakoram, from S-Tibet up to the Himalaya-S-slope and on the E-margin of Tibet: so, e.g., in the Shaksgam-, Shimshal-, Hunza-, Hispar-, Barpu-, Hassanabad-, Bar-, Braldu-, Bassna-, Indus valley, etc., and connected massifs; in the Zanskar-, Bhagirathi (Gangotri)-, Nandakini-, and Alaknanda valleys in the Garhwal Himal; in the Kanjiroba-, Dhaulagiri-, Annapurna-, Damodar-, Manaslu-, Langtang-, Rolwaling-, Everest-, and Kangchendzönga massifs with accompanying valley systems; in the Minyang valley, the Konka Shan, and in the Anymachin (Kuhle, 1982, 2007b).

Glacial horns, roches moutonnées, flank polishings, abraded mountain spurs, glacially streamlined hills, etc., but also high erratics prove a large-scale ice cover. Important ice thicknesses do occur according to transfluences: e.g., in the Hunza valley system a 2,000-m-thick Hunza glacier reached down from the Khunjerab-pass as far as into an Indus trunk glacier. The joint glaciers flowed up to Sazin and then 20 km down the lower Indus valley up to below 870 m asl (35°32′N/73°18′E). This glacier was part of a continuous ice stream network. In the N, via the Khunjerab-pass, it was connected to the ice of the E-Pamir, via the Shimshal-, Hispar-, and Barpu glaciers to the Shaksgam-, Basna-, and Shigar glaciers (Kuhle, 1997, 2001, 2006).

In the Nanda Devi-Kamet group, in the Alaknanda valley, the lowest ice margin was near Pipalkoti (30°26′N/79°25′40″E) at 1,000–1,100 m asl. In the Mandakini valley it was at c. 1,300 m, in the Nandakini valley at 1,200–1,400 m, and in the Bhagirathi valley at 1,050 m asl, 3 km downward from Uttarkashi (Kuhle, 2005, Figure 2, 2007b).

LGP-glacier traces (Würm) reached down to at most 460 m asl, i.e., to Dumre near the exit of the Marsyandi Khola or to Thuma at 890 m in the Tamur Khola. This corresponds to ELA-depressions of c. 1,660 m (Kuhle, 1997, 1998).

The LGM-Minyang glacier was one of the larger E-Tibetan outlet glaciers flowing down to c. 1,040 m asl. It came to an end c. 45 km S of Wenchuan. The Ice Age

Hailuogou- and Yantsöko glaciers flowed down from the Minya Konka SE- and NE-flanks into the Dadu main glacier, which had still a thickness of c. 300 m. Accordingly, the lowest LGM ice margin of this E-outlet glacier of the Tibetan inland ice must have been situated at c. 1,150 m asl at 29°30′N/102°11′30″E below Wantung (Kuhle, 2001, 2007b).

In the S-slopes of the Mt. Everest-Makalu-Cho Oyu massifs (Khumbu and Khumbakarna Himal) an ice stream network has been reconstructed for the last glacial period (MIS 4-2) (Kuhle, 2005). It has communicated across transfluence passes with the neighboring ice stream networks toward the W and E. The ice stream network has also received inflow from the N, from a Tibetan ice stream network, by the Kyetrak-Nangpa-Bote Koshi Drangka in the W, by the W-Rongbuk- into the Ngozumpa Drangka, by the Central Rongbuk- into the Khumbu Drangka, and by the Arun transverse-valley in the E of the investigation area. The ice thickness of the glacier sections above the snowline was 1,000–1,450 m. The most extended parent glaciers have measured 70 km in length (Dudh Koshi-glacier), 67 km (Barun-Arun-glacier) and 80 km (Arun-glacier). The Arun-glacier flowed down to 500 m asl and the Dudh Koshi-glacier to 900 m asl. The current climatic glacier snowline in the research area runs about 5,500 m asl. The snowline depression of the last glacial period calculated by four methods has run about 3,870 m asl so that an ELA-depression of 1,630 m has been determined. This corresponds to a lowering of the annual temperature by 8–10°C.

From this most important past glacier extension up to the current glacier margins 13 glacier stages have been differentiated and in part 14C-dated. They were four glacier stages of the late glacial-, three of the neoglacial-, and six of the historical period. By means of 130 glaciers the corresponding ELA-depressions have been calculated in comparison with the current courses of the orographic snowline. The number of glacier stages since the maximum glaciation agrees with that in many other mountain systems on globe since the last glacial period. Accordingly, this is an indication of the Würm-age of the lowest ice margin positions.

As to the 11–13 glacier positions met also in the further test areas (see above), which can be differentiated from the current glacier tongues up to the lowest Last Glacial end moraines, and also with regard to a global snowline depression about 1,200–1,500 m as against the current snowline altitude, High Asia corresponds with the global glacier reconstructions as they have been established, e.g., in the Alps, the Rocky mountains, New Zeeland, and the Andes (ibid.).

A recently formulated alternative position as to the outlined extensive LGP glaciation of High Asia is represented by Seong et al. (2008) and Owen et al. (2008) on the basis of OSL- and TCN datings. However, these datings are inconsistent and contradictory; moreover, in comparison with the conventional radiocarbon data, they are overrated. The factor of overrating lies between c. 4 and 10 (Kuhle, 2008).

A possible reason for this chronological overrating of the datings goes back to the calculation of the scaling factors for the Ice Age High Asia which is insufficient so far. But due to the atmospheric cosmogenic isotope chronology, it is certain that the intensity of the cosmic ray flux during the cold phases in general was higher than today. However, since the age determination is dependent on the local cosmic ray intensity, the modulation of which during the past was determined by the complex interrelations between the solar and terrestrial magnetic fields and their secular excursions, a reliable calibration of the OSL- and TCN-techniques for High Asia is not yet possible. The overrating of the age determinations might indicate that the scaling models so far underrate the Ice Age radiation and thus produce age determinations that are too high. In case minima of the terrestrial and solar magnetic field overlie each other – as this must have happened several times during the past – the TCN-productivity is at least by the factor 4.5 higher than today (Beer, 2000, Figures 2 and 4; Lifton et al., 2005; Pigati and Lifton, 2004) and an irradiation of 1 Ka is enough to simulate an age of 4.5 Ka. A wrong calibration like this cannot be identified by the datings itself. Therefore the CRONUS-Earth project recommends the search for "Production Rate Calibration Sites," that are made safe by conventional radiocarbon data. Even more important is the fact that a calibration of the TCN-technique can only proceed from the basis of an already existing Quaternary-geological chronology and not the other way round. The papers concerning High Asia, which contain OSL- and TCN-datings (ibid.), are not able to cope with this procedure. However, all these papers contain the following circular argument: if a moraine, situated at an insignificant distance from the recent glacier tongues, is dated by OSL- or TCN-techniques as being of a High Glacial (LGM) age, indications to a more extensive glaciation either are ignored or shifted to an older glacial period, without providing a further argument that is independent of the dating.

Accordingly, here a non-calibrated scale (namely, the OSL- and TCN-data) is interpreted to be an absolute scale and at the same time the scale of the indispensable glacio-geological method is given up.

The comprehensively documented Quaternary-geological indicators of the LGM-glaciation in High Asia described above, which indicates an ELA-depression between 1,200 and 1,500 m asl that is coherent with the N-hemispheric glaciation and shows a parallel chronological period of time, are not defeated so far. In the contrary, in the meantime regional findings and their glacio-geologically establised classification into the LGM have been confirmed among others by Hewitt (2009). Their paleoclimatic acceptability is evidenced by the relative chronology of the stages as well as state and extent of the preservation of the glacigenic indicators and 14C-datings.

Summary

It is not easy to summarize the current state of knowledge of the Asian ice cover during the Last Ice Age in a map, because up to now the interpretations of the ice-age researchers are contradictory as to this largest continent. In spite of that the author refers to a presentation of the then ice cover which seems to him to be the temporarily best compromise between the positions of a minimum and maximum glaciation (see Kuhle, 2010, Figure 1 (in chapter "*Ice Age*" in this volume)). Besides this cartographic summary of the glacier areas during the Weichsel-period, the extracted heights of the snowline (ELA) are especially appropriate guidelines that present the product of past temperature and precipitation in summary. Thus they make possible to get a Paleoclimatic overview over Asia during the Ice Age: According to the glacier reconstruction (see above N-Asia, Siberia) the ELA in the Siberian Arctis ran at sea-level (0 m asl); toward the middle- up to S-Siberian mountains (see above The Siberian mountains) it was uplifted to 1,250–1,450 m asl (E-Sayan- and Khama Darban Mountains, 53°–52°N); to the S, to the Altai and Tienshan (44°–40°N) it increased to 2,200–2,900 m asl; from the N-margin of Tibet (Kuenlun 36°N) up to the Himalaya (28°N) (see above High Asia) it was uplifted from 3,600 to 3,700 m up to 4,000–4,300 m and then decreased again to 3,600 m asl in the Himalaya-S-slope. From here further to the S (see above The mountains to the S and E outside of Siberia) the ELA drops as far as close to the equator to 3,500–3,100 m asl (Malaysia and Indonesia). On the E-margin of Asia in the Japanese Hidaka Mountains (42°–43°N), the maritime influence led to an altitude of the snowline about max. 1,400 m asl, that has increased toward the equator via Taiwan (3,300 m asl at 22°–25°N). The most astonishing climatic depressions of the snowline to only ELA = 2,500–3,050 m asl have been reconstructed in the currently semiarid SW-Asia (Zagros, 29°–37°N).

RECRYSTALLIZATION OF ICE

Ashok Kumar Verma
Department of Geography and Environmental Studies, Cold Regions Research Center, Wilfrid Laurier University, Waterloo, ON, Canada

Recrystallization of ice refers to the formation and deposition of the large ice particle on the expense of smaller ice particles. The process of recrytallization occurs through when the deformed form of the crystal behaves as the nuclei for the new crystal formation and this process continues till the original nucleus is totally consumed.

This process governs by the two major events such as nucleation and grain size growth. Each event is highly dependent on the temperature and supersaturation (Rogers and Yau, 1989). Nucleation is the first step toward the crystal formation which solely depends on the solute concentration and temperature condition of the underlying environment. Once the formation of the stable nuclei accomplished, the clustering of the nuclei begins to reach the critical size that enhance the recrytallization process toward the growth of ice particles.

In glaciers, the process of the recrystallization is continuous. This process of recrystallization primarily depends on the temperature, the melting point, and stress on the ice. Recrystallization always tends to increase the size of the crystal. The new size was directly proportional to temperature and inversely proportional to stress (Paterson, 1981). Ice near the melting point recrystallizes rapidly but recrystallizations tend to stop below −10°C (Rigsby, 1960). Collectively all these factors decide the metamorphism of the ice (Lock, 1990). The process of recrystallization helps to understand the development of creep and fracture within the glacial systems which result due to deformation in glacial ice (Evans and Benn, 1998).

REFREEZING OF MELTWATER

Ashok Kumar Verma
Department of Geography and Environmental Studies, Cold Regions Research Center, Wilfrid Laurier University, Waterloo, ON, Canada

Refreezing of the meltwater occurs through the release of latent heat from the meltwater. These processes are important in describing the glacier accumulation in the temperate regions (Benn and Evans, 1998).

Processes: The melting from snow/ice occurs in the day time when the surface air temperature at the snowpack is higher than 0°C. The meltwater produced in day time percolates at the base of snowpack. In night time when snow–surface temperatures are below 0°C, the percolated meltwater in the snowpack refreezes in the night releasing the latent heat (Dingman, 2002).

Regelation

REGELATION

Ashok Kumar Verma
Department of Geography and Environmental Studies, Cold Regions Research Center, Wilfrid Laurier University, Waterloo, ON, Canada

Regelation is a process of generation of melt water from ice which is subjected to higher pressure. Higher pressure of ice mass lowers the melting point and causes to melt the ice. The ideal example that demonstrates this phenomenon would be the melting from the glacier ice. The huge mass of glacier ice can exert a sufficient amount of pressure on its lower surface (glacier base) to lower the melting point of its ice. The melting of the ice at the glacier's base allows it to move from a higher elevation to a lower elevation due to ice movement within the course of glacier advancement and retreat.

Regelation related with formation of melt arises from the subglacial systems in the form of a water film. The principle role of water film is to transfer the water from high-pressure areas of glacier bed to the areas of regelation (often described as low-pressure area). These forms of water film are described as *regelation water films*. The regelation can be identified as a possible mechanism for transferring ice past obstacle which is known as *regelation sliding* (Benn and Evans, 1998). In this process, there is an occurrence of melting on the upglacier side of obstacle and refreezing on the downside of glacier followed by the glacier ice movement (sliding) over the rough glaciers terrain. This process provides the resistance to the glacier movement which results in developing the local high pressure and consequently lowering of melting temperature. Regelation process found important in explaining the glacier sliding (Clarke, 1987).

REMOBILIZATION (OF DEBRIS)

Renoj J. Thayyen
Western Himalayan Regional Centre, National Institute of Hydrology, Jammu (J&K), India

Debris produced in a glacial system undergo several cycles of movement and remobilization before final deposition.

Remobilization debris in a glacial system occurs through supraglacial, englacial, and subglacial environments. Two important processes of remobilization of debris in a glacial system are gravitational mass movement and transport by water. Supraglacial zone of the glacier receives debris from exposed rock faces and walls adjacent to the glacier ice margins, released by freeze – thaw weathering. The surface relief of the glacier undergoes continuous change and the gravitational remobilization of debris occurs along the sloping glacier surfaces and characteristics of such mass flows are strongly depended on the water content and other factors such as mean grain size, maximum flow thickness, shear strength, porosity, and bulk density (Boulton 1968, 1971; Lawson, 1982). Remobilization, which occurs in supraglacial and englacial zones, is considered as passive transport as the original characteristics of the sediment such as particle size and shape are retained during the movement. However, debris movement through the subglacial system is subjected to modification by rolling, sliding, crushing, and abrasion. Entrainment of englacial sediment mainly occurs at firn zone of the glacier. It also occur through crevasses and moulin, fed by the supraglacial debris and moved through "high level" sediment transport pathways in a englacial system. It is also possible that the sediment movement across the glacier occurs from subglacial zone to supraglacial zone. Such movement occurs close to the glacier snout, where under compression flow-lines turn upward or thrust-faulting is developed in the glacial system. Remobilization of debris by meltwater flow can take place in supraglacial, englacial, and subglacial zones and its margins.

RESEDIMENTATION

Subhajit Sinha
DBS College, Dehradun, Uttarakhand, India

Sediments are any particulate matter that forms by the breakdown of pre-existing igneous, metamorphic, and sedimentary rocks and the process by which these broken particulates are deposited is called sedimentation process. There are three main processes operating in a sedimentary system: erosion, transportation, and deposition. Resedimentation is a process whereby these previously deposited sediments are moved from its original place of deposition through a process generated by the mechanical behavior of flow. For example, the term

"sediment gravity flow" was introduced to describe the major flow types involved in resedimentation processes and was defined as the flow of sediments or sediment–fluid mixture in which the interstitial fluid is driven by the grains moving under the action of gravity. Instability of the earlier sediments is the prerequisite for generation of flows involved in resedimentation processes. Such instability normally comes into existence either due to oversteepening of the parent deposit or through some process of liquidization including seismogenic slumping and storm wave-induced landslide.

RETREAT/ADVANCE OF GLACIERS

Luke Copland
Department of Geography, University of Ottawa, Ottawa, ON, Canada

Definition

The retreat and advance of glaciers traditionally refers to changes in the position of a glacier terminus over time. More recently, quantification of the retreat/advance of glaciers has been extended to include measurement of ice thickness changes, which provides a more direct picture of how ice volume is changing as it is directly related to mass balance. These measures are the most common way in which the response of glaciers to climate change is monitored, as conditions favorable for positive glacier mass balance (e.g., increasing snowfall, lower temperatures) typically result in glacier advance, while negative mass balance conditions (e.g., lower snowfall, higher temperatures) typically result in glacier retreat (Figure 1).

Controls on glacier terminus advance/retreat patterns

The position of a glacier terminus is primarily defined by the balance between two factors: ice motion that is driving the ice front forward, and melt/calving that results in loss of the ice front. Changes in either, or both, of these factors control the ultimate terminus position. For example, the terminus of a glacier will retreat if surface melt is greater than the rate of forward ice motion, even if there is still substantial ice flow along the lower glacier. In another example, a glacier will advance if surface melt rate stays constant but ice velocity increases.

The initial reaction time of a change in terminus position to a climate perturbation can be asymmetric as an increase in air temperature can lead to a rapid retreat via immediate melting at the terminus, whereas an increase in snowfall can take years or longer to produce a terminus change due to the time it takes for ice to flow from the top to bottom of a glacier. The reaction time differs from the response time, which is defined as the time it takes for a glacier to completely adjust to a climate perturbation (Haeberli and Hoelzle, 1995). The response time and total change in terminus position for a given climate forcing depends to a large extent on the original size of the glacier, with larger glaciers experiencing larger terminus changes due to the requirement for mass conservation (Nye, 1965; Johannesson et al., 1989). When combined with models of ice dynamics, this enables reconstruction of past mass balances from glacier length changes (e.g., Hoelzle et al., 2003) and the prediction of future glacier advance/retreat patterns for given climate forcings (Oerlemans et al., 1998). The change in terminus position for the same external forcing will also vary between glaciers depending on the geometry of the valley in which they lie. Glaciers which have a large, broad accumulation area that feeds into a narrow valley will undergo large changes in terminus position in response to changes in mass balance. Conversely, ice masses that have broad ablation areas (e.g., ice caps) would see much less variation in terminus position for the same change in mass balance.

Given the above considerations, the relationship between the retreat/advance of glacier termini and climate is rarely straightforward. Glaciers are always adjusting to their surrounding conditions, since weather and climate can and do vary on much shorter timescales than glaciers. Glacier terminus changes typically reflect a low-frequency response to external forcing (UNEP, 2007), with short-term climate variations being averaged out over timescales of a few years to decades for glaciers in wet, maritime climates where there is high mass turnover and relatively fast flow (e.g., New Zealand Alps, Patagonia, Alaska; Paterson, 1994; Raper and Braithwaite, 2009). In contrast, glaciers in drier, more continental climates (e.g., Arctic Canada) have a lower mass turnover and flow relatively slowly, which means that it can take them decades to centuries or longer to respond to changes in climate.

As techniques for monitoring glaciers have developed (e.g., airborne laser altimetry; Hopkinson and Demuth, 2006), it is clear that measurement of the position of a glacier terminus over time provides an imperfect measure of how the glacier is responding to external factors such as climate. Measurements of changes in ice thickness provide a more direct measure of these effects, as the response time of glacier surface height changes to external forcing is typically much shorter than the response time of changes in terminus position (UNEP, 2007). Increases in surface elevation typically mean that a glacier is healthy and gaining mass (e.g., due to increasing snowfall and/or reduced melt), while decreases in surface elevation typically indicate that a glacier has a negative mass balance and is wasting away. These techniques are discussed in more detail elsewhere in this volume (e.g., see under "*Glacier Mass Balance*").

Historical terminus advance/retreat patterns

Despite the limitations and uncertainties in interpreting the causes of changes in glacier terminus position, they are

Retreat/Advance of Glaciers, Figure 1 Photo illustrating retreat of the terminus position of the Easton Glacier, North Cascade Mountains, USA, between 1985 and 2003. (Source and copyright: http://en.wikipedia.org/wiki/File:Eastonterm.jpg).

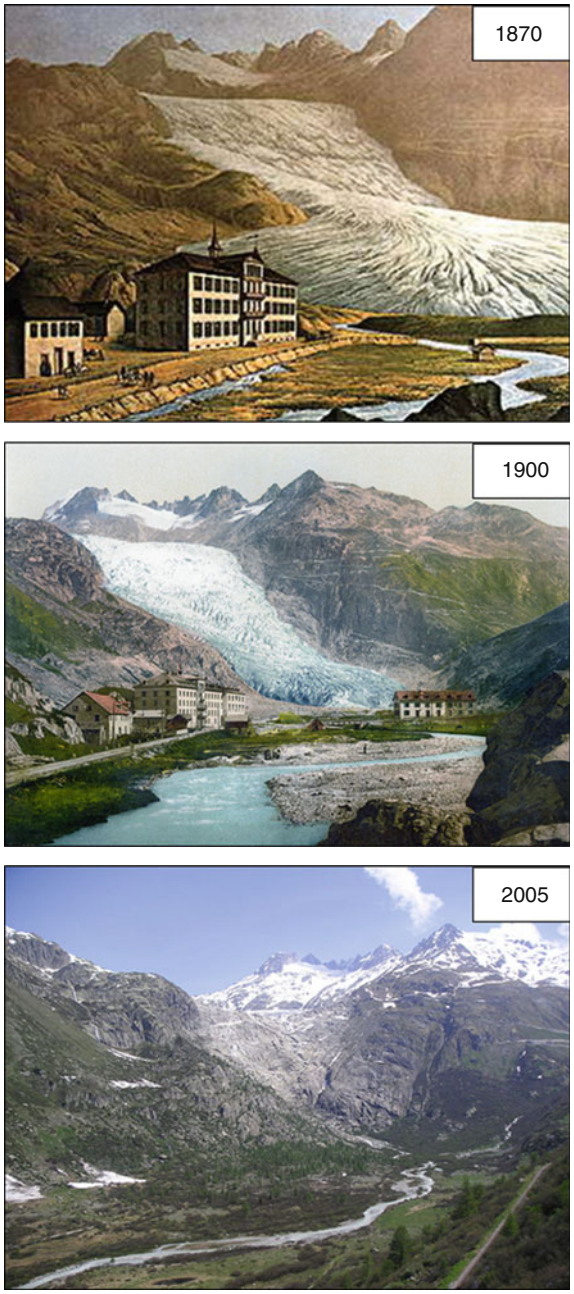
still one of the most widely used measures of glacier health. This is because glacier terminus position is one of the most visible and easily measured glaciological indicators, both in historical sources (e.g., paintings, photography) and modern satellite imagery. For example, the longest known record of changes in glacier length is provided by the Untere Grindelwaldgletscher, Switzerland (Oerlemans, 2005), whose cumulative length changes have been reconstructed since 1534 (Zumbühl, 1980). Over long time periods, air temperature provides the dominant control on terminus position as it provides the main control on glaciologically important climate parameters such as the long-wave radiation balance, the ratio of solid to liquid precipitation, and turbulent heat exchange (WGMS, 2008).

It can be problematic to connect climate changes to the advance/retreat pattern of a single glacier, but consistent changes across many glaciers in the same region increases confidence that air temperature is providing a dominant control. For example, widespread advance of glaciers in the European Alps during the Little Ice Age between ~1650 and 1850 occurred as a response to cooler conditions during this time (Grove, 1988). Since then, there has been widespread glacier retreat in this region as a response to climate warming. For example, the terminus of the Rhonegletscher has retreated dramatically between 1870 and the present day (Figure 2). Useful comparisons of glacier changes over time are available at http://www.swisseduc.ch/glaciers/index-en.html.

Complicating controls on terminus advance/retreat patterns

Interpretation of the terminus retreat/advance pattern of glaciers as an indicator of climate change can be complicated in situations where morphological and internal processes provide a strong control on glacier changes. In particular, there are three types of glaciers where this can be a factor (WGMS, 2008):

1. Surging glaciers: on these ice masses, dramatic changes in terminus position and surface height are mainly related to periodic redistribution of mass within the glacier due to changes in internal flow dynamics. For example, the terminus of the Kutiàh Glacier, Pakistan, advanced by 12 km over an approximately 3-month period in 1953 due to a surge (Desio, 1954). These changes are largely unrelated to external climate conditions, which means that surge-type glaciers are usually omitted from inventories that use glacier advance/retreat patterns to assess the impacts of climate change.
2. Tidewater glaciers: glaciers that end in freshwater or marine locations have floating termini, which can display complex terminus responses defined by relationships between factors such as water depth, pinning points, ice dynamics, tides, and climate forcing (Benn and Evans, 1998). Consequently, advance/retreat patterns of individual tidewater glaciers are often problematic to interpret in terms of climate forcing, particularly over short timescales. However, tidewater



Retreat/Advance of Glaciers, Figure 2 Retreat of Rhonegletscher, Switzerland, from the end of the Little Ice Age (1870) to the present day. (Source and copyright: http://de.wikipedia.org/wiki/Rhonegletscher).

glaciers can provide useful information on climate changes if they display consistent terminus advance/retreat patterns over large areas and for long periods (e.g., Joughin et al., 2008). The tidewater advance/retreat pattern is typically asymmetric, with advances occurring over long periods (centuries) and retreats occurring relatively rapidly (decades). Consequently, a majority of calving glaciers would be expected to be advancing in a constant climate.

3. Debris-covered glaciers: glaciers in tectonically active mountain ranges (e.g., Himalayas) are frequently heavily debris covered over their lower ablation areas, with debris thicknesses of >1 m common (Shroder et al., 2000). This debris is effective at protecting the ice from melting, which means that their terminus advance/retreat patterns are commonly muted compared to nearby non-debris covered glaciers (WGMS, 2008). Negative mass balance on these ice bodies often results in downwasting of the glacier in situ, rather than a distinct retreat of the terminus.

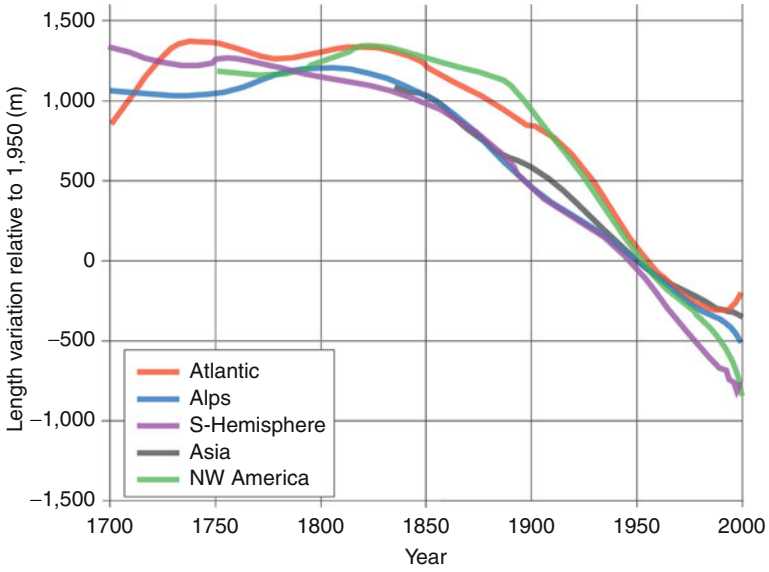
World glacier monitoring service

The World Glacier Monitoring Service (http://www.geo.unizh.ch/wgms/), based at the University of Zurich, Switzerland, maintains the main global database of the advance/retreat patterns of glaciers. Researchers from around the world are encouraged to provide standardized annual measurements of parameters such as glacier mass balance, volume, area, and length that are inventoried by WGMS. Since the late 1950s, they have published the "Fluctuations of Glaciers" series every 5 years that provides the main record of these parameters and how they are changing over time. This information is used by agencies such as the Intergovernmental Panel on Climate Change in the compilation of their reports on the impacts of climate change (e.g., IPCC, 2007). In addition, WGMS/UNEP also recently published the book on "Global Glacier Changes: Facts and Figures" that provides a valuable summary of glacier advance/retreat patterns around the world (WGMS, 2008).

The WGMS assesses the advance/retreat patterns of glaciers within a hierarchy of measures of glacier health under the auspices of the Global Terrestrial Network for Glaciers (http://www.geo.unizh.ch/wgms; Haeberli et al., 2000). Within this strategy, detailed monitoring of glacier mass balance and flow dynamics on an annual basis is limited to a relatively small number of sites ($\sim 10^1$–10^2) where access and logistical cost allows. These locations provide the most direct measure of glacier health, but are limited by their lack of spatial coverage. To expand on this coverage, monitoring of changes in glacier length is completed at a much larger number of glaciers ($\sim 10^2$–10^3) on a less regular basis (approx. every 5–10 years). This provides a global picture of how glaciers are changing over time, and monitoring over longer time periods increases confidence that changes in terminus position represent long-term trends rather than annual anomalies.

Recent advance/retreat patterns of glaciers and ice caps

One of the most comprehensive analyses of glacier terminus advance/retreat patterns is provided by Oerlemans (2005), who compiled mean length variations of 169 glaciers over the period 1700–2000 (Figure 3). The spatial



Retreat/Advance of Glaciers, Figure 3 Large-scale regional mean length variations of glacier tongues (Oerlemans, 2005). The raw data are all constrained to pass through zero in 1950. The curves shown are smoothed with the Stineman (1980) method . Glaciers are grouped into the following regional classes: SH (tropics, New Zealand, Patagonia), northwest North America (mainly Canadian Rockies), Atlantic (South Greenland, Iceland, Jan Mayen, Svalbard, Scandinavia), European Alps and Asia (Caucasus and central Asia). (Source: IPCC 2007, their Fig. 4.13). (Source and copyright: http://www.ipcc.ch/publications_and_data/publications_and_data_figures_and_tables.htm).

and temporal coverage of these records is incomplete due to the lack of continuous long-term monitoring of glaciers, but the changes are still remarkably similar from many different regions around the world. In the early period (1700–1850), glacier lengths were largely stable during the Little Ice Age, when mean temperatures were approximately 1.0°C cooler than at present (Oerlemans, 2005). Consistent retreat began around 1850 and has continued up to the present day, with glacier fronts on average ~2 km further back in 2000 than in 1850. In the European Alps, this has coincided with a loss of approximately two third of glacier volume between 1850 and the early 2000s (Zemp et al., 2006).

Glacier terminus retreats have accelerated since the early to mid-1980s in many parts of the world (Solomina et al., 2008; WGMS, 2008). In single very warm and dry summers, such as 2003, losses of up to 5–10% of the total remaining ice volume of the European Alps have been observed. This has lead to concerns that the remaining glaciers may almost entirely disappear within the next few decades (Zemp et al., 2006). Similar dramatic reductions have been recorded in North America, with widespread glacier area and volume losses in the Rocky Mountains (De Beer and Sharp, 2007; Demuth et al., 2008) and Alaska/Yukon (Arendt et al., 2002; Larsen et al., 2007), particularly at low elevations. Similar changes have also occurred in the Patagonia Icefields (which hold most of the ice in South America), with the majority of outlet glaciers dramatically retreating since the mid-1900s (Lopez et al., 2010), including a doubling of ice thinning rates over 1995–2000 compared to 1968/1975–2000 (Rignot et al., 2003).

Many high-altitude tropical glaciers in locations such as New Guinea and Africa have completely disappeared during the latter part of the twentieth century (Cullen et al., 2006; Klein and Kincaid, 2008), with a poor outlook for the remaining ice bodies in these areas (WGMS, 2008).

While most glaciers and ice caps have undergone widespread retreat over the past century, there are a few areas where glacier advances have been observed. In particular, glaciers on the west coast of New Zealand and Norway showed marked advances between the early 1980s and 2000 (WGMS, 2008). These areas are climatologically similar, being dominated by westerly atmospheric circulation across open ocean that produces very high precipitation amounts (>10,000 mm yr^{-1} in some parts of New Zealand). Their recent advances have been linked to increases in the strength of this circulation, with an increase in El Niño/Southern Oscillation (ENSO) events corresponding to increased precipitation in New Zealand, and a strongly positive North Atlantic Oscillation (NAO) corresponding to increased precipitation and a seasonal shift to more winter precipitation in Norway (Chinn et al., 2005). Recent glacier advances and velocity increases have also been reported for the Karakoram Himalaya, again as a response to increases in precipitation (Hewitt, 2005; Quincey et al., 2009).

To put these recent changes in context, it is also useful to consider the changes in glacier extent that have occurred since the end of the last glacial period. At the peak of the last glaciation (21 ka), ice covered approximately one third of the land surface on Earth (Paterson, 1994), with most of North America and Northern Europe

covered by the Laurentide and Eurasian Ice Sheets, respectively. Available field evidence indicates that warming during the Early Holocene caused dramatic glacier retreats in most mountainous areas such as the Alps, with glaciers reaching similar extents ~11–10 ka as those at the end of the twentieth century (WGMS, 2008). These retreats were punctuated by temporary readvances, such as one at 8.2 ka that appears to be related to changes in thermohaline circulation of the oceans (Alley and Agustsdottir, 2005). However, glaciers in most parts of the world continued their general retreat and reached their minimum extents ~4–6 ka (Solomina et al., 2008). Minor advances and retreats have occurred since then, with the most recent glacier advances occurring during the Little Ice Age that ended around 1850.

The above examples highlight the complexity of glacier responses to climate change over different time periods. The vast majority of glaciers and ice caps around the world have undergone dramatic retreat since the end of the Little Ice Age, but these patterns have been occasionally punctuated by local advances, particularly in response to increases in precipitation. These local increases appear to be largely temporary in nature, however, and are insufficient to counteract the dramatic losses that have occurred elsewhere. Glacier retreat patterns during most of the Holocene appear to be largely driven by natural changes in incoming solar radiation caused by changes in the Earth's orbit (Solomina et al., 2008). In contrast, glacier length changes in the past couple of decades have occurred at rates that cannot be explained by natural variability, making it highly likely that human-induced forcing (e.g., due to increased atmospheric CO_2 levels) is the primary cause (IPCC, 2007).

Summary

In summary, advance/retreat patterns of glacier termini provide one of the most easily measured and recognizable indicators of climate change. Advancing glaciers typically indicate positive mass balance conditions and a healthy glacier, while terminus retreat is usually indicative of negative mass balance. There are many factors that can complicate interpretation of the causes of changes in terminus position, but in general similar advance or retreat patterns across many glaciers in the same region can be interpreted in terms of changes in climate. Air temperatures typically provide the primary control, although precipitation can also be important in some locations (e.g., maritime regions). Modern satellite imagery now enables the monitoring of glacier terminus positions over large areas, which has revolutionized understanding of the spatial patterns of recent changes.

RIME ICE

Renoj J. Thayyen
Western Himalayan Regional Centre, National Institute of Hydrology, Jammu (J&K), India

The white, granular deposits of ice formed on cold surfaces by freezing of supercooled vapor or water droplets carried by the wind are known as rimed ice.

The rimed ice is formed on objects that are at a temperature below the freezing point. Rime occurs when supercooled water droplets (at a temperature lower than 0°C) come in contact with a surface that is also at a temperature below freezing. The droplets are so small that they freeze almost immediately upon contact with the object. Rime ice is commonly formed on windward upper slopes of mountains that are enveloped by supercooled clouds. These rime deposits generally take the form of long plumes of ice oriented into the direction of the wind. Rime is composed of small ice particles with air pockets between them and causes its typical white appearance and granular structure. Because of the rapid freezing of each individual supercooled droplet, there is relatively a poor cohesion between the neighboring ice particles, and the deposits may easily be shattered or removed from objects they form on. Rime ice can form on various surfaces like aircraft, glacier surface, trees, grass, etc.

RIVER ICE HYDROLOGY

Hung Tao Shen
Department of Civil and Environmental Engineering, Clarkson University, Potsdam, NY, USA

Definition

Hydro-meteorological effects on river ice evolution and its effect on river hydrology.

Introduction

In cold and temperate regions of the world, wintertime operation of river systems is a key element in the management of surface water resources. River ice is known to affect many of the world's largest rivers. In the Northern Hemisphere, about 60% of rivers experience significant seasonal effects of river ice (Prowse, 2005). The formation and evolution of river ice is affected by the river discharge supplied by the catchment. The hydrological effect of river ice is mainly its influence on the river discharge and stages. In addition to ice-induced extreme flow events, river ice can also have serious environmental and ecological effects (e.g., Prowse, 2001a, 2001b). In the last couple of decades, significant progress has been made on river ice research. Several books and reviews on river ice processes and the state of research have been published (Ashton, 1986; Beltaos, 1995, 2008a; Beltaos and Prowse, 2009; Donchenko, 1987; Gerard, 1990; Prowse, 2005; Shen, 2003, 2006). An overview of river ice processes and its hydrological effects will be presented.

River ice processes

River ice phenomena include formation, evolution, transport, accumulation, deterioration, and dissipation of various forms of ice. These phenomena involve complex interactions between hydrodynamic, mechanical, and thermal processes, under the influence of meteorological and hydrological conditions.

Freeze up

In the beginning of winter, when the water temperature drops to the freezing point, further heat loss will lead to supercooling and frazil ice formation. Subsequently, various types of ice can form in the river depending on the flow intensity. In slow flowing areas, where the turbulence intensity is not strong enough to mix the water or frazil ice crystals from the surface over the depth, skim ice can form on the supercooled water surface even before the depth-averaged water temperature drops to the freezing point. In slow flowing shore zones, this appears in the form of border ice (Svensson et al., 1989). Further cooling will lead to thermal growth of skim ice and border ice, and supercooling of turbulent flow in the river.

When mixed in supercooled turbulent water, frazil crystals can grow in size, multiply in number, and agglomerate into flocs (Daly, 1984; Hammar and Shen, 1995; Osterkemp, 1978). Frazil crystals entrained to the bottom of the channel under supercooled conditions can attach to the bed and underwater objects to form anchor ice (Kerr et al., 2002). The presence of anchor ice can cause changes in flow resistance, water level, and discharge. As the frazil particles and flocs grow in size and quantity, the increase in buoyancy may overcome the vertical mixing to form a surface layer of moving ice. Depending on the turbulence condition and travel time in the river, the surface ice run could consist of ice pans or slush ice. Ice pieces on the river surface will grow in size and strength due to further accumulation of frazil ice from the suspension, freezing of interstitial water, and thermal thickening. Surface ice elements may either sinter into large floes while traveling along the river, or break into fragments when encountering rapid sections. Partial coverage of the water surface by surface ice floes will result in a reduction of the net ice production rate due to the insulating effect of the surface ice (Lal and Shen, 1991). In addition to thermal growth, lateral growth of border ice can occur due to the accumulation of surface ice along edges of existing border ice (Michel et al., 1982; Miles, 1993). This type of lateral growth of the ice cover is limited by the stability and strength of surface ice elements in contact with the existing edge of the border ice. Limited field observations showed that the border ice growth would cease when the local depth-averaged velocity exceeds a critical value of about 0.4 m/s (Matousek, 1990; Shen and Van DeValk, 1984). In rapid reaches, the high turbulent intensity of the flow will limit the size of flocs by turbulent shear and prevent them from rising to the surface. In this case, the frazil flocs in the supercooled water will evolve into frazil granules entrained in the flow to form a suspended frazil ice run. Shen (2006) described the evolution process of different types of ice runs. Matousek (1984) provided a useful empirical method for determining the occurrence of various types of ice formation, but a theoretical formulation still needs to be developed.

Ice cover evolution and ice jams

As more and more ice is produced and surface ice concentration increases, downstream transport of the surface ice will eventually lead to *bridging* or jamming of surface ice across the river (Shen et al., 2000). Jamming of the surface ice run by congestion initiates the accumulation of surface ice into an ice cover. Once an ice cover is initiated, it will progress upstream through the accumulation of the incoming surface ice (Pariset and Hausser, 1961). A cover formed under any hydraulic condition has to reach a thickness and strength so that it is capable of withstanding the forces acting on it. These forces include water drag, wind drag, weight of the cover, and bank resistance. The formation of a thin crust near the top of the newly formed cover due to freezing can significantly increase the strength of the cover. Surface ice jam formation is a part of this surface ice cover progression process. Ice jams appear as localized thick accumulations when subject to larger external forces (Beltaos, 1995; 2008b). As the cover progression encounters high velocity reaches, where incoming surface ice can underturn or become entrained at the leading edge, the cover progression will cease. The limiting condition for cover progression has been defined by the Froude number at the leading edge of the cover. This limiting Froude number is about 0.09 (Sun and Shen, 1988). The transport and deposit of the entrained ice on the underside of the cover can form thick accumulations commonly known as hanging dams. In addition, when the progression of an ice cover stops at a cross section due to the high flow velocity, the rapid reach upstream of the leading edge will remain open during the winter. This open water reach will continue losing heat through the water surface and produce frazil. Since the open water reach has relatively high velocity, the ice in the reach will likely be in the form of frazil granules entrained in the flow. When the frazil granules enter the ice-covered reach, they rise to the underside of the cover and transport and accumulate along the cover to form a frazil jam. The evolution of frazil jam is governed by the ice transport capacity similar to the bed load transport in alluvial rivers (Shen and Wang, 1995). Localized frazil jams have been viewed as another type of hanging dam.

The formation of surface ice, especially a stationary surface ice cover or jam, adds to the flow resistance and causes an increase in channel storage with the backwater effect. This will raise the water level in and upstream of the ice covered reach and reduce the discharge downstream. Ice jam accumulations often lead to severe flooding. The water level rises with the increase of ice

accumulation thickness. In the case of a frazil jam, the level rises gradually over the winter with the gradual increase in the size of the jam before it recedes with the erosion of the undercover accumulation. In the case of a surface jam, the water level could increase rapidly over a very short period due to the rapid jam formation process (e.g., Gerard, 1990; Beltaos, 2008b). Analytical formulations for the hydraulics of flow in rivers with moving or stationary surface ice have been developed (e.g., Lal and Shen, 1991; Shen et al., 1995, 2000). One difficulty in analyzing flow in the presence of ice is the determination of the hydraulic resistance of the ice. Some empirical guidelines exist for floating ice covers. It has been observed that the ice roughness diminishes with time due to thermal and hydraulic smoothing. This time dependent variation of cover roughness may be represented by an exponential decay function (Nezhikovskiy, 1964; Yapa and Shen, 1986). For surface ice jams, Beltaos (2001) and Shen et al. (2000) suggested that the roughness increases with the jam thickness.

As heat exchange continues through a consolidated ice cover, water-filled voids in the ice accumulation will freeze from the free surface downward. This thermal growth will continue beyond the initial thickness of the cover into the underlying river water (Shen and Chiang, 1984; Shen and Yapa, 1985; Shen et al., 1995).

Breakup

At the beginning of spring, or during a warm spell in the winter, decay of the ice cover occurs. The warm spring runoff can also significantly accelerate the thermal erosion process through the turbulent heat transfer between river water and the ice cover. The thermal erosion of ice cover and the deterioration of cover through internal melting by solar radiation lead to the reduction of cover strength (Ashton, 1985; Prowse et al., 1990). The weakening of ice cover makes it more susceptible to mechanical breakup. However, if the river discharge remains relatively steady, the ice cover will remain stable until the eventual meltout.

A mechanical breakup begins with a detachment of the cover from the banks with increasing river flow, followed by the formation of far-spaced transverse cracks (Beltaos, 1984). Beltaos (1990) defined the onset of the breakup as the time when sustained ice movement occurs at a particular site and formulated an empirical method for predicting its occurrence based on the boundary constraints of the river plane geometry in allowing the movement of the large ice plates. If a rapid increase in river discharge occurs, as the result of a runoff increase, an upstream ice jam release, or a surge produced by a hydropower station, the traveling river wave will produce a pressure disturbance underneath the cover. This disturbance may further crack and fragment the cover (Xia and Shen, 2002).

An ice run will occur after the fragmentization of the cover, if the water level rises further. The ice rubble moving along the river can incorporate additional ice fragments by breaking the stationary ice covers downstream. Intermittent stoppage and movement of the rubble field, accompanied by ice jam formation and release, can occur during the downstream progression of the ice run. The basic dynamics of breakup surface ice run and ice jam is essentially the same as those that occurred during the freeze up period. However, the breakup ice runs can be more abrupt and violent, especially if the breakup occurs early in the spring with a high water discharge.

Sudden release or failure of ice jams accompanied by the release of channel storage often generates surges of water with high water velocity and rapid increase in stage (Jasek, 2003). Liu and Shen (2004) showed that the ice resistance has significant effects on both stage and discharge hydrographs during an ice jam release. A flood wave produced by jam release propagates slower than a flood wave without ice. The ice resistance also lowers the peak discharge significantly.

Summary

River ice processes are affected by the ambient meteorological and hydrological conditions and interact in a complex manner with the river flow. River ice affects river hydrology mainly through its influence on the river flow by introducing additional hydraulic resistance. One of the most recognized effects of ice on river hydrology is the influence of ice cover and jams on the stage and discharge. Both the increase in wetted perimeter due to the presence of ice cover and the reduction in flow cross section by the cover or jam thickness contribute to the additional flow resistance. Other processes such as anchor ice growth, and the internal ice resistance in a surface ice run, can also affect the river flow. Significant progress has been made on river ice research in the last couple of decades. Further research to gain fundamental understanding on many of the individual ice processes, such as the evolution of the freeze up ice run and the development of methods for simulating breakup processes are needed.

ROCHE MOUTONNEES

Himali Panthri
Department of Geology, D.B.S (P.G) College, Dehradun, Uttarakhand, India

Roche moutonnees are asymmetrical mounds or hillocks having a gradual, smooth, and striated abraded slope on one side and a comparatively craggy and steep slope on the other side. Continental glaciers being several hundred kilometers long and thick exert tremendous amount of pressure upon the ground beneath while moving. As the ice advances, the onset or the stoss side is smoothened by combined mechanisms of abrasion and polishing, and the down flow or lee side is steepened due to greater intensity of plucking on this side. Roche moutonnees commonly occur in swarms, often with a common alignment that indicates the direction of the movement of the ice.

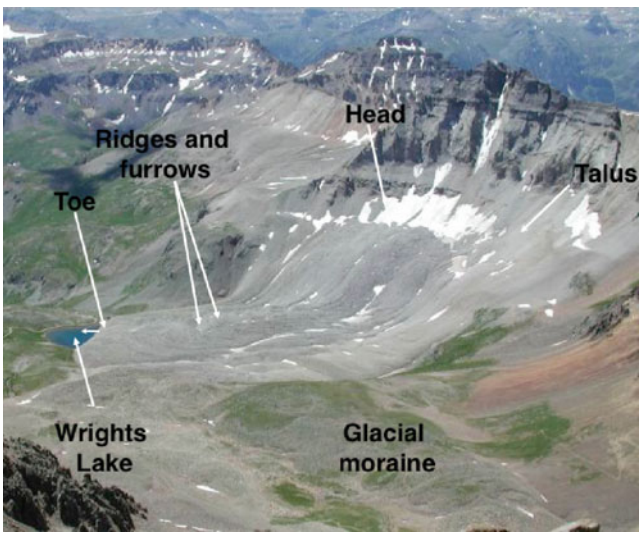
Definition

A rock glacier is a lobate or tongue-shaped landform consisting of rock debris and either an ice core or an ice-cemented matrix. This landform is distinguished by its distinctive series of ridges and furrows on the surface, which give the form its characteristic "wrinkled" pattern. Rock glaciers serve as distinctive reservoir for debris and water in alpine drainage basins.

Introduction

The surface of Earth, a patchwork of landforms, is shaped by various geologic and geomorphic processes influenced by the various subsystems of Earth (Figure 1). Individual landforms on a continuous surface serve as magnifying glasses into the history of Earth by providing a record of how past climates and environments interacted with the surface through erosion and deposition. Rock glaciers, often spectacular landforms, are one of the most ambiguous forms regarding human understanding of the process(es) of formation. This essay will explain the form of rock glaciers and the processes associated with formation. Moreover, perspectives on the role of rock glaciers in landscape development will be advanced.



Rock Glaciers, Figure 1 Yankee Boy Basin Rock Glacier, Colorado. (Photograph taken by J. R. Giardino.)

What is a rock glacier?

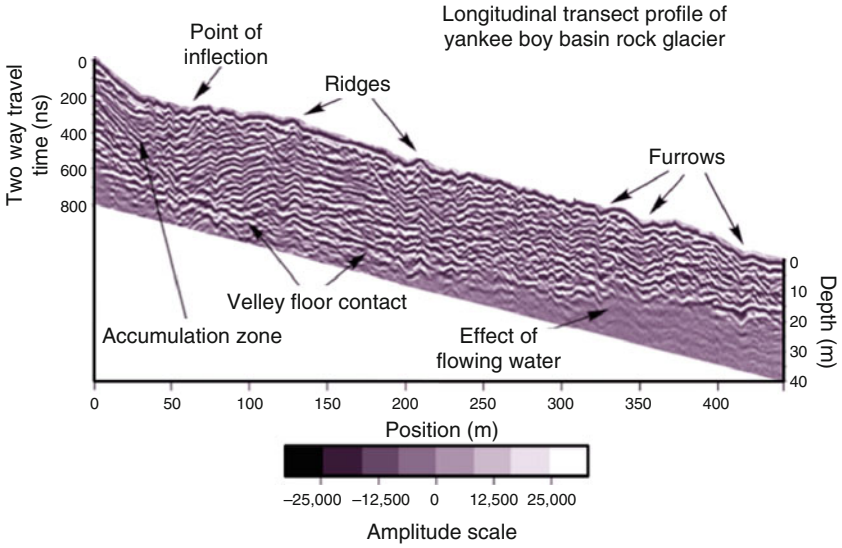
A rock glacier, one form in the landscape continuum, has been mistakenly confused with other landforms (e.g., rock streams, talus flows, and rubble streams). It is separated from the surrounding terrain by a steep front and side slopes and exhibits a surface expression of ridges and furrows that are generally perpendicular to the direction of flow (Giardino et al., 1987). The "wrinkled" pattern of ridges and furrows influenced Capps (1910) to coin the term "rock glacier" for the forms that he observed in Alaska. The downslope movement or flow of this rock debris has been estimated to be between a few centimeters and decimeters per year. Research has shown that movement is the result of plastic deformation of ice contained within the blocky debris of the form. Simplicity, however, is not the norm because of the wide range of rock glaciers around the world. The mineralogy of the rock debris varies considerably as do the elevation and latitude of these forms, which influence debris transport. From hundreds of papers cited in the literature by the mid-1980s, the literature has exploded into thousands of investigations that have and continue to investigate all aspects of this interesting landform. Whereas citing even the majority of the research is not possible in this short essay, key articles will help readers uncover the rich literature that exists on the various topics addressed herein.

A rock glacier is a transitional phenomenon between glacial and non-glacial processes. Size, location, microrelief, and distribution are its distinguishing characteristics. The surface of the lower parts of the rock glacier commonly consists of parallel ridges and furrows that are arced in the downstream direction; the length and width of a rock glacier are controlled by local condition. The toe slope tends to be at or greater than the angle of repose for rock debris where the process of deformation is active, and the head of a rock glacier may merge smoothly with the talus cone.

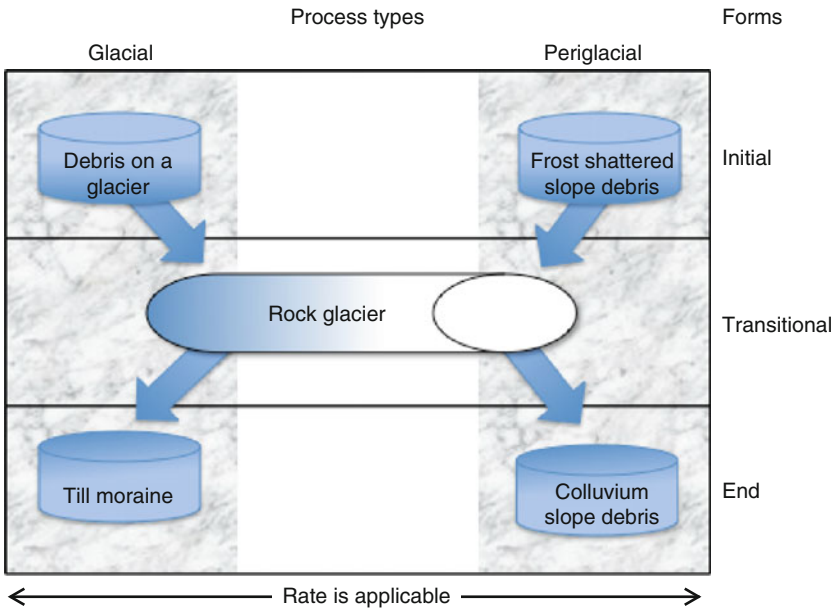
The morphology of a rock glacier is controlled by lithology, geographic location and position, microclimate, aspect, and local conditions (Johnson and Thackray, 2008). A rock glacier is a deposit of poorly sorted, angular and blocky to tabular debris held together by massive ice or a matrix of ice-cemented fine clastics (Giardino and Vitek, 1988). The surface structures supported by the internal structures (Figure 2) can be best used to explain the mechanics of development and movement.

Process of formation

Whereas the term "glacier" is used to denote a landform and a process, a rock glacier is simply a form that moves in response to a variety of processes, many of which are poorly understood. Giardino and Vitek (1988) developed a conceptual diagram (Figure 3) to show the relationship between form and process and demonstrates that a rock glacier is a transitional form regardless of the process(es) that formed it. With the passage of time and processes



Rock Glaciers, Figure 2 Topographically corrected 25 MHz GPR profile of Yankee Boy Basin. (Adapted from Degenhardt and Giardino, 2003.)



Rock Glaciers, Figure 3 Alpine landscape continuum. (Modified from Giardino and Vitek, 1988.)

operating on this accumulation of rocky debris, the rock glacier will cease to exist and will become a sedimentary deposit in the rock record.

Many authors incorrectly use the terms "fossil," "inactive," or "active," to describe a rock glacier. These terms should refer to the process rather than the form. The process may be "active" or "inactive" and subsequently the form will change although the rate of change can vary from imperceptible to observable. Sharp crested, cascading front slopes, sharp and defined surface features indicate recent movement and are the key characteristics to identify active processes in a rock glacier. Rounded crests at the toe and stable fronts with mature lichens on talus, which means debris is no longer supplied to the rock glacier, are related to inactive processes in the rock glacier. The movement of a rock glacier can also be defined in terms of the basal shear stress, although it is relatively difficult to calculate. Giardino and Vick (1987) determined that basal shear stress for active rock glaciers lies between 1.0 and 2.0 bars and Wahrhaftig and Cox (1959)

determined that basal shear stress for inactive rock glacier is less than 1.0 bar.

The basic components of a glacier, primarily ice with rock debris mixed in, contribute directly to the rate of motion and the effects of the glacier on the landscape. In contrast, the visible portion of a rock glacier consists of unsorted boulders and clasts and particles of various sizes. This material can be deposited over a former glacier, in which mechanics attributable to glacial processes may dominate surficial appearance and movement characteristics. Some rock glaciers, however, have formed in areas that have not been glaciated (Giardino and Vitek, 1985; Giardino and Vitek, 1988). In these locations, interstitial ice is the major factor of formation and change. Periglacial processes, therefore, are capable of developing rock glaciers with similar surficial characteristics like rock glaciers derived from glacial processes. In reality, rock glaciers in glacial environments experience periglacial conditions although the impact of these conditions on resulting forms and processes are difficult to assess.

Composition of rock glacier

The mechanics and the development of the rock glaciers can be best explained by internal structure. Two types of the rock glaciers, based on the internal structure near the landform surface and margins, can be distinguished. The first is the rock glacier having predominantly interstitial ice that consists of an accumulation of clasts from boulders to fines. The second type is the rock glacier that contains predominantly massive ice and plugs of ice that are covered by ice-saturated talus or landslide rock debris.

Classification of rock glacier

Shapes, various modes of origin, geomorphic position, and ice content, among other factors, are the major characteristics of a rock glacier. Several classification schemes for rock glaciers exist: some are genetic classifications and some are geometric classifications. In genetic classifications, rock glaciers are described as debris-covered glaciers, ice-cored rock glaciers, and ice-cemented rock glaciers. In geometric classifications, rock glaciers are categorized on length to width ratios. They also can be described as moraine rock glaciers, talus-derived rock glaciers, avalanche rock glaciers, and protalus rock glaciers.

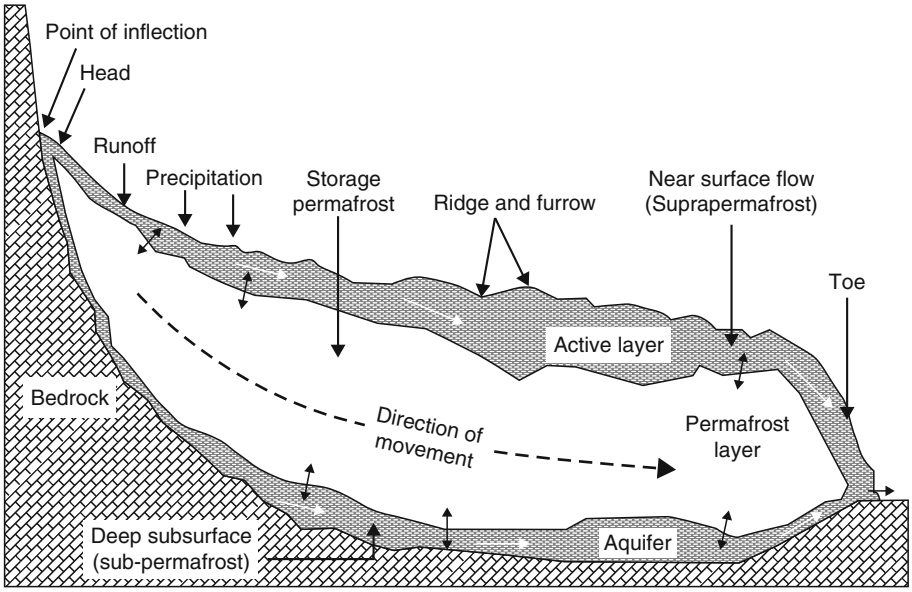
Hydrology and climate warming

Rock glaciers have been identified and studied as unique features for over a hundred years (Cross and Howe, 1905), but the hydrological relationship between rock glaciers and watersheds has been more or less overlooked. Johnson (1981) examined the relationship between internal structure and water flow in rock glaciers in Canada. Giardino et al. (1992) examined the chemical aspects of rock glacier-fed streams in Colorado. Brenning (2005) studied the hydrological aspects of rock glaciers in the Andes.

The hydrological properties of the rock glacier are controlled by the local weather conditions, thermal properties of the debris layer, and the physical mechanisms that control the flow of meltwater through the rock glacier (Figure 4). Therefore, the seasonal variation of water supply controls the variation in the discharge through a rock glacier. During summer, water from thunderstorms and snowmelt increases the discharge from a rock glacier. Likewise during the summer, the water temperature of the rock glacier lies constantly below 1°C and the electrical conductivity remains low as a result of high amounts of meltwater derived from snow, ice melt, and precipitation. The electrical conductivity increases during cold weather and during autumn when discharge is very low and consists of mainly groundwater (Burger et al., 1999).

Giardino et al. (1992) suggested that the interior of a rock glacier can act as an aquifer and the hydrological characteristics of the rock glacier can be viewed as a system. In their model (Figure 5), water input to the rock glacier is directly from precipitation, runoff from adjacent slopes, avalanche, and groundwater, and water output as surface runoff, surface discharge, subsurface seepage, sublimation evaporation, and ice storage. This model considers water flow as near subsurface flow above the permafrost and as deep subsurface flow below the permafrost. A permafrost layer acts as an impermeable layer between these two layers. The hydrological cycle of a rock glacier is viewed as a cascading system to define the manner in which water moves through the landform (Giardino et al., 1992). Water in a rock glacier can occur in liquid and solid forms. The net change in the water storage is governed by the microclimate (Johnson, 1981) and the insulating nature of the rock mantle; the change in the net storage over a long period is very slow (Burger et al., 1999).

Rock Glaciers, Figure 4 Tongue-shaped rock glaciers in the Mount Sneffels Area, Colorado. (Photograph taken by J. R. Giardino.)



Rock Glaciers, Figure 5 A model of waterflow pathways through a rock glacier. (Modified from Giardino et al., 1992.)

The hydrologic cycle of a rock glacier can vary slowly with long-term climatic change and more rapidly with seasonal fluctuations in ambient temperatures (Johnson, 1981). Burger et al. (1999) described how water discharge through the rock glacier varies with the season. During late winter, water within the active layer is frozen and discharge originates entirely from ground water flow systems at the base of the rock glacier. During late spring/early summer, the thawing front moves downward toward the top of the perennial permafrost; melting snow and ice recharge the upper portion of the rock glacier and create a seasonal aquifer perched on top of the frozen core. During summer, free water within the upper portion of the rock glacier disappears and discharge originates from the base of the rock glacier. Meltwater from snow patches in depressions on the surface continue to melt throughout the summer. During late summer/early fall, falling temperatures create freezing fronts that move upward from the perennial permafrost and downward from the rock glacier surface, confining the remaining water in the central portion of the rock glacier. Seasonal thunderstorms replenish free water in the active layer.

Rock glaciers play an important role in the hydrological cycle of alpine watersheds. They provide both long-term and short-term water storage. Water is stored as ice cores and interstitial ice in the interior of the rock glacier. In addition, the contact of the ice in the rock glacier with underlying permafrost in many arctic locations provides a recharge pathway for groundwater in the watershed. From a short-term perspective, rock glaciers provide a pathway for meltwater from snow and avalanches to maintain stream flow during summer and fall. Many streams in alpine watersheds are fed from spring melt; flow is maintained through summer via melt from lingering snow patches, glaciers, and rock glaciers. Climate conditions, the past hundred years, have maintained the contributions from snow, glaciers, and rock glaciers to stream flows.

Global warming is negatively impacting glaciers and permafrost. The volume of glacial ice and permafrost is decreasing in many locations. This direct impact on glaciers occurs because the surface of the glacier is unprotected from direct incoming radiation. Permafrost, on the other hand, whereas having a covering of soil and vegetation several meters thick is not sufficient to retard melting. Ice cores and interstitial ice in rock glaciers are also negatively impacted by global warming, but to a lesser degree because of the insulating mantle of rock debris on the rock glacier.

Rock glaciers form an important part of the alpine sediment cascade. Because of a long persistence in the landscape, they play a vital role in sediment storage. Water contained in the ice of rock glaciers or rock-ice-features (RIFs) is protected from rising air temperatures by the insulating effect of the rock mantle. As a result, thaw of ice in rock glaciers significantly lags behind ice glaciers. For this reason, rock glaciers are likely to become increasingly critical alpine water reservoirs as temperatures rise. The role of rock glaciers is also of critical importance in arid mountain ranges as snowpack decreases and ice glaciers retreat and soon become the primary sources of persistent groundwater for high mountain regions. Global warming appears to be reducing summer stream flows and drying out meadows. Rock glaciers, therefore, are important water storage and water input systems.

Rock glaciers and paleoclimatic implication

Information about the climate (i.e., paleoclimate) can be deduced from the characteristics of rock glaciers. Evidence of past environments may be abundant if the complex relationship between form, process, and climate can be discerned.

Survival of the debris ice matrix in the rock glacier depends on the ambient temperature, precipitation, and the instability of the bedrock. Cooler climates are effective in debris production, formation of interstitial ice, and flow of a rock glacier (Refsnider and Brugger, 2007). An increase in temperature increases the rate of ice melt in a rock glacier and eventually increases the deformation and the velocity of the rock glacier (Patterson, 1994; Whalley and Azizi, 1994; Haeberli et al., 2006; Janke and Frauenfelder, 2008). Temperature and precipitation control the formation of rock glaciers because they control the amount of snowfall, which is an important component in the formation of a rock glacier. Generally, glaciers retreat because of a decrease in precipitation and an increase in temperature. Furthermore, glacier unloading and permafrost melting can promote catastrophic rockfalls and rock slides. Rock glaciers form within specific precipitation and temperature regimes (King, 1986) although low temperatures and high precipitation promote the growth of glaciers (Harrison et al., 2008). Research suggests that rock glaciers can form where temperatures and precipitation totals are relatively low (e.g., Haeberli, 1985; Barsch, 1988). The three factors (temperature, precipitation, and the availability of the debris source or the instability of the cliff) complicate the paleoclimatic signal of the rock glacier. Furthermore, the genetic types of rock glaciers probably reflect the environmental conditions of formation (Harrison et al., 2008) but at present, the knowledge to identify the climatic boundary is insufficient. Records from ice cores show that periods of rapid cooling occurred throughout the Late Pleistocene (Andrews, 1998; Alley et al., 2003), and the climatic conditions suitable for the formation of rock glaciers in many parts of the world may have prevailed during this time. Based on the study of the rock glaciers and RIFs in the Sierra Nevada, USA, Miller and Westfall (2008) estimated the temperature during the Pleistocene as 3.3–4.1°C colder than current (Holocene) temperatures.

Conclusions

Rock glaciers demonstrate that glacial and periglacial processes have been active on alpine slopes. Rock debris has been entrained and is moving, albeit slowly, to a lower and more stable elevation. Form and process are intertwined and care must be taken when using adjectives such as active, inactive, and fossil. The form demonstrates that processes have been involved but does not provide definitive answers about all of the processes that can be present. Because rock glaciers have never been found in the rock record, we have noted in our model that it is a transitional form to a moraine or colluvial deposit, material which has been identified in the rock record.

Variability in climate and weather can be detected in how water flows through this rock debris. New technology, including ground-penetrating radar and global positioning satellites, will enhance the quality of the data acquired and the interpretation of these forms relative to future change. Although the number of research papers has soared in recent years, researchers must be careful to clearly distinguish between the interactions of form and processes, including the use of terminology in how these interesting forms are described.

ROCKY MOUNTAINS

Eric M. Leonard
Department of Geology, Colorado College, Colorado Springs, CO, USA

Definition

The Rocky Mountains are a system of mountain ranges in western North America, extending about 3,000 km from north-central New Mexico (USA) in the south to northeastern British Columbia (Canada) in the north (Figure 1).

Location and topography

The Rocky Mountains comprise the easternmost ranges of the North American Cordillera, rising from the Great Plains to the east. To the west they are separated from the Pacific Ocean by a 500–1,000 km-wide region of generally high topography – an "intermontane" zone of valleys, mountain ranges, and plateaus, and further west the Pacific Mountain System, which includes the Coast and Insular Ranges of British Columbia, and the Cascade Range, Olympic Mountains, Sierra Nevada, and Coast Mountains of the western United States. The Rocky Mountains form the drainage divide for much of North America, separating Atlantic and Arctic Ocean drainage on the east from Pacific drainage on the west.

The United States portion of the Rocky Mountains generally consists of individual ranges separated by broad basins or "parks" (Figure 1). The Canadian Rockies, and their southward extension into northern Montana, are more topographically continuous. The highest terrain in the Rockies is located near their southern end, particularly in Colorado where approximately 600 summits exceed 4,000 m. The highest summit is 4,399 m Mount Elbert in the Colorado Sawatch Range. Overall altitude, but not relief or ruggedness, decreases northward. There are no 4,000 m peaks north of Wyoming, although Mount Robson in British Columbia reaches nearly that altitude and stands much higher above local tree line and snow line than summits in the U.S. Rockies.

Although the distinction between the U.S. and Canadian Rocky Mountains is an arbitrary one in terms of most environmental characteristics, this entry focuses on the former as the Canadian Rockies are covered in another entry (Canadian Rockies and Coast Mountains of Canada).

Climate

The Rocky Mountains have a continental climate with larger diurnal and seasonal temperature fluctuations and lower precipitation than the ranges further west. Moisture comes dominantly from the west, although southerly and southeasterly moisture sources are also significant, particularly along the eastern flank of the Rockies. Fall-through-spring precipitation is dominated by westerly cyclonic storms, summer precipitation by monsoonal flow and local convection (Mock, 1996). Nearly all fall-through-spring precipitation falls as snow, most summer precipitation as rain. Local precipitation patterns reflect orographic influences.

The storm track over the western U.S. is controlled by the position and intensity of the Pacific jet stream. This jet stream undergoes substantial subseasonal-to-interannual variability, and controls the frequency and location of cyclonic storms impinging upon the west coast. Storms associated with northwesterly flow into western North America bring fall-through-spring snowfall mainly to portions of the Rockies from central Colorado northward. Southwesterly flow, commonly associated with a southerly position of the jet, brings heavy snowfall to the southern Rockies (Changnon et al., 1993). These storms commonly also draw southeasterly moisture flow from Gulf of Mexico, leading to heavy "upslope" snowfall along the eastern margin of the southern Rockies, especially during spring and fall. When the jet is weakened or far to the south during the winter, polar air from the north and northeast may impinge on the eastern flank of the Rockies, bringing extremely low temperatures, but generally little snowfall. Interannual-to-multidecadal climate oscillations, including El Niño-Southern Oscillation (ENSO), the Pacific Decadal Oscillation (PDO), and the Pacific-North America Oscillation (PNA), influence

Rocky Mountains, Figure 1 Location map of the Rocky Mountains (*insert*). The western boundary of Rockies in the United States (*dashed line*) is not well defined. Some workers extend the term "Rocky Mountains" northward into the Yukon and Alaska. Main map identifies features of the U.S. Rockies mentioned in the text. L/GNP, Lewis Range/Glacier National Park; B, Beartooth Mountains; YP, Yellowstone Plateau; T, Teton Range; WR, Wind River Range; LB, Pleistocene Lake Bonneville; W, Wasatch Range; U, Uinta Mountains; F, Colorado Front Range; S, Sawatch Range; SJ, San Juan Mountains; SC, Sangre de Cristo Mountains.

the magnitude and distribution of Pacific-derived precipitation in the Rockies (Cayan, 1996; Clark et al., 2001; McCabe and Dettinger, 2002). El Niño conditions, for example, are statistically associated with higher-than-normal snowfall in the southern Rockies, lower-than-normal in the north. La Niña conditions tend to reverse these departures from normal.

In the U.S. Rockies summer precipitation is due primarily to local convection. Convection is particularly strong when associated with monsoonal flow involving northward advection of moist air from the eastern Pacific/Gulf of California area and/or the Gulf of Mexico, resulting from summer heating of the Great Basin and Colorado Plateau. Monsoonal flow commonly results in heavy summer precipitation in the southern U.S. Rockies.

Snowpack

Snowpack data are currently (2010) collected at more than 400 automated Snowpack Telemetry (SNOTEL) sites throughout the U.S. Rocky Mountains (http://www.wcc.nrcs.usda.gov/snow/). Historical data are available for more than 1,000 snow survey courses, many of which have been discontinued in recent years (http://www.wcc.nrcs.usda.gov/snowcourse/).

Snowpack is strongly controlled by elevation, although in many ranges it is asymmetric, with greater accumulation on the range flank facing the predominant winter moisture source and a "snow-shadow" on the opposite side. Typically more accumulation occurs on the west sides of ranges although in the Sangre de Cristo, and possibly other ranges along the eastern flank of the Rockies,

this pattern is reversed with more accumulation on the east, due to a prevalence of southeasterly "upslope" precipitation. Within-range patterns may be complex. The Colorado Front Range receives precipitation from both westerly winter cyclonic and southeasterly upslope storms, the latter primarily during the spring. Stations on the west side of the range and those at highest altitude on the east have winter snowfall maxima, reflecting westerly storms. Those lower on the east side have spring maxima, reflecting both a winter snow-shadow and spring upslope conditions (Barry, 2008). Regionally, snowpack generally decreases west-to-east reflecting the dominance of westerly-sourced winter precipitation, and north-to-south.

Wind redistribution of snow is important in the Rocky Mountains for several reasons including (1) low moisture content of the snow, (2) presence of large areas above tree line, and (3) presence in some ranges, especially the Colorado Front Range and Uinta Mountains of Utah, of broad, low-relief areas above tree line along topographic divides. Wind drift is critical to the preservation of modern glaciers in the Front Range (Outcalt and MacPhail, 1965). Wind loading, the prevalence of temperature-gradient snowpack metamorphism, and the episodic nature of heavy snowfall make Rocky Mountain snowpacks particularly susceptible to avalanching.

Over the last 50 years snowpack water-equivalent depth (SWE) has broadly decreased across the western United States, due to a combination of generally decreased winter precipitation and increased temperature (Mote et al., 2005). In the Rocky Mountains SWE has decreased from central Colorado northward. In southern Colorado and New Mexico, however, many sites show an increase in SWE, apparently due to an increase in winter precipitation that outweighs effects of warming.

Modern glaciers and permanent snow and ice

Modern glaciation in the U.S. Rocky Mountains is limited to cirque and niche glaciers, most with areas of less than 1 km^2, typically in topographically and microclimatically favored sites. The 3.3 km^2 Gannett Glacier in the Wind River Range is the largest in the U.S. Rockies (Fountain, 2006). Drawing primarily on Graf (1977), Krimmel (2002) identified 80.2 km^2 of glacier ice in the U.S. Rockies, largely in Montana (42.5 km^2 – primarily in the Lewis and Beartooth Ranges) and Wyoming (35.0 km^2 – primarily in the Wind River Range). A few very small glaciers exist in Colorado, Idaho, and Utah. Fountain (2006) identified 2,982 permanent ice or snow bodies covering 149.3 km^2 in the U.S. Rockies. Equilibrium-line altitudes of modern glaciers range from about 2,200 m in northern Montana (Locke, 1989) to about 3,700 m in Colorado.

No long-term glacier mass-balance data are available for the U.S. Rockies. Short-term studies have been undertaken in Montana, Wyoming, and Colorado (Mayo, 1984; Reardon et al., 2008). Glacier areas and volumes have decreased significantly over the last 100–150 years. More than 80% of the glaciers that existed in Glacier National Park in Montana in the mid nineteenth century have since disappeared (Reardon et al., 2008) and the remaining glaciers have lost on average about 60% of their area since 1900 (http://glaciers.research.pdx.edu/). Twentieth century loss of glacier area was slightly less in the Wind River Range and Colorado Front Range, around 40% (http://glaciers.research.pdx.edu/).

Quaternary glaciation

Rocky Mountain glacial history has long been a topic of study, recently reviewed by Pierce (2004). Working in the Wind River Range, Blackwelder (1915) established the current regional stratigraphic nomenclature, including the name "Pinedale Glaciation" for the last Pleistocene glaciation. Evidence for multiple earlier Pleistocene glaciations has also been found throughout the Rockies. In northwestern Montana and northern Idaho ice of the Cordilleran Ice Sheet flowed south from British Columbia along major valleys. Elsewhere only local alpine ice was present in the U.S. Rockies – valley and cirque glaciers in many ranges as far south as New Mexico, and mountain icecap/outlet glacier complexes in several highlands areas, notably northwestern Montana, the Yellowstone Plateau, and the San Juan Mountains (Porter et al., 1983; Locke, 1995). Pinedale equilibrium-line altitudes ranged from about 1,800 m in northwestern Montana and northern Idaho (Pierce, 2004) to about 3,700 m in parts of the San Juan and Sangre de Cristo ranges in Colorado (Refsnider et al., 2009). Estimates of Pinedale temperature depression from the present based on glacial and periglacial evidence range from about 6°C to 15°C, but it is difficult to disentangle effects of temperature and precipitation changes (Pierce, 2004; Leonard, 2007). Timing of the Pinedale maximum ice stand varies somewhat range-to-range, even valley-to-valley (Licciardi and Pierce, 2008; Thackray, 2008). These differences may reflect (1) changing regional synoptic climatology, (2) changing local moisture sources, and/or (3) different dynamics of ice bodies of different size and morphology. Pinedale advances in the southern and central Rockies, as far north as the Wind River Range, generally correspond closely in time with the global Last Glacial Maximum (LGM), about 21 ± 2 ka. In the Yellowstone region further north, Pinedale advances culminated several 1,000 years later (Licciardi and Pierce, 2008). Climate models generally suggest that at the global LGM northwesterly flow into the northern U.S. Rockies was weakened as a result of southward migration of the jet stream and/or of the development of easterly anticyclonic circulation associated with the Laurentide Ice Sheet to the northeast (Bartlein et al., 1998), changes that could explain the relatively limited LGM extent of Yellowstone glaciers and their post-LGM advances. Glaciers in the Wasatch and Uinta Ranges of Utah also reached their Pinedale maxima after the global LGM, likely responding to post-LGM expansion of Lake Bonneville, a significant local moisture source for those ranges (Munroe et al., 2006; Laabs et al., 2009).

At several sites in the U.S. and Canadian Rockies, moraines far upvalley from the LGM moraines have been attributed to small glacier readvances during the Younger Dryas interval (ca 13–11.5 ka; reviewed in Pierce, 2004). Valleys in many ranges contain multiple Holocene moraines, commonly suggesting a three-fold sequence of advances during the Neoglacial interval of the last 5,000 years, with the final advance during the Little Ice Age interval of the last several centuries (Davis, 1988).

Permafrost and periglacial processes

Discontinuous permafrost is present at higher elevations throughout the U.S. Rockies. At the Canadian border the lower limit of permafrost is at about 2,000 m, in New Mexico at about 3,500 m (Péwé, 1983). Relict Pleistocene periglacial features occur in the mountains as much as 600–1,000 m lower than modern permafrost (Péwé, 1983; Janke, 2005). Modeling by Janke (2005) indicates that warming of 2°C would cause a 94% reduction in the area of permafrost in the Colorado Front Range.

Rock glaciers, perhaps the most conspicuous active periglacial features in the Rockies, are found in most ranges. Rock glacier dynamics have been studied in Wyoming (Konrad et al., 1999) and Colorado (Leonard et al., 2005). Throughout the region many cirques occupied by true (ice) glaciers in the late Pleistocene supported only rock glaciers during the Holocene, likely only during the last 3–5,000 years. Limited data from Colorado suggest that rock glacier flow has slowed in response to post-Little Ice Age warming.

Summary

The Rocky Mountains are a system of ranges in the interior of western North America that form the hydrologic divide for much of the continent. Snowfall in the Rockies is derived from several sources, but primarily from westerly cyclonic storms whose tracks reflect the position and intensity of the Pacific Jet Stream. Local snowpack is strongly influenced by altitude, aspect, and wind. Modern glaciation in the U.S. Rockies is very limited, but there is abundant evidence of more extensive Pleistocene glaciers. Range-to-range differences in Pleistocene glacial history appear to reflect a combination of changing position of the jet stream and changes in local moisture sources. Discontinuous permafrost and active periglacial features are present at higher elevations throughout the Rockies.

RÖTHLISBERGER (R)-CHANNELS

Renoj J. Thayyen
Western Himalayan Regional Centre, National Institute of Hydrology, Jammu (J&K), India

Definition

Semicircular subglacial tunnels incised upwards from the glacier bed into the overlying ice are called Röthlisberger or R-channels. These channels were named after H. Röthlisberger who proposed the numerical frame work for such subglacial channels (Röthlisberger, 1972).

Description

Röthlisberger or R-channels are one of the two fundamental types of subglacial channels which are incised up into the glacier ice (other is the N-channels, which are incised down to bedrock or sediment). R-channels in a glacier are similar to the englacial conduit with an exception that they are floored by rock rather than completely surrounded by ice. R-channels are kept open by melting of the tunnel wall by frictional heat. Contraction of R-channel occurs by ice creep due to pressure difference between glacier ice and tunnel. Therefore, the size of these channels and water pressure within them reflects a balance between channel enlargement and closure by ice creep (Röthlisberger, 1972; Shreve, 1972). The path taken by the R-channel is governed by the hydraulic gradient at the glacier bed. At equilibrium conditions, most of the hydraulic gradient is due to the surface slope of the ice and a small component is contributed by the gradient of the bed. It suggests that R-channels need not follow the slope of the bed, but can flow across the slope or even uphill. Eskers are formed by infilling of R-channels.

RUNOFF COEFFICIENT

Manmohan Kumar Goel
Water Resources System, National Institute of Hydrology, Roorkee, Uttarakhand, India

Definition

Runoff coefficient is a dimensionless factor that is used to convert the rainfall amounts to runoff. It represents the integrated effect of catchment losses and hence depends upon the nature of land surface, slope, degree of saturation, and rainfall intensity. It is also affected by the proximity to water table, degree of soil compaction, porosity of soil, vegetation, and depression storage. Some of its probable values for different land uses (Mutreja, 1990; Subramanya, 1991) are presented in Table 1. The joint committee of the American Society of Civil Engineers and Water Pollution Control Federation has recommended values of runoff coefficient for a variety of land uses, soil types, and surface slopes (ASCE and WFCP, 1969).

In addition to various catchment factors as mentioned above, runoff coefficient also varies for different storm

Runoff Coefficient, Table 1 Usual values of runoff coefficient for different types of areas

Type of area	Runoff coefficient
Urban	0.30–0.50
Forest	0.05–0.20
Commercial and industrial	0.70–0.90
Parks and pastures	0.05–0.30
Pavements and roads	0.70–0.95
Flat agriculture	0.10–0.50
Hilly agriculture	0.30–0.70

events (from nearly zero [for small storms] to a relatively high value [for a major storm]) depending upon the initial moisture content. Considerable judgment and experience are required in selecting satisfactory values of runoff coefficient for design. Field inspection and aerial photographs can prove useful in estimating the nature of surface in a basin. A reasonable coefficient must be chosen to represent the integrated effects of various factors.

Runoff coefficient is used in the *rational method* which is one of the widely used methods for peak flow predictions in small catchments, urban drainage design, and design of small culverts and bridges. The rational method (described by statement $Q_p = C.I.A$) states that if rainfall intensity "I" over a catchment area "A" continues beyond the time of concentration "t_c," then the peak runoff "Q_p" would occur at time t_c when all the catchment will contribute to the flow at the outlet. The ratio of inflow rate in the catchment ($I.A$) to the peak runoff Q_p is termed as runoff coefficient "C". Because of its popularity, the method is sometimes also known as *runoff coefficient method*. Normally, runoff coefficient is applied to storm events, but it can also be used for monthly and annual rainfall and runoff values.

Effective snowmelt generation; Excess precipitation generation; Glacial melt runoff generation; Infiltration excess generation; Overland flow generation; Saturation excess generation; Surface runoff generation

Definition

Runoff. It is a major component of the hydrologic cycle and is generated when water from precipitation or snow and glacial melt flows over the land. It is often referred to as the surface runoff. It is the water that is not absorbed by the soil.

Introduction

Runoff is the portion of precipitation or snow and glacial melt that flows across the landscape until it reaches streams, rivers, and, ultimately, oceans. Surface runoff generation depends on rainfall or snowmelt characteristics (amount, duration, intensity, and time distribution) and landscape characteristics (vegetation, land use, topography, soil texture and structure, and antecedent soil moisture conditions).

Conditions of runoff generation

Runoff during non- or partially frozen ground conditions occurs as *infiltration excess* or *saturation excess* when surface water inputs (rainfall or snowmelt) exceed the infiltration capacity of the soil (also referred to as *Hortonian overland flow*; Horton, 1933) and when liquid precipitation falls on an already saturated soil (Hewlett and Hibbert, 1967; Dunne and Black, 1970). The critical controls for runoff generation are precipitation intensity, duration of precipitation, and infiltration/storage capacity (related to the permeability of the soil and the antecedent soil moisture pressure gradient) of the soil (e.g., Tindall and Kunkel, 1999). On an impermeable surface or completely frozen soil, runoff starts almost immediately and is equivalent to precipitation less abstractions due to vegetative interception and surface depressional storage. Additionally, return flow is subsurface water that returns to the surface and contributes to overland flow.

Runoff generation from direct precipitation

Runoff generation within a watershed is a dynamic process that varies in both space and time. According to Beven (2001), in many areas, particularly on vegetated surfaces, infiltration excess rarely occurs unless the soil becomes saturated, thereby decreasing the infiltration capacity. Infiltration capacities will first be exceeded in areas of low permeability soils and high initial water contents. Only a small portion of a watershed may contribute to infiltration excess, a concept known as the *partial-area* concept of infiltration excess overland flow (Betson, 1964). Areas of saturated soil tend to occur first where antecedent soil moisture is high (e.g., valley bottoms) or on areas where storage capacity is limited or in low permeability and low slope areas that tend to stay wet during recession periods (Beven, 2001). Areas of saturated soil tend to expand and contract during a precipitation event, leading to the concept known as *variable source area* runoff (Hewlett and Hibbert, 1967; Dunne and Black, 1970).

Runoff generated from snowmelt

Runoff generated as a result of snowmelt varies with landscape position since elevation and aspect affect air temperature and radiation inputs to the snow. According to Singh and Singh (2001), rainfall or snowmelt at the surface of

a snowpack will pass through the snowpack and flow as interflow after reaching the ground. When meltwater reaches the base of the snowpack, a thin saturated layer is formed over the ground surface due to the accumulation of percolating water. It is possible that water generated at the snow surface may not contribute to runoff. For example, at the beginning of the melt season, if there is a deficiency in the cold content or liquid water of the snowpack, water generated at the surface may be used in the ripening (the process by which a snowpack reaches a state where it can yield meltwater) of the snowpack (Singh and Singh, 2001). As the snowmelt season progresses and air temperatures increase, the depth and extent of snow-covered area decreases and melting rates increase. The main factors that influence snowmelt runoff generation are surface melt, stratigraphic features of the snowpack, movement of water through the snowpack, interaction of meltwater with underlying soil, and lateral flow at the base of the snowpack (Singh and Singh, 2001).

Runoff generated from glacial melt

Runoff from glaciers may occur as flow of ice sheets or as meltwater. Glaciers receive precipitation both in liquid and solid form, store water as ice, and release it when melted, depending upon the climatological factors (Jansson et al., 2003). These glaciers are often referred to as the temperate glaciers. In late spring, such glaciers are covered by a thick snowpack subjected to a melting temperature. The liquid precipitation and the melt water move through the snowpack, percolating at a slow rate, until they reach well-defined meltwater channels in the solid ice downstream. During the summer, the snowpack is thinner. Hence, there are well-defined drainage paths that migrate the liquid precipitation and the snowmelt rapidly through the glacier. During the winter, the snow accumulates rendering a frozen surface layer. Thus, migration of meltwater and precipitation is reduced or subsides at the surface. The ice reservoir, however, continues to drain.

Runoff generated in permafrost regions

Regions underlain by permafrost cover approximately a quarter of the land surface of the earth. These regions also suffer from sparse and extremely uneven distribution of hydrometeorological data network. However, recent increase in attention to studies associated with the global processes and the protection of the northern environment have diverted attention toward investigation of permafrost hydrological processes and especially the runoff generation from these areas (Kuchment et al., 2000). According to Kuchment et al. (2000), "the hydrology of the permafrost regions has several common well-expressed peculiarities which make it clearly distinguishable from the hydrology of other geographical zones." According to Woo (1990), these peculiarities are: (1) the frozen ground has limited permeability, (2) most hydrological activities are confined to the seasonally frozen and thawed zone above the permafrost table (the active layer), (3) energy and water fluxes are closely linked as water storage and redistribution are modified by freeze-thaw events, and (4) snow and ice storage on a seasonal or multi-annual basis affects the temporal distribution of water. Due to small permeability of the frozen ground, runoff generation is governed by evaporation, water storage in depressions, peat mats, and soils with high porosity. During snowmelt, overland flow is the major mechanism of runoff generation in these regions. According to Sokolov (1975) as cited in Kuchment et al. (2000), "a part of the melt water can refreeze in the snow, in the peat mats or in the ground during the nightly lowering of air temperature and because of the low ground temperatures. The water frozen in the surface basin storage and in the active layer of the ground can generate a significant portion of river runoff during the entire warm period. There are the river basins where floods occur as a result of *ice melting* after cessation of snowmelt. Subsurface flow starts after the beginning of the ice melt in the ground and can become the main mechanism of rainfall runoff generation on the mountainous slopes." Most of the annual runoff in permafrost regions is of ice and snowmelt origin but in the southern regions rainfall runoff can dominate (Kuchment et al., 2000).

Summary

Runoff generation occurs due to excess liquid precipitation, snowmelt, or glacial ice melt. The major difference between catchments fed by glaciers and those by precipitation is that the runoff from glacierized catchments is dominated by energy, while the other catchments are dominated by quantity of precipitation, soil moisture capacity, antecedent soil moisture, and other physical factors. Catchments that receive snow as precipitation are partially dominated by energy and partially by other physical conditions. Runoff generation in permafrost areas are governed by evaporation, water storage in depressions, peat mats, and soils with high porosity. Melting of ice in the permafrost regions can cause major floods in the streams of the region. Most of the annual runoff in permafrost regions is of ice and snowmelt origin but in the southern regions rainfall runoff can dominate.

Definition

Runoff. The component of precipitation that moves across the land surface or through surface channels.
Observation. An act of recognizing and noting a fact or occurrence often involving measurement with instruments (weather observations); a record or description so obtained (source: Merriam-Webster's Online Dictionary).

Introduction

Runoff observations from precipitation events, snowmelt, or glacier-melt are critical in the planning of various hydrological projects in the basins. For example, Linacre (1992) has provided maximum daily snowmelt rates in various locations of the globe. Such data are useful in engineering planning and flood forecasting exercises. Melting of glaciers provides significant amounts of source water for many rivers and lakes around the globe. With the current discussion on climate warming resulting in increased glacial melting, runoff from those could result in global sea-level rise and spell disaster for coastal areas. Thus, observation of glacier-melt runoff needs significant attention and has been the focus of recent studies. The runoff observations from any source are usually recorded by a runoff hydrograph.

The runoff hydrograph

Runoff observations are represented graphically by a runoff hydrograph or plot of the time distribution of water discharge at a particular point of interest. A streamflow, or total, hydrograph represents the combined effects of direct runoff (surface runoff and short-term interflow) and baseflow (long-term interflow and groundwater discharge). The total runoff hydrograph represents the combined influence of physical characteristics of the drainage basin and rainfall, snowmelt, or ice melt characteristics. The depth and extent of snow cover in a basin affects the shape of the streamflow hydrograph. According to Singh and Singh (2001), "The availability of snow causes a much delayed response to rainfall or snowmelt because water available at the surface takes time to pass through the snowpack and flow as interflow after reaching the ground. In case rainfall occurs over snow, it is soaked in the snowpack like a sponge and the rain water behaves as snowmelt thereafter. Depending on the cold content and liquid water deficiency of the snowpack, as in the beginning of the melt season, it is also possible that water generated at the surface does not contribute to runoff at all. Under such conditions, the water generated either from rainfall or melting of surface is used up in the ripening of the snowpack. When cold content and liquid water deficiency are satisfied, rainfall or snowmelt moves through the snowpack and appear as delayed runoff . . .. As the snowmelt season progresses, both the depth and extent of snow-covered area of the basin decrease and melting occurs at a higher rate because of the increase in temperature. Therefore, a relatively faster response of the basin is obtained in the summer time." In shallow snowcovers (e.g., those encountered in Prairies), nighttime radiation losses can result in negative heat storage which must be satisfied before snowcover runoff occurs the following day, resulting in a diurnal cycle in the runoff hydrograph mainly during the early part of the melt season (Male and Gray, 1981). Measured meltwater from a snowpack follows a diurnal wave with maximum discharge decreasing with depth from the surface (Colbeck and Davidson, 1973). Delay and attenuation of runoff can occur as a result of storage in the snowpack. Drainage way obstructions from snow accumulation can impede runoff water and store snowcover runoff, delaying the time of peak streamflow occurrence.

In mountain regions, the precipitation temporarily stored within the snowpack is released during warm months. Over a large portion of the northern hemisphere, runoff from snowmelt contributes significantly to the annual water yield and spring flooding (Male and Gray, 1981). In the western United States, spring/early summer snowmelt runoff accounts for 50–80% of the total annual

runoff from snowmelt-dominated basins (Stewart et al., 2004). Rango (1995) reports that the snowmelt season in the mountainous areas is occurring progressively earlier. Slope aspect can have a large impact on snowmelt rates (e.g., Murray and Buttle, 2003). Snow on a south facing slope melts faster than snow on a north facing slope due to differences in the amount of solar radiation received. Snowmelt rates are generally enhanced under shrub canopies compared to open snowfields (Carey and Pomeroy, 2009). Snowmelt runoff rates vary depending on climate and vegetation; for example, Male and Gray (1981) summarize runoff rates ranging from 1.7 to 4.57 mm/(°C·d) for forested basins with deep snowpacks and average runoff rates of 3.9, 4.78, and 10.96 mm/(°C·d) for stubble, pasture, and fallow conditions, respectively.

In addition to meteorologic factors, snowmelt runoff depends on the depth, aerial extent, and snow water equivalent of the snowpack. Snow depth can be measured using snow stakes or optical snow depth meters. Snow water equivalent (SWE) is the vertical depth of water that is produced upon melting the snow cover. Instrumentation for measuring SWE includes snow pillows, snow surveys, and gamma-ray snow-gauges. Snow pillows typically have a flat stainless steel surface area. The pillow below the flat surface is filled with antifreeze solution and the pressure in the pillow is related to the water-equivalent depth of the snow on the platform (source: Webster's Online Dictionary). A gamma-ray snow-gauge determines snow water content by measuring the amount of gamma radiation absorbed by the snow overlying the transmitter that is placed at the surface (source: American Meteorologic Society Glossary of Meteorology). The aerial extent of snow can be measured using ground observations; however, visual and physical obstructions combined with travel to observation points render this method difficult. Methods with greater potential for studying runoff from large or remote areas include the use of aerial photography and satellite imagery.

Stewart (2009) discusses the intrinsic link between the timing, volume, and extent of mountain snowpack, and the associated snowmelt runoff, and seasonal climate variability and change. For example, warmer cold season temperatures reduce snow accumulation, while warmer spring temperatures hasten snowmelt. Therefore, runoff occurs earlier and later season flows are reduced. Also noted by Stewart (2009) is that the season in which precipitation occurs affects the amount stored as snow and consequently the volume of spring snowmelt.

"The changes in the extent and timing of the annual snowpack and melt have impacted the volume and timing of snowmelt-dominated streamflow on the continental to global scale," Stewart (2009).

Runoff measurement methods

Runoff can be measured using a variety of methods and instrumentation depending on the landscape position and the level of runoff information desired. Runoff can be measured or observed at the edge of a small plot or field or in a stream channel. Runoff measurement from a plot or field typically requires physical bounding of a contributing drainage area (i.e., runoff plot). Runoff generated from within the border is collected at the downslope edge and focused into a collection and flow measurement device. Flow measurement devices can be grouped into those that measure the total volume of runoff (e.g., a simple collection bucket) and those that measure the time varying rate of runoff (e.g., tipping bucket or hydraulic flume). Streamflow measurement or streamgaging requires continuous measurement of stream stage (or depth) combined with periodic measure of discharge to establish a relationship between stage and discharge. This relationship between stage and discharge is used to determine a continuous record of streamflow from the continuous measure of stage. Methods for measuring discharge in an open channel include dilution (flow is measured by how much of a known mass of tracer is diluted), area-velocity (cross-sectional area and velocity are measured and multiplied to determine discharge), and use of hydraulic controls (e.g., weirs, flumes). Streamflow monitoring sites are generally sparse at higher elevations and daily streamflow records (many of which are discontinuous) seldom exist for more than a few decades (Stewart, 2009).

Summary

With the global climate change in effect, runoff observations have become critical as increased runoff due to increased precipitation, snowmelt, and glacier-melt rates have impact on flooding, sea-level rise, and lake water volumes. As such, the observations of runoff from basins have been accomplished by recording streamflow stage-discharge changes along with other hydrological parameters that affect generation of surface runoff. Additional sites have been instrumented and remote sensing imagery tools are being deployed and used to provide continuous observation of runoff on a temporal scale. Glaciers have gained more focus due to their increased rate of receding in the recent years thus resulting in production of substantial quantity of runoff that has resulted in rise in the level of the sea in the world.

RUNOUT DISTANCE

A. K. Singh
DIAT (Deemed University), Pune, Maharashtra, India

Landslides and avalanches occur on hilly slopes. A landslide takes place primarily during the wet season and occurs due to intensive rainfall. They may also occur during the dry season by earthquakes and volcanic eruptions. Essential elements for avalanche are deep snow and steep slopes. Due to variation in snow and terrain conditions, avalanche appears in various forms and sizes with 30–45° slopes experiencing maximum avalanche activity.

In the runoff zone, avalanches decelerate and stop on terrain with a low inclination. Topographic parameters that describe and predict avalanche runout are mean path, slope angle (which is a dependent variable that defines the runout distance), and slope of the path above the 10° profile point.

One of the main problems affecting the estimates of runout distance is the lack of information and uncertainties about the values of the friction coefficients, that is, friction coefficient (μ) which depends on snow properties and magnitude of flow depth (decreases considerably with flow depth) and a resistance due to ground roughness, (coefficient ξ) which is proportional to the square of the speed. Significant experience is needed to make realistic estimate of runout distance because selection of the beginning of the runout zone and the point from which runout distance should be measured is critical and difficult in terrain having a gentle change of slope.

Runout distance information is used in landslide and avalanche of debris movement as assessment of debris flow is essential for hazard/risk management.

S

SALINITY

C. K. Jain
National Institute of Hydrology, Centre for Flood Management Studies, Dispur, Guwahati, Assam, India

Synonyms

Brininess; Salinity; Salt; Saltiness

Definition

Concentration of dissolved salts found in a sample of water. It is measured as the total amount of dissolved salts in parts per 1,000. Seawater has an average salinity of about 35 parts/1,000.

Nearly all water contains dissolved chemicals, even rainwater. These dissolved chemicals are called salts. The salinity of normal ocean water is about 35 parts per 1,000, total dissolved solids. This is written as 35‰ or 35 ppth. A salinity of 35‰ is the same as 3.5%. The symbol resembles a percentage sign (%), but percent means per 100. But the symbol with two zeros on the bottom of the fraction (‰) means per 1,000.

Salinity varies slightly from place to place around the world, and also varies somewhat with the seasons (affected by temperature and precipitation). The salinity of seawater ranges from about 30‰ to 40‰. Warm temperatures and high evaporation rates (particularly in shallow seas) raise the salinity. Warmer waters will tend to have higher salinity than cooler waters.

Water of salinity between freshwater and seawater is called brackish. Brackish water can be found in estuaries. Water with salinity greater than normal seawater is called hypersaline. For example, the Great Salt Lake, Utah, and the Dead Sea are hypersaline. Hypersaline lakes tend to occur in arid areas. They are land-locked basins with no outlet for the waters to flow from the lake. The salts are concentrated as a result of evaporation. Evaporation is so extreme in some lakes (ephemeral lakes or playa lakes) that they dry up completely every few years, leaving a saltpan.

Freshwater input (rivers, precipitation, or melting ice) lowers the salinity. In polar areas where glaciers and ice caps are melting, the seawater has lower salinity.

SALTATION

C. K. Jain
National Institute of Hydrology, Centre for Flood Management Studies, Dispur, Guwahati, Assam, India

Saltation is a specific type of particle transport by fluids such as wind, or the denser fluid water. It occurs when loose material is removed from a bed and carried by the fluid, before being transported back to the surface. Examples include pebble transport by rivers, sand drift over desert surfaces, soil blowing over fields, or even now drift over smooth surfaces such as those in the Arctic or Canadian Prairies.

At low-fluid velocities, loose material rolls downstream, staying in contact with the surface. This is called *creep*. Here the forces exerted by the fluid on the particle are only enough to roll the particle around the point of contact with the surface. At higher speeds, the lift and moment exerted by the fluid on the particle is enough to pull it away from the surface and into the flow. Initially the particle moves quite rapidly compared to the flow and so has high lift, moving it away from the surface. As the particle moves into the faster flow away from the bed, the velocity difference between particle and flow decreases and so lift decreases. When the particle weight is greater than the lift force, the particle sinks back toward the

Vijay P. Singh, Pratap Singh & Umesh K. Haritashya (eds.), *Encyclopedia of Snow, Ice and Glaciers*, DOI 10.1007/978-90-481-2642-2,

surface. During its descent, the particle keeps some of the speed it picked up in the faster moving flow, and so returns to the surface at higher speed than the fluid near the surface. This gives the particle a parabolic trajectory through the fluid, which is the defining characteristic of saltation. Depending on the surface, more loose material could be dislodged by the impacting particle, the particle might disintegrate on impact, or the particle could continue bouncing downstream. In rivers, this process repeats continually, gradually eroding away the riverbed, but also transporting in fresh material from upstream.

Scandinavia: Geographical area in northern Europe consisting Norway, Sweden, and northwestern part of Finnish Lapland.

Introduction

Scandinavia is located in northern Europe between latitudes 55–71° North (Figure 1). The mountains that run through mainland Scandinavia from south to north are not very high but in many places they are very steep. The highest peaks reach well over 2,000 m above the present sea level. Their northern location and moisture from the North Atlantic Ocean to the west of Scandinavia has caused the formation of many glaciers in the coastal areas as well as further inland several times, particularly during the past 2.6 million years. At present, the glaciers in Scandinavia are relatively small and cover mostly mountainous areas, occurring in a wide latitudinal range from ca. 60° N to 70°N. Although glaciated areas in Scandinavia consist of only 0.2% of the ice coverage in Arctic regions (Dowdeswell and Hagen, 2004), they have provided valuable records on the behavior of glaciers and proxy data for recent climate events in northwestern Europe.

History of the Scandinavian glaciers

The Fennoscandian Shield, including Scandinavia, has hosted glaciers many times throughout Earth's history, although its latitudinal position and topography has changed constantly in time as a result of plate tectonism. The geological record from Scandinavia, extending back to the Precambrian, includes metasedimentary rocks of glacial origin, for example, in Finnish North Karelia, on the Kola Peninsula, and on the Varanger Peninsula, Norway. This evidence indicates that glaciers covered Fennoscandia several times during the Early Proterozoic around 2.4–2.2 billion years ago and in the Neoproterozoic Era ca. 700–600 million years ago (cf. Siedlecka and Roberts, 1992; Melezhik, 2006). However, there is no geological evidence to indicate that any major glaciers existed in the Fennoscandian shield between the Palaeozoic and Mesozoic Era (540–65 million years ago).

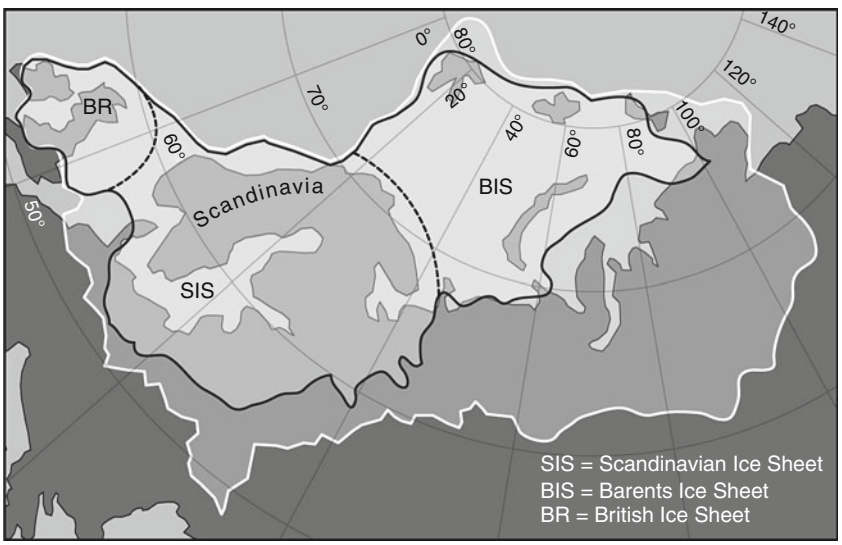
Results from the central Arctic Ocean and Norwegian-Greenland Sea suggest that continental glaciers were present around the Arctic Basin during the Late Eocene as early as 35 million years ago (Moran and ACEX Members, 2006; Eldrett et al., 2007), but the distribution and extent of these ice masses are not known in detail. Ice-Rafted Detritus (IRD) in the deep-sea sediments west of Norway indicate that glaciers must have existed in Scandinavia already about 11 million years ago (Mangerud et al., 1996).

Glaciers in the Scandinavian mountains are thought to have been the nucleus of the Scandinavian Ice Sheet (SIS) that spread over the southern and eastern continental areas adjacent to Scandinavian mountains and was confluent with the Barents and British Ice Sheets several times during the Quaternary period (cf. Mangerud, 2004) (Figure 2). It has been estimated that during the past 2.6 million years, the Scandinavian mountains were covered by glacial ice ca. 90% of the time (cf. Holmlund, 2005). Geological evidence indicates the presence of an ice sheet over Scandinavia for most part of the Elsterian (ca. 500,000–450,000 years ago), Saalian (ca. 390,000–130,000 years ago), and Weichselian (115,000–11,500 years ago) glaciations (cf. Donner, 1995; Mangerud, 2004; Svendsen et al., 2004). During the last glacial maximum (LGM) ca. 20,000–18,000 years ago the Scandinavian Ice Sheet was at its largest for at least the past 130,000 years extending from the North Sea and the Norwegian shelf areas to the Russian Plain (Figure 2). At the LGM, the modelled thickness of the ice sheet over Scandinavia was ca. 2.5 km (Siegert and Dowdeswell, 2004) and during the Younger Dryas cold climate event (ca. 12,500–11,500 years ago) SIS still covered most of Fennoscandia (Figure 1). It is thought that glaciers started to melt relatively fast at the beginning of the Holocene and may have disappeared completely at least once during the period from 8,000–4,000 years ago (Nesje et al., 2008). After their disappearance most of the Scandinavian glaciers attained their largest extent during the Little Ace Age most likely about 1,750 A.D. (cf. Whalley, 2004).

Present glaciers in Scandinavia

At present the total number of glaciers in Scandinavia is ca. 1,900, of which slightly over 1,600 in Norway and ca. 300 in Sweden (Østrem and Haakensen, 1993; Schytt, 1993). The average sizes of the glaciers in Norway and Sweden are 2.6 km^2 and 1 km^2, respectively (cf. Holmlund, 2005). Morphologically the largest glaciers are categorized as ice caps and ice fields or plateau glaciers while the medium-size glaciers are valley glaciers and cirque glaciers. The largest glacier in Scandinavia, and also in mainland Europe, is Jostedalsbreen (487 km^2), which is located in Norway. Other sizeable

Scandinavian Glaciers, Figure 1 Location map of the glaciers in Scandinavia (*squares*) with names of the glaciers mentioned in text. The Younger Dryas ice limit (ca. 12,500–11,500 years ago) is also indicated.

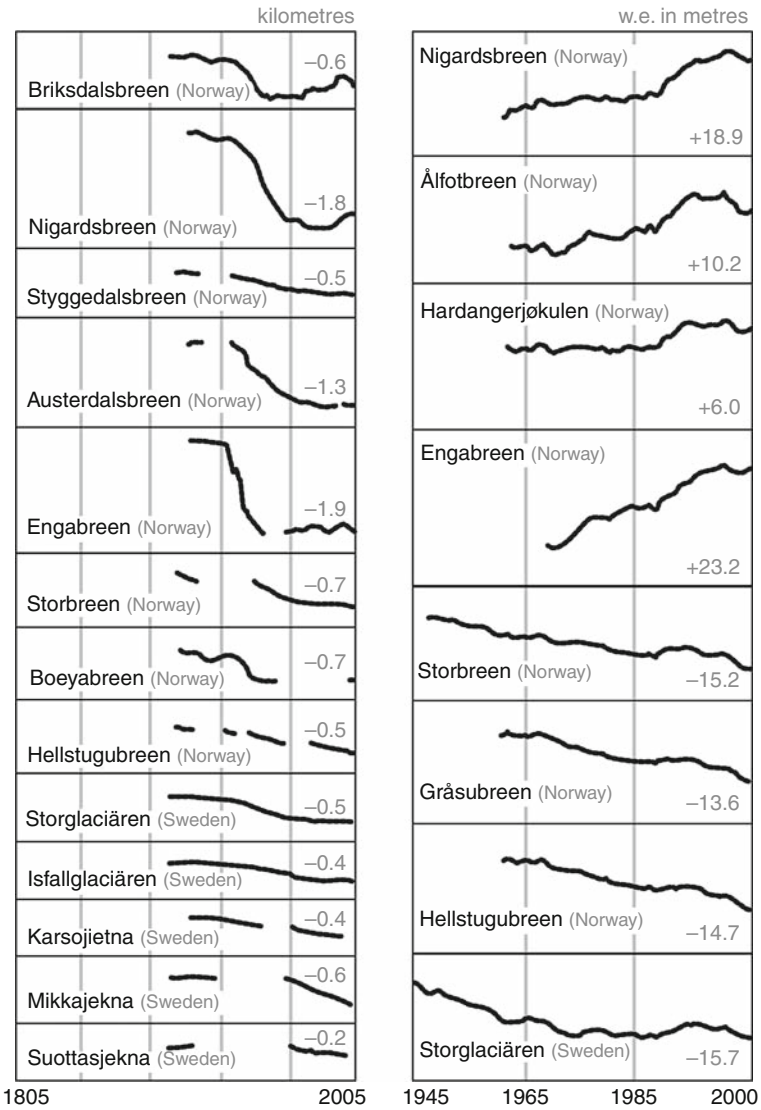


Scandinavian Glaciers, Figure 2 The reconstruction of the Eurasian ice sheet at the Saalian glaciation ca. 160,000–140,000 years ago (*white line*) and at the last glacial maximum ca. 20,000–18,000 years ago (*black line*).

glaciers in Norway are Svartisen West (221 km^2), Folgefonna South (168 km^2), and Svartisen East (148 km^2) (Figure 2). The total glacier volume of Norway is estimated to be 164 km^3 (Nesje et al., 2008). Glaciers in Sweden are relatively small compared to those in Norway. The largest glaciers in Sweden are Stourrajekna and Ålmaijekna both less than 12 km^2 (Schytt, 1993).

Glaciers in mainland Scandinavia cover an area of approximately 2,900 km^2 (cf. Whalley, 2004). In this area, glaciers occur mainly in mountainous areas, that is, in the Scandinavian Mountain range (Figure 2). Climate in the western part of the mountain range is locally maritime, becoming more continental on the eastern side of the mountains. In the maritime climatic areas, the glaciers on the mountains are normally fed by orographic precipitation while in the climatically more continental eastern part of the mountain range precipitation is lower and the glaciers here are fed by wind-driven snow accumulation (cf. Holmlund, 2005).

The largest glaciers are built up in the maritime climate of the Norwegian west coast between 60–62° N and 66–70° N latitudes within 180 km of the coast (Østrem and Haakensen, 1993; Grove, 2004). Annual accumulation in the glaciated areas close to the western coast of Norway is ca. 3–4 m (snow water equivalent), while the annual accumulation in the more easterly located glaciers in Sweden and Norway is less than 1 m (snow water equivalent) (cf. Holmlund, 2005). The glaciers in



Scandinavian Glaciers, Figure 3 The diagram on the *left* shows glacier frontal changes and the total frontal change in kilometers of different Scandinavian glaciers (*left* panel) up to the year 2005. The diagram on the *right* panel shows the mass balance variations and the total mass balance change in water equivalent of different glaciers up to the year 2005 in Scandinavia.

Scandinavia are mainly warm-based but a few glaciers are polythermal and some glaciers on high mountain plateaux are cold-based (cf. Whalley, 2004 and references therein).

Glacier frontal position and mass balance

Systematic monitoring of the Scandinavian glaciers already began at the turn of the twentieth century with observations on the ice-marginal positions (the glacier change in length) in many glaciated areas. At present data on changes of ice-marginal position from around the world are reported in every fifth year by the World Glacier Monitoring Service (http://www.geo.uzh.ch/wgms/) in their report entitled *Fluctuations of Glaciers*. The ice-frontal position record of most outlet glaciers in Scandinavia indicates a clear overall receding trend of the glacial margins from the mid-1930s to the present (Figure 3). The ice-frontal position for the past ca. 70 years generally indicates a total retreat between 0.3 km and 2.4 km in most of the glaciers observed (Zemp and van Woerden, 2008). During the twentieth century the retreat of the ice margins has not been continuous. While most of the inland glaciers have retreated during the whole observation period starting at the turn of twentieth century, many maritime glacier margins have experienced several advance periods. Maritime glaciers have advanced particularly around 1910 and 1930, late 1970s and 1990s (cf. Andersen et al., 2005; Zemp and van Woerden, 2008). A relatively fast retreating trend has been observed in most glaciers in Scandinavia since 2001 (Andersen et al., 2005).

Mass balance measurements are highly important when studying and describing glacier behavior and their response to variations in climate. The first mass balance measurements of the Scandinavian glaciers were begun late in the 1940s (Schytt, 1959; Liestøl, 1967). The summer, winter, and net-mass balance record of Storglaciären in the Kebnekaise area, Sweden extends back to 1945 and that of Storbreen in Jotunheimen, Norway back to 1949. These two mass balance records are the longest records in the world. Nowadays mass balance data from a number of glaciers from around the world are reported every second year by World Glacier Monitoring Service (http://www.geo.uzh.ch/wgms/) in their *Glaciers Mass Balance Bulletin*.

The mass balance record from the Scandinavian glaciers indicates slight variation over time within individual glaciers depending on local climate conditions, such as the amount of precipitation, but the general trend over the past decades is relatively clear (Figure 3). In general, the maritime glaciers have had a positive mass balance trend from the beginning of the early 1960s. Mass balance became even more positive between the late 1980s and 2000. It has also been shown that there is a clear correlation between the North Atlantic Oscillation (NAO) index and the mass balance records of the maritime glaciers in southern Norway (Nesje et al., 2000; Reichert et al., 2001). In contrast, the mass balances of the more continental glaciers, such as Storglaciären and Storbreen, have had a negative trend over decades. However, all glaciers in Scandinavia have lost mass since 2001 (Anderssen et al., 2005).

Conclusion

Research on past and present Scandinavian glaciers has a long history. Datasets on past and present glaciers, compiled over a century, are one of the most extensive in the world. Despite this fact, the behavior of the past glaciers and ice sheets, their environmental impact, and the relationship between climate and glaciers are still not fully understood. It seems to be vital to seek more high resolution proxy data from terrestrial and marine archives and integrate that with ice sheet modelling in order to understand the causes and mechanisms of the past environmental and climate changes.

Extensive mass balance and other glaciological data on Scandinavian glaciers, together with climatic records, have formed a firm foundation for a detailed study of diverse range of glaciers throughout the region. In addition, reliable field data is essential to test models of glacier behavior. Research on mass balance variations of the Scandinavian glaciers and climate has already shown important results on glaciers' behavior under different climate conditions. Mass balance changes are strongly dependent on climate and therefore it is highly important to understand the mechanisms and response times behind glaciers' mass balance variations in different climate and glacial settings in order to predict glacial behavior in the future climate change.

SEA ICE

Matti Leppäranta
Department of Physics, University of Helsinki, Helsinki, Finland

Definition

Any form of ice found at sea that has originated from the freezing of seawater (WMO, 1970). Icebergs and ice islands, also found in the polar oceans, are *ice of land origin*.

Introduction

Sea ice occurs in about 10% of the surface of the world ocean. Perennial ice is found in high polar latitudes in the Central Arctic Ocean, in the East Greenland Current, and in the western Weddell Sea. The seasonal sea ice zone extends on average to 60° latitudes, not so low in the Northeast Atlantic Ocean but more south in subarctic shallow semi-enclosed seas. Sea ice renewal time is short due to ice melting and advection; perennial ice is mostly less than 10 years old. Solid sea ice lids are statically unstable and break into fields of ice floes, undergoing transport, as well as opening and ridging that altogether create the exciting sea ice landscape as it appears to a human eye (Figure 1).

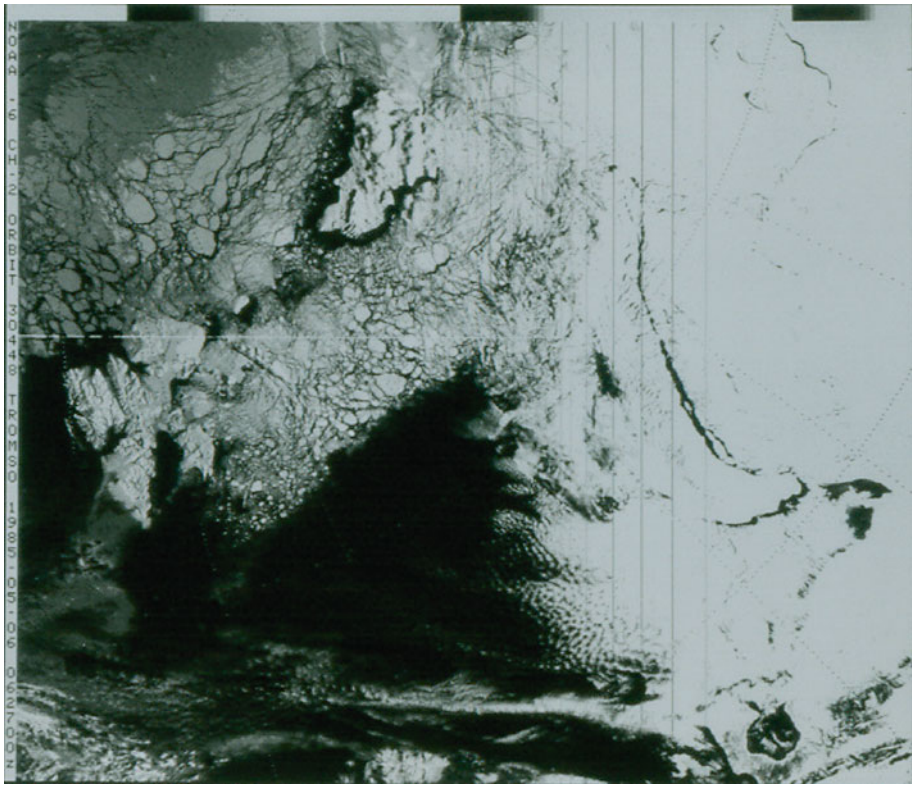
The history of sea ice science initiated in the l800s with the polar expeditions constructing the geographical picture of the sea ice world (Weeks, 1998b). Microscale structural sea ice models were prepared in the 1950s, and sea ice thermodynamics problem and the closure of sea ice dynamics problem were completed. The modern era commenced in the 1970s based on new technological innovations. Satellite remote sensing revealed the character of time-space variations of sea ice conditions, computing technology made realistic sea ice models possible, and automatic monitoring systems were introduced. The present research focuses on scaling issues, ice thickness observation methods, and the climate problem, with applications to shipping, oil, and gas exploration and ecology of freezing seas.

Sea ice structure and properties

Sea ice physics covers a wide range of scales. *Microscale* includes individual grains and impurities extending from sub-millimeter size to 0.1 m. *Local scale*, 0.1–10 m, considers sea ice as a polycrystalline continuum, and *ice floe scale* extends from 10 m to 10 km, including ice floes and types such as pressure ridges. When the scale exceeds the floe size, the sea ice medium is called *drift ice*.

Microscale – crystal structure and impurities. The freezing point of seawater is $T_f = -1.8°C$. In calm weather, a thin primary ice layer forms first but in windy conditions frazil crystals are generated forming a solid sheet when their buoyancy overcomes the turbulence. Ice crystal platelets overlain together form macrocrystals. Due to constitutional supercooling in the molecular diffusion of salt and heat, cellular ice–water interface forms and encloses liquid brine pockets between the crystal platelets and the crystal boundaries become jagged (Weeks, 1998a). The salinity of new ice is 25–50% of the water salinity. The brine salinity always corresponds to the freezing point of the ambient temperature, that is, brine volume changes with temperature, and salts crystallize in their eutectic temperatures (Figure 2). In summer, the brine pockets expand into drainage network and much brine flows out. Brine pockets serve as biological habitats, for algae with primarily light-limited growth. The most active layer is the bottom layer or so-called skeleton layer.

Local scale – forms of sea ice. Sea ice formation is based on three main mechanisms resulting in *congelation ice*, *frazil ice*, and *superimposed ice* (Weeks, 1998a). Congelation ice crystals are columnar and grow down from the

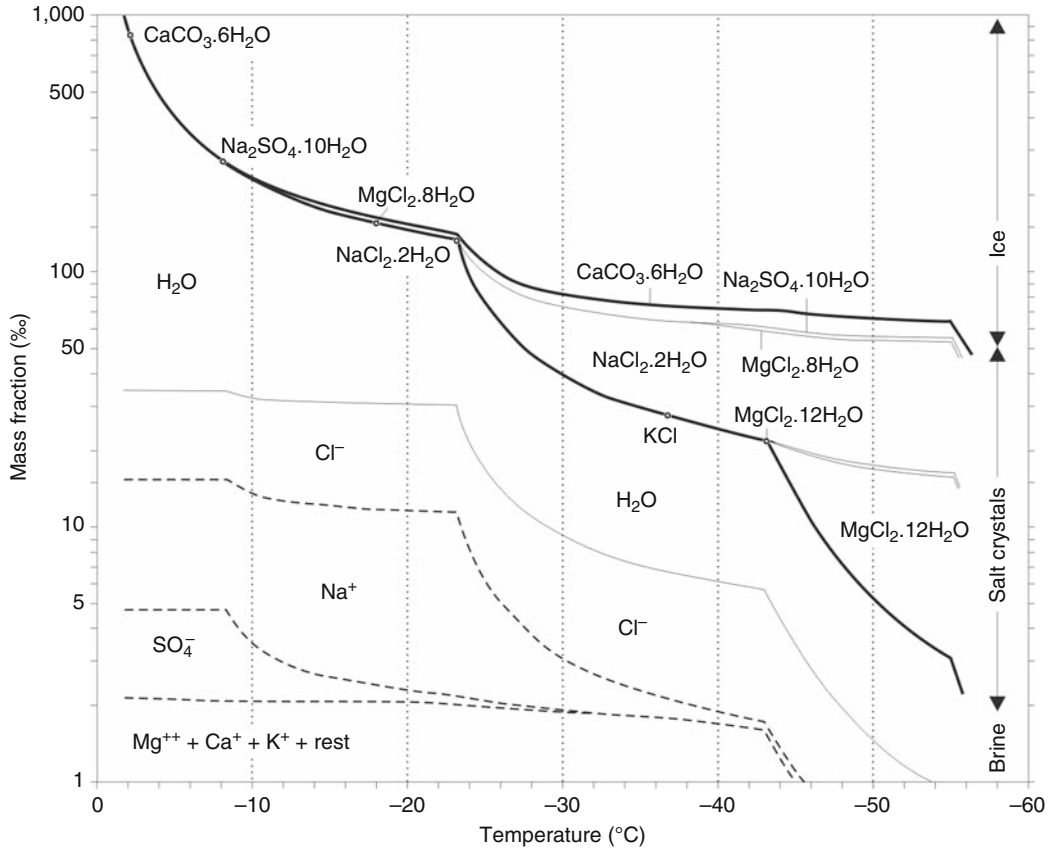


a

b

Sea Ice, Figure 1 Sea ice cover over the Barents Sea and part of the Central Arctic Ocean shown in a NOAA image and a field photograph.

ice–water interface; it is dominant type in the Arctic Ocean. Frazil ice forms in open water areas, with small crystal size; in Antarctica, this is the dominant type. In shallow waters, frazil may attach into the sea bottom to form anchor ice, which may rise up with bottom material. In superimposed ice formed of slush, the crystals are small. Sea ice contains gas bubbles, which have a major influence on scattering of electromagnetic waves, and sediment particles originating from the water body, sea bottom, or atmospheric fallout. Optical properties of sea ice



Sea Ice, Figure 2 Sea ice phase diagram with the proportions of ice, brine, and solid salts as a function of temperature. The chemical symbols show the eutectic points of the main salts. Redrawn from Assur (1958).

are influenced by the salt and gas content. Sea ice is less transparent than seawater, the attenuation coefficient being around 1 m^{-1} for normal sea ice.

Drift ice – fields of ice floes. A sea ice landscape consists of ice floes with ridges and other morphological features, as well as *leads* and *polynyas*. The central drift ice pack is free of influence from the boundaries, and the length scale is the size of the basin. (Land) fast ice extends from the shore to about 10–20 m depths. Further out is the shear zone (width 10–200 km), where the mobility of the ice is restricted by the boundary and strong deformation takes place. Marginal ice zone (100 km) lies along the boundary to open sea, characterized as the zone, which "feels the presence of the open ocean." Drift ice is a peculiar geophysical medium (Leppäranta, 2005). It is granular – ice floes are the basic elements – compressible, and highly nonlinear. For continuum models, the size of material particles D must be satisfied, $d << D << \Lambda$, where d is the floe size and Λ is the gradient length scale. The ranges are in nature $d \sim 10^1$–10^4 m, $D \sim 10^3$–10^5 m, and $\Lambda \sim 10^4$–10^6 m. An ice state is defined for the material description, usually taken as the ice thickness distribution (Thorndike et al., 1975), defined by the spatial density function $\pi = \pi(h)$ in a grid cell.

Sea ice growth and decay

In ice growth, latent heat is released and conducted through the ice to the atmosphere. The thicker the ice, the slower is the conduction and growth – mostly less than 5 cm/day for very thin ice and less than 1 cm/day for ice thicker than 1 m. Sea ice has no definite melting point, but always there is melting involved when sea ice warms to dilute the brine and vice versa. The melt rate is of the order of 1 cm/day, mainly due to the net radiation and oceanic heat flux. Where the summer melt is less than the winter growth, multi-year ice develops. First-year ice grows up to 2 m and multi-year ice to 3–4 m.

A simple, analytic approach for the ice growth problem is Zubov's model. The basic assumptions are to ignore solar radiation, oceanic heat flux, and snow. The thickness of ice is

$$h = \sqrt{aS + d^2} - d \tag{1}$$

where $a = 2\kappa/\rho L \approx 11$ cm $(°C \cdot day)^{-1}$, κ is thermal conductivity of ice, ρ is ice density, L is latent heat of freezing, $S = \int_o^t (T_f - T_a)dt'$, usually referred as the "sum of freezing-degree-days," T_a is air temperature ($T_a \leq T_f$), and $d \approx 10$ cm is the insulation efficiency of the atmospheric

surface layer. In the melting season, there is no conduction but the ice melts at the boundaries by the surface fluxes and inside by the solar radiation. Melting of ice goes into ice thickness and porosity ν:

$$\frac{\mathrm{d}\nu h}{\mathrm{d}t} = -\frac{Q}{\rho L} < 0 \tag{2}$$

where Q is the total heat flux into the ice. Snow protects the ice cover due to its high albedo and small optical depth. The equilibrium thickness of multiyear ice is obtained when the summer melt Δh equals the winter growth:

$$h_e = \frac{h_1^2}{2\Delta h} - \frac{\Delta h}{2} \tag{3}$$

where h_1 is the thickness of first-year ice; h_1 = 2 m, and Δh = ½ m gives h_e = 3.75 m. More detail level thermodynamics are examined by numerical modeling (Maykut and Untersteiner, 1971). The results show that the thickness of first-year ice is sensitive to snowfall and oceanic heat flux and the thickness of multi-year ice additionally to albedo.

Drift ice dynamics

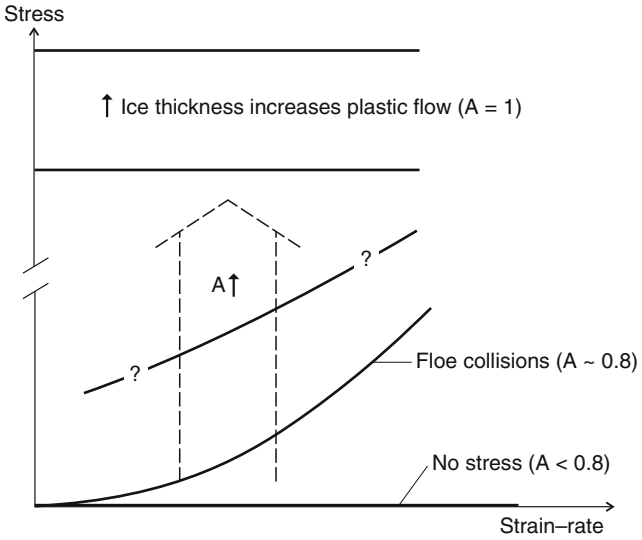
Ice kinematics. Drift ice speed is 1–100 cm/s. In the Arctic Ocean, the Transpolar Drift Stream takes ice across the Eurasian side through the Fram Strait into the Greenland Sea, while in the American side ice rotates clockwise in the Beaufort Sea Gyre. Average velocities are 1–5 cm/s, higher toward the Fram Strait. In Antarctica, the governing features are westward flow zone close to the continent and eastward drift zone farther out, driven by the easterly and westerly winds. Meridional displacements interchange ice floes between the two annuli, in particular up along the Antarctic Peninsula in the Weddell Sea. Frequency spectra of ice velocity reach highest levels at the synoptic time scales, and secondary peaks appear at tidal and inertial periods. The ice–wind–ocean current correlation is usually good, but remarkable noncoherent changes appear due to the internal friction of the ice.

Conservation of ice. Ice conditions are modified by thermal and mechanical processes, dictated by the ice conservation law. Mechanical deformation occurs as opening and closing of leads, rafting, and ridging. The general form is (Thorndike et al., 1975)

$$\frac{\partial \pi}{\partial t} + u \cdot \nabla \pi = \psi - \pi \nabla \cdot u + \frac{\partial \phi(h)\pi}{\partial h} \tag{4}$$

where ψ is the mechanical ice thickness redistributor and ϕ is the growth rate of ice.

Drift ice rheology. The main mechanisms behind internal ice stress σ is friction between ice blocks in mechanical deformation (secondary, come floe collisions, floe breakage, and potential energy production). Stress level is negligible for compactness less than 0.7, but compact ice has significant yield strength. The rheological law is formally $\sigma = \sigma(\pi, \varepsilon, \dot{\varepsilon})$, where ε is strain and $\dot{\varepsilon}$ is strain-rate (Figure 3). At compactness more than 0.8 floe collisions



Sea Ice, Figure 3 Schematic presentation of the sea ice rheology as a function of ice compactness *A* and thickness *h*. The cut in the ordinate axis tells of a jump of several orders of magnitude (Leppäranta, 2005).

and shear friction between ice floes increase the stress and plastic flow results, yield strength increasing with ice thickness. Normally, compressive strength is taken twice the shear strength, and for changes in compactness the e-folding strength scale is taken as 5%.

Equation of motion. Integration through the thickness of ice gives the two-dimensional system as (e.g., Leppäranta, 2005)

$$\rho H\left(\frac{\partial u}{\partial t} + u \cdot \nabla u + f k \times u\right) = \nabla \cdot \sigma + \tau_a + \tau_w - \rho H g \beta \tag{5}$$

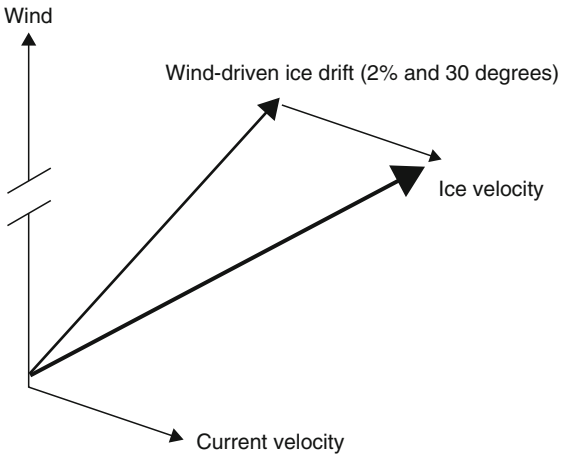
where ρ is ice density, f is the Coriolis parameter, g is acceleration due to gravity, and β is the sea surface slope. The air and water stresses are turbulent drag laws with drag coefficients and Ekman angles as their parameters. The sea ice dynamics solution is divided to three cases/categories. *Stationary ice cover* results when the forcing is below the yield level. In *free drift*, internal friction is absent and the solution is obtained as vector addition:

$$u = u_a + U_w \tag{6}$$

where U_w is the geostrophic surface current and u_a is the wind-driven ice drift, 2–3% of the wind speed and 20–40° to the right (left) of the wind direction in the northern (southern) hemisphere (Figure 4).

For *ice drift in the presence of internal friction*, numerical continuum models are employed (Hibler, 1979; Hibler and Bryan, 1987). A full model consists of four elements: ice state, rheology, equation of motion, and ice conservation law. The first and second elements constitute

the heart of the model. The primary geophysical parameters are the air and water drag coefficients and compressive strength of ice. The mean annual velocity comes out well from the simulation together with the mean thickness field, validated against submarine data (Figure 5). Models predict that there is always a small amount of open water or thin ice present in the Central Arctic, and further that the annual cycle of the mean thickness has about the same amplitude as in thermodynamic models but the level drops down by about one meter. The maximum ice thicknesses are 5–8 m due to mechanical deformation off the northern coast of Greenland.



Sea Ice, Figure 4 The free drift solution as the vector sum of wind-driven ice drift and geostrophic ocean current.

Short-term modeling (1 h to 10 days) applications are in shipping and marine technology, while in long-term modeling (1 month to 100 years) the main objective is the climate problem. Sea ice drift transports latent heat and fresh water, modifies the ice boundary and air-sea interaction, and by freezing and melting the ice has a major influence on the hydrographic structure of the ocean. Differential ice drift opens and closes leads bringing major changes to the air-sea heat fluxes, and ridging accumulates ice blocks adding large amounts to the total volume of ice.

Sea ice literature is rather limited. Extensive lecture notes from summer schools are given in Untersteiner (1986) and Leppäranta (1998). Wadhams (2000) presented an excellent general book of the sea ice geophysics, Leppäranta (2005) focused on the drift of sea ice, and McPhee (2008) on the ice–ocean interaction.

SEA-LEVEL

Anny Cazenave
Laboratoire d'Etudes en Géophysique et Océanographie Spatiales (LEGOS), LEGOS-CNES, Observatoire Midi-Pyrénées, Toulouse, France

Definition

Sea level is the height of the sea surface with respect to a given reference. Sea level variations are called "absolute" or "relative" depending in which reference frame (inertial or terrestrial) they are expressed. Absolute sea level variations generally represent change in the volume of water in ocean basins (either due to water density change or water mass change) while relative sea level variations designate sea surface height changes with respect to the ground (accounting thus for both "absolute" sea level variations plus ground motions).

Spatiotemporal scales of sea level variations

Sea level may vary globally or regionally depending on the causes. Global (uniform) variations are sometimes called eustatic. However this term should be avoided because it is sometimes misused and attributed to water mass change of the oceans only (by opposition to water density change). Superimposed to any global mean sea level change, regional variations may also occur (see below). Temporal sea level variations spread over a very broad spectrum. The largest global-scale sea level changes (10–100 m amplitude) occur on geological time scales (10–100 Myr) and depend primarily on tectonics processes (e.g., large-scale change in the shape of ocean basins associated with seafloor spreading and mid-ocean ridges expansion). Formation of long-live ice sheets (e.g., formation of the Antactica ice sheet about 30 Myr ago) is also able to produce >50 m global sea level variations. On shorter time scales (tens to hundred thousand years), quasiperiodic growth and decay of polar ice caps driven by changes of the Earth's obliquity and orbit around the sun represent another cause of global-scale sea level change, with amplitude on the order of 100 m. Century- to millenium-scale sea level fluctuations are mainly driven by climate change in response to natural forcing factors (e.g., solar radiation, volcanic eruptions) and internal variability of the climate system (related, for example, atmosphere-ocean perturbations such as El Nino-Southern Oscillation –ENSO, North Atlantic Oscillation –NAO, Pacific Decadal Oscillation-PDO, etc.).

Recent past and present-day sea level variations

For the last century and past few decades, sea level variations depend on global climate changes induced by natural climate variability and eventually anthropogenic forcing. The two main factors causing sea level change (globally and regionally) are thermal expansion of sea waters and fresh water mass exchange between land and oceans. For example, as the ocean warms in response to global warming, sea waters expand, and thus sea level rises. When mountain glaciers melt in response to increasing air temperature, sea level rises because of fresh water mass input to the oceans. Similarly, ice mass loss from the ice sheets causes sea level rise. Modification of the land hydrological cycle due to climate variability and direct anthropogenic forcing may lead to increased or decreased runoff, hence ultimately to sea level change.

Observations of recent past and present-day sea level variations

Twentieth century

Our knowledge of past century sea level change comes from tide gauge measurements located along continental coastlines and islands. The largest tide gauge database of monthly and annual mean sea level records is the Permanent Service for Mean Sea Level (PSMSL, www.pol.ac.uk/psmsl/) which contains data for the twentieth century from ~2,000 sites maintained by about 200 nations. The records are somewhat inhomogeneous in terms of data length and quality. For long-term sea level studies, only ~10% of this data set is useable because of data gaps and limited tide gauge distribution in the past. Tide gauges measure sea level relatively to the ground, hence monitor also ground motions. In active tectonic and volcanic regions, or in areas subject to strong ground subsidence due to natural causes (e.g., sediment loading in river deltas) or human activities (ground water pumping and oil/gas extraction), tide gauge data are directly affected by the corresponding ground motions. Post glacial rebound, the elastic response of the Earth crust to last deglaciation (also called Glacial Isostatic Adjustment), is another process that gives rise to vertical land movement.

After the ~120 m sea level rise associated with the last deglaciation that started about 15,000 years ago, geological and archeological observations indicate that the mean sea level remained almost stable during the last 2–3 millennia (Lambeck et al., 2010). But tide gauges available since the late nineteenth century have reported significant sea level rise during the twentieth century, especially since 1950, with a mean rate of ~1.7 mm/year over the past 50 years (Church et al., 2004).

Satellite altimetry era

Since the early 1990s, satellite altimetry has become the main tool for precisely and continuously measuring sea level with quasi global coverage and a few days revisit time. Compared to tide gauges which provide sea level relative to the ground, satellite altimetry measures "absolute" sea level variations. The concept of the satellite altimetry measurement is simple: the onboard radar altimeter transmits microwave radiation toward the sea surface which partly reflects back to the satellite. Measurement of the round-trip travel time of the signal provides the height of the satellite above the instantaneous sea surface (called "range"). The quantity of interest in oceanography is the sea surface height above a reference fixed surface (typically a conventional reference ellipsoid). It is obtained by the difference between the altitude of the satellite above the reference (deduced from precise orbitography) and the range measurement. The estimated sea surface height needs be corrected for various factors due to atmospheric delay and biases between the mean electromagnetic scattering surface and sea at the air–sea interface. Other corrections due to geophysical effects, such as solid Earth, pole, and ocean tides, are also applied. High-precision altimetry started with the launch of the Topex/Poseidon satellite in 1992. Its successors, Jason-1 and Jason-2, were launched in 2001 and 2008, respectively. The precision of an individual sea surface height measurement based on these missions has reached the 1–2 cm level, allowing a precision on the global mean rate of rise of ~0.4 mm/year (Ablain et al., 2009). The temporal evolution of the global mean sea level from satellite altimetry since early 1993 (Figure 1) shows an almost linear increase (except for two temporary anomalies associated with the 1997–1998 El Nino and the 2008 La Nina). Over this 18-year-long period, global mean sea level has been rising at a rate of ~3.3 $\pm$ 0.4 mm/year (Ablain et al., 2009; Nerem et al., 2010), a value significantly higher than the mean rate recorded by tide gauges over the past decades.

Sea level budget for the recent years/decades

Ocean warming

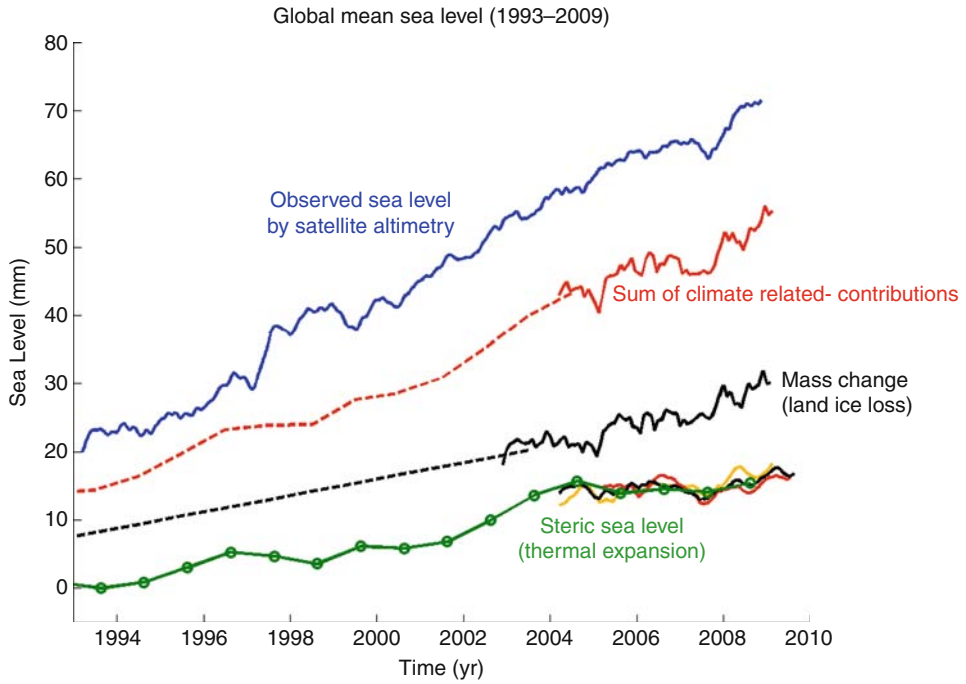
Analyses of in situ ocean temperature data collected over the past 50 years by ships and recently by profiling floats indicate that ocean heat content, and hence ocean thermal expansion, has significantly increased since 1950. Ocean warming explains about 25% of the observed sea level rise of the last few decades (Bindoff et al., 2007). This number is likely a lower bound, due to the lack of hydrographic data in remote regions of the southern hemisphere and in the deep ocean (below 1,000 m) (Dominguez et al., 2008). A steep increase is observed in thermal expansion over the decade 1993–2003 (Bindoff et al., 2007). Since about 2003, thermal expansion rate has reduced (Cazenave and Llovel, 2010) but this likely reflects short-term natural variability rather than a new long-term trend. On an average, over the satellite altimetry era (1993–2009), the contribution of ocean warming to sea rise accounts for ~30% (Cazenave and Llovel, 2010).

Glaciers melting

Being very sensitive to global warming, mountain glaciers and small ice caps have retreated worldwide during the recent decades, with significant acceleration during the 1990s. From mass balance studies of a large number of glaciers, estimates have been made of the contribution of glacier's ice melt to sea level (Lemke et al., 2007; Cogley, 2009). For the period 1993–2009, glaciers and ice caps have accounted for ~30% of sea level rise (Cazenave and Llovel, 2010).

Ice sheets

If totally melted, Greenland and West Antarctica would raise sea level by about 7 and 5 m, respectively. Thus, even a small amount of ice mass loss from the ice sheets would produce substantial sea level rise, with adverse societal and economical impacts on vulnerable low-lying coastal regions. Since the early 1990s, different remote sensing observations based on airborne laser and satellite



Sea-Level, Figure 1 Evolution of the global mean sea level observed by satellite altimetry (*upper blue curve*), thermal expansion (*botton green curve*), land ice contribution (*middle black curve*), and total climate contributions (*middle red curve*).

altimetry, as well as Synthetic Aperture Radar Interferometry (InSAR) technique and space gravimetry (GRACE space mission), have provided important observations of the mass balance of the ice sheets. These indicate accelerated ice mass loss in coastal regions of Greenland and West Antarctica (Allison et al., 2009; Velicogna, 2009; Steffen et al., 2010). For 1993–2003, <15% of the rate of global sea level rise was due to the mass loss of the ice sheets of Greenland and Antarctica (Lemke et al., 2007), but this contribution has clearly increased after 2003 (Velicogna, 2009) (Figure 2). On an average, over 1993–2009, the two ice sheets have contributed by 30% to sea level rise, with almost equal amount from Greenland and West Antarctica (Cazenave and Llovel, 2010).

Land water storage

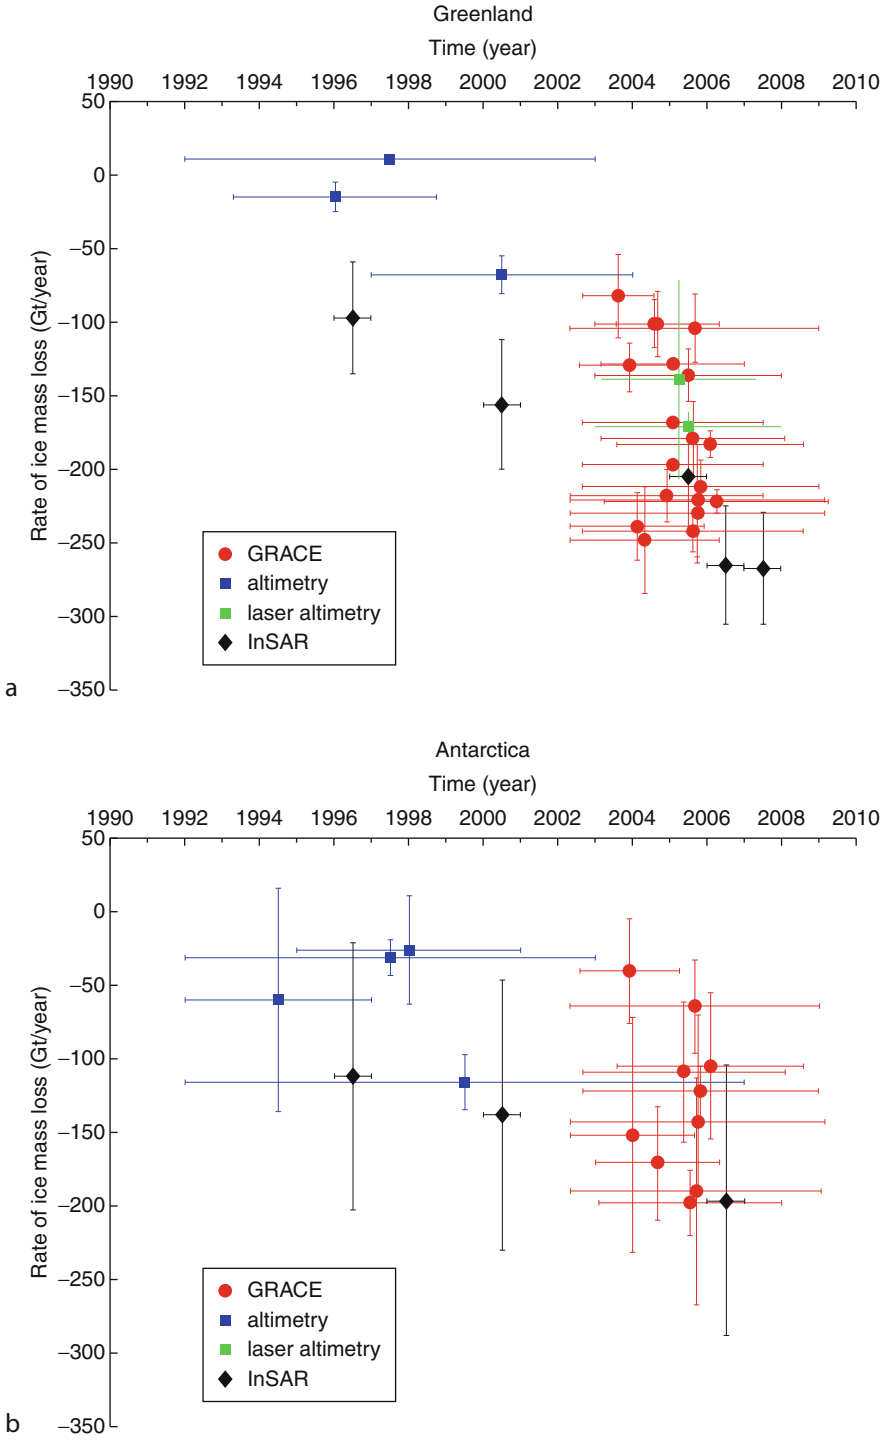
Change in land water storage, due to natural climate variability and human activities (i.e., anthropogenic changes in the amount of water stored in soils, reservoirs and aquifers as a result from dam building, underground water mining, irrigation, urbanization, deforestation, etc.), is another potential contribution to sea level change. Model-based estimates of land water storage change caused by natural climate variability suggest no long-term contribution to sea level for the past few decades, although interannual/decadal fluctuations may have been significant. Since 2002, space gravimetry observations from the GRACE space mission now allow determination of the total (i.e., due to climate variability and human activities) land water contribution to sea level. The land water signal is dominated by interannual variability with only a modest contribution (<10%) to the trend (Cazenave and Llovel, 2010).

Sea level budget over the years 1993–2009

Although none of the climate factors discussed above change linearly with time, on an average over the 1993–2009 time span, ocean warming, glaciers melting, and ice sheet mass loss have each contributed by ~30% to global mean sea level rise (Cazenave and Llovel, 2010). Figure 1 compares the thermal expansion and total land ice loss contributions with observed sea level rise.

Regional variability in sea level trends

Satellite altimetry has revealed that sea level is not rising uniformly. In some regions (e.g., western Pacific), the rates of sea level rise are faster by a factor up to three times the global mean rate. In other regions rates are slower than the global mean (e.g., eastern Pacific). The regional variability in sea level trends is mainly due to large-scale changes in the density structure of the oceans and its interaction with the ocean circulation (Wunsch et al., 2007). The largest regional changes in sea level trends result from ocean temperature change (i.e., from non uniform thermal expansion), but in some regions, change in water salinity is also important (Wunsch et al., 2007). Observations of



Sea-Level, Figure 2 Mass balance of the ice sheets estimated by remote sensing techniques; compilation of published results (see Cazenave and Llovel, 2010); *horizontal bars* correspond to the time span of data analysis and *vertical bars* represent uncertainty. (**a**) Greenland ice sheet; (**b**) Antarctica ice sheet.

ocean temperature over the past few decades show that trend patterns in thermal expansion are not stationary but fluctuate both in space and time in response to natural perturbations of the climate system such as ENSO (El Nino-Southern Oscillation), NAO (North Atlantic Oscillation), and PDO (Pacific Decadal Oscillation) (Bindoff et al., 2007). As a result, sea level trend patterns observed by satellite altimetry over the last 18 years may be different from those of the last 50 years.

Future sea level rise

IPCC AR4 projections based on coupled climate models indicate that sea level should be higher than today's value by ~38 cm by 2100 (within a range of ±15 cm due to model results dispersion and uncertainty on future greenhouse gases emissions) (Meehl et al., 2007). However this value is possibly a lower bound because AR4 projections only accounted for future ocean warming and glaciers melting. A large proportion of Greenland and West Antarctica ice mass loss results from coastal glacier flow into the ocean through complex dynamical instabilities (Allison et al., 2009; Steffen et al., 2010). Such processes have begun to be understood only recently and were not taken into account in the AR4 sea level projections.

Present-day sea level rise is not uniform; this is also expected for the future. The regional sea level map for 2090–2100 provided by IPCC AR4 (average of an ensemble of models) shows higher than average sea level rise in the Arctic Ocean and along a narrow band in the south Atlantic and south Indian ocean. However, as noticed in IPCC AR4 (Meehl et al., 2007), geographical patterns of sea level change from different models are not generally similar, reflecting current model deficiency in modeling regional changes, in particular those associated with decadal/multidecadal natural variability. This is a research area where improvements are crucially needed, in particular for assessing future coastal impacts of sea level rise. It is worth noticing that IPCC AR4 regional projections are different from present-day observed patterns of sea level rise, a result of spatiotemporal change in spatial trend patterns.

Impacts of sea level rise

Sea level rise is a major concern for populations living in low-lying coastal regions (about 25% of human beings) because it will give rise to inundation, wetland loss, shoreline erosion, saltwater intrusion in surface water bodies and aquifers, and will rise water tables (Nicholls, 2010). Moreover, in many coastal regions of the world, the effects of rising sea level act in combination with other natural and/or anthropogenic factors, such as decreased rate of fluvial sediment deposition in deltaic areas, ground subsidence due to tectonic activity or ground water pumping, and hydrocarbon extraction.

Besides factors that modify shoreline morphology (e.g., sediment deposition in river deltas, change in coastal waves and curren), what does matter in coastal regions is relative sea level rise, i.e., the combination of sea level rise and vertical ground motions. In many coastal regions of the world, these two factors are currently of the same order of magnitude and most often of opposite sign (sea level rises and ground subsides). Accelerated ground subsidence is reported in many regions, either because of local groundwater withdrawal or hydrocarbon extraction. Whatever the causes, ground subsidence directly interacts with and amplifies climate-related sea level rise (long-term trend plus regional variability). However, if sea level continues to rise at current rates and more likely accelerates, the climate factors (sea level rise) will become dominant. But as mentioned above, IPCC AR4 sea level projections could be underestimated. In addition climate models do not yet provide reliable regional variability projections (that superimposes to the global mean rise) for the next few decades. Hence, it is very difficult to quantify future sea level rise in specific regions where various factors interfer in a complex way.

Summary

Measuring sea level rise and understanding its causes has considerably improved in the recent years, essentially because new in situ and remote sensing observations have become available. Sea level is presently rising at a sustained rate and will continue in the future decades because of expected increased global warming. However, the exact amount of sea level rise by 2100 is presently an open question. The main source of uncertainty is the future behavior of the Greenland and Antarctica ice sheets in a changing climate. Ice mass loss in these regions has accelerated in the recent years but we do not know yet how fast and how much the ice sheets will continue to lose mass, hence how they will affect sea level in the future. Improved understanding and modeling of the complex dynamical response of the ice sheets to global warming is one of the priorities of current climate research.

SEASONAL FROST

Chelamallu Hariprasad
Centre for Studies in Resource Engineering, IITB Powai, Mumbai, Maharashtra, India

The occurrence of ground temperatures below 0°C for only part of the year is known as seasonal frost. This may occur in the regions where temperature prevails at subzero temperature for a period of time.

SEASONAL SNOW COVER

Amit Kumar
Department of Geology, Centre of Advanced Study in Geology, Punjab University, Chandigarh, India

During winter, when climate conditions do not allow melt of the deposited snow, a snow cover is formed by the deposition of successive snowfall events. Although highly stratified with many layers, the seasonal snow cover is often treated as a homogeneous medium. Each layer has its own physical properties due to the initial snow condition at the time of deposition on the previous surface layer and subsequent metamorphosis, which is mainly determined by the varying field conditions and load and arrangement of ice particles in the layer. Thus, a snow cover has a stratified structure because snowfall is deposited in a series of layers. Individual layers corresponding to different snowfall event may be thick or thin. Thick layers are the result of steady snowfall in calm weather, whereas thin layers occur due to ice crusts formed due to melting, freezing, and wind conditions on the surface of deposited snow cover depends on the topography and the presence of vegetation. A seasonal snow cover is deposited and melted within 1-year cycle, and is normally developed from a series of winter storm. In addition to being an important component of water considered it is also a major component of regional and global hydrology balance. Permanent snowfields, which turn into glacier gradually, are developed at high places where total accumulated snow is not melted away in the summer season.

The changes in snow cover depend upon the prevailing weather conditions such as temperature, precipitation radiation, and wind. In warm conditions, the snow may melt away or stay for a short period. Snow cover that stays only for a few days and then depleted due to climate conditions is known as temporary snow cover.

Snow cover constitutes the largest component of the cryosphere and plays a significant role in the global climate and climate response to global changes. The extent and variability of seasonal snow cover are important parameters in climate and hydrologic systems due to effects on energy and moisture budgets. Seasonal snow can cover more than 50% (50 million km^2) of the Northern

Hemisphere land surface during the winter, making it the largest single component of the cryosphere.

SEDIMENT BUDGETS

Helen E. Reid, Gary J. Brierley
School of Environment, The University of Auckland, Auckland, New Zealand

Definition

A sediment budget is an account of sediment movement within a defined spatial unit (e.g., hillslope, river reach, or catchment) over a given time frame. It is measured as:

$$O - I \pm \Delta S = 0$$

where O = sediment output, I = sediment input, and ΔS refers to the change in sediment storage over a given time frame. If sediment inputs exceed outputs then net deposition (storage) has occurred within the system. If outputs exceed inputs, then net erosion has occurred.

Introduction

Sediment budgets are an integral part of geomorphic enquiry (Slaymaker, 2003). They can be applied to any situation where sediment is being transported, whether over land, within water bodies, or within the atmosphere (Thomas and Goudie, 2000). In terrestrial terms, sediment budgets can be performed over a wide range of spatial scales for differing compartments of a landscape. In general, however, they are applied at the (sub)catchment scale (Reid and Dunne, 1996), reflecting the primacy of the catchment as the fundamental geomorphic unit (Chorley, 1969). As drainage basins operate as closed systems, they are the ideal unit/spatial scale at which sediment budgets can be performed (e.g., Reid and Dunne, 1996). However, sediment budgets may be a useful tool at smaller scales, such as reach-scale analyses of sediment transfer along a river or plot-scale analyses of soil erosion on farms.

River systems act as conveyer belts that move sediments from source zones (hillslopes of headwater areas, where net erosion occurs) through transfer zones in mid-catchment where erosion and deposition are approximately in balance, to accumulation zones (i.e., oceans or inland basins; Schumm, 1977). Analysis of sediment budgets entails identification of sediment sources and erosion rates (whether primary erosion or reworking of sediment stores), measurement of sediment accumulation within landscape compartments (i.e., deposition and restorage of materials), and determination of sediment output at the outlet of the spatial unit that is being studied. Changes to relationships between sediment sources, storage elements, and pathways of sediment movement may bring about dramatic changes to landscape form and sediment flux.

Sediment yield refers to the quantity of sediment that reaches the outlet of a drainage basin (Thomas and Goudie, 2000). The primary difference between analysis of sediment yield and derivation of sediment budgets is consideration of the processes that fashion sediment storage, and the efficiency with which sediment stores are reworked. The sediment delivery ratio defines the "proportion of sediment leaving an area, relative to the amount of sediment eroded in that area" (Brown et al., 2009: 37). Residence times for sediment reworking vary markedly for differing sediment storage units, whether on hillslopes or along the valley floor (both channel and floodplain compartments). In a sense, the nature and pattern of sediment stores reflects spatial variability in accommodation space within a landscape (i.e., places where sediments may be stored, however effectively) and the nature of geomorphic processes that rework these sediments (i.e., the magnitude–frequency relationships of reworking processes, and the sequence of events that determine whether sediments in stores are eroded, or additional materials are added to that store). Meaningful differentiation can be made between short-term *stores* that are prone to reworking (e.g., mobile sediments that make up mid-channel bars in river systems) and long-term *sinks* that are spatially isolated from reworking processes (e.g., cohesive sediments that make up floodplain and/or terrace features; Fryirs and Brierley, 2001). Residence time for sediment storage within a unit reflects the effectiveness of erosion, transport, and deposition processes that fashion the behavior of that landscape compartment which, in turn, is affected by the position of that feature within the landscape, the surrounding topography, climatic conditions, and vegetation cover (Brown, 1987). Residence times usually increase downstream within a catchment, as slopes decrease and accommodation space increases (Fryirs et al., 2007a).

The nature and rate of sediment movement through a landscape reflects the connectivity of the system (Harvey, 2002; Fryirs et al., 2007b). In highly coupled systems, sediment from hillslopes is delivered directly to the channel. High gradient, headwater channels are highly coupled with their hillslopes, directly inputting materials into channels. High slopes generate high steam power; so competence-limited channels are able to flush all but the largest material. As a result, sediment stores are limited in these highly connected parts of landscapes. Once slope flattens in downstream reaches, accommodation space and sediment stores increase. Floodplain pockets disconnect hillslope-derived sediments from within-channel features such as mid-channel bars and benches. Terraces have even longer residence times than the contemporary floodplain, further acting to decouple the system. In general terms, the residence time of sediment stores tends to

increase with distance downstream. Indeed, as sediments are buried and the thickness of the basin fill increases, subsidence increasingly traps and compresses sediments, facilitating their incorporation into the rock record.

Buffers, barriers, and blankets impede sediment conveyance within a catchment (Fryirs et al., 2007a, b). Buffers restrict sediment transfer from hillslopes to the channel network, as sediments are stored within features such as intact valley fills, piedmont zones, alluvial fans, floodplain pockets, and terraces. Barriers inhibit downstream movement of sediment along channels, as features such as dams and bedrock steps induce base level controls along longitudinal profiles. Blankets smother landforms, protecting underlying sediments from reworking. The more connected the system, the more efficient the rate of sediment transfer.

Sediment movement is not uniform over time. Rather, pulses in sediment reflect stochastic inputs and transfer mechanisms, such as landslides, rainfall events, earthquakes, and fires (Benda and Dunne, 1997). The amount of sediment moved by a single event is linked to the magnitude and duration of the event, whereas the amount of sediment that is moved over a period of time reflects the frequency of events of different sizes. Each landscape compartment is subjected to a suite of processes that have their own magnitude–frequency domain (or spectra). The sediment budget reflects the synchronicity of these relationships across differing compartments of the landscape (i.e., sediments sourced from one unit may be flushed to the outlet, or become trapped elsewhere within the system). This is most readily exemplified by the transfer of sediments from hillslopes to a channel system. If sediment generation from hillslopes is too high, and the channel is unable to remove all sediments, aggradation occurs on the valley floor. Alternatively, if sediment supply from hillslopes is too low, the channel will incise into its bed. In both instances, the channel adjusts to mediate conditions operating on hillslopes. The relationship between hillslope and river processes determines the rate of sediment flux (and storage) in differing parts of river systems.

Using sediment budgets to place landscape responses to human disturbance in light of natural variability

Long-term changes in sediment flux must be understood before the imprint of human disturbance upon a system can be determined (Brierley and Fryirs, 2005; Houben et al., 2009). Sediment storage and movement reflect the interaction of geologic, climatic, and anthropogenic memory, highlighting how the imprint of the past upon sediment stores is key to predicting future sediment fluxes (Brierley, 2010). For example, Pleistocene glacial stores continue to influence contemporary sediment fluxes in some systems (Church and Slaymaker, 1989). In their modelling of sediment flux at the global scale, Syvitski and Milliman (2007) found that geological controls explained 65%, climate 14%, and anthropogenic factors 16% of the viability in sediment loads. Therefore, natural geologic characteristics including basin area, lithology (i.e., erodibility), relief (i.e., erosivity, as determined by potential energy), and ice erosion are major determinants on the amount of sediment a landscape generates.

As sediment movement is largely stochastic, large events may cause fundamental shifts in the functioning of the system, prospectively bringing about a change in system state as threshold conditions are exceeded (Schumm, 1977; Reid and Dunne, 1996; Brierley and Fryirs, 2005). For example, landslides may block a channel system from reworking sediments. Sediment budgets can be used to understand landscape responses to natural, commonly high magnitude events such as volcanic eruptions (Tagata et al., 2005), landslides (Peart et al., 2005), bush fires (Wallbrink et al., 2005), and system responses to climatic fluctuations (Aalto et al., 2003).

Human activities have had a profound impact upon sediment movement in landscapes, and sediment budgets are commonly used to analyze the nature and extent of system responses to human disturbance (Houben et al., 2009). Every system is unique, its functioning driven by landscape history and more contemporary patterns of anthropogenic activity (Brierley, 2010). Wilkinson and McElroy (2007) assert that reworking of sediment stores generated in response to forest clearance is testimony to the primacy of human disturbance as the greatest influence upon contemporary sediment budgets across the Earth's surface. Examples of the use of sediment budgets to analyze the impact of contemporary land uses include agricultural impacts (Trimble 1983, 2009), mining (Knighton, 1991), logging (Roberts and Church, 1986), dams (Bogen and Bonsnes, 2005), roads (Megahan et al., 1986; Ramos-Scharron and MacDonald, 2007), and urbanization (Nelson and Booth, 2002). Tracking of contaminants and heavy metal pollutants, and analyses of carbon, nitrogen, and phosphorus cycles can be a component of sediment budget analyses (e.g., Houghton et al., 1999; Prosser et al., 2001; Slaymaker et al., 2003). Vorosmarty et al. (2003) highlight the primary role of dams in storing sediments of river systems. Understanding how human activities have altered sediment flows between compartments of a system allows for targeted management, identifying and mitigating the areas that are having the most detrimental affect on the system.

What techniques are used to derive sediment budgets?

Any sediment budget must give careful consideration to the spatial scale at which it is to be applied. Typically, a trade-off must be made between scale and precision and the level of accuracy that is sought (Brown et al., 2009). Local scale studies tend to be more fieldwork intensive, involving in-depth investigation into the relationships among specific components that make up the system (e.g., Bartley et al., 2007; Trimble, 1983). In contrast, sediment budgets undertaken at national

(Hicks et al., 1996) or global (Syvitski and Milliman, 2007) scales tend to consider sediment yields (outputs) rather than identification of sources and stores.

Given the stochastic nature of the forcing elements that determine sediment movement and storage, timescale of analysis is a critical consideration in the derivation of sediment budgets. Long-term perspectives may incorporate changes in climatic periods, land use, and sea level whereas short-term, more contemporary analyses can be used to analyze system responses to a given event (or sequence of events), such as impacts of floods, fire, or land-use alterations. Seasonal changes may be an important driver of sediment flux (e.g., tropical wet-dry seasonality, or impacts of snowmelt). Sediment flux at any given time is greatly influenced by the amount of sediment that is available to be moved at that time, especially the availability of readily accessible stores. Conditions experienced at the time of measurement have major implications when extrapolating data over longer time periods.

Techniques used to derive and analyze sediment budgets range from simple qualitative conceptualizations used to examine process interactions to in-depth quantitative analyses that derive volumetric information about the rates at which sediment is entering and leaving landscape components (Reid and Dunne, 2003). Most budgets use a mixture of desk, field, and analytical techniques.

Conceptual models of sources, sinks, and the pathways of transfer are used to identify the primary processes and units that influence sediment flux within a system (Reid and Dunne, 1996; Bartley et al., 2007). Various analytical techniques are used to assess processes of erosion, transport, and deposition that affect different units. Aerial photographs and maps aid identification of erosion rates for differing surfaces such as erosion scarps or gully complexes (Reid and Dunne, 1996). Historical images can be used to interpret the types and magnitude of channel and hillslope change (e.g., differences in active versus vegetated bar surface areas over time (Ham and Church, 2000)). The availability of map, photograph, and archival sources makes it much easier to interpret human impacts upon natural systems in the New World than elsewhere (Brown et al., 2009).

Most small-scale sediment budgets have a fieldwork component applying repeat surveys such as cross section analysis, erosion pins, flumes, ground-penetrating radar, bed load transport, floodplain coring, or trenches to assess the level of floodplain deposition (Bartley et al., 2006, 2007; Brown et al., 2009; Trimble, 1983; Walling et al., 1998; Reid and Dunne, 1996). Sediment-rating curves can be derived from analyses of turbidity (suspended sediment loads) and bed load sampling at gauging stations. Fieldwork provides important contextual information with which to ground modelling applications. However, use of field techniques in isolation can be problematic, as getting accurate data is very expensive and time consuming, and issues always arise regarding reliability and representativeness (Brown et al., 2009). Ideally, modelling techniques are supported and verified using field-based evidence (e.g., Bartley et al., 2007). However, more ground can be covered with higher accuracy when computer-based techniques are used (Brown et al., 2009).

Advances in computer-based technology, remote sensing imagery, and Geographic Information Science (GIS) have aided the development of more detailed and complex sediment budgets, increasing what can be achieved in terms of speed, accuracy, and scale (Brooks et al., 2008; Brown et al., 2009). GIS allows large datasets to be overlayed with greater spatial accuracy (e.g., Ramos-Scharron and MacDonald, 2007). Repeat surveys using advanced remote sensing technologies such as light detection and ranging (LiDAR) can be applied to generate precise digital elevation models from which fine resolution sediment budgets can be derived (Brown et al., 2009).

Paleo-records can be used to interpret how sediment fluxes have changed over time, isolating responses to different forcing mechanisms such as different cycles in climate or extreme events. The further back that analysis is based, the more likely it is that changes in climate and morphology have driven the system, altering cause–response relationships (Houben et al., 2009). Applications of dating techniques to derive sediment age and source are an integral part of sediment budget analyses. While dating can be expensive and have a degree of error, it allows more accurate interpretation of the timescales and rates over which landscape evolution has occurred. Finally, sediment fingerprinting using environmental and fallout radionuclides and chemical sediment characteristics can be used to trace the sources and pathways of sediment movement and accumulation (Walling, 2003; Walling and Horowitz, 2005; Wallbrink et al., 2005).

Summary

Sediment budgets are an integral part of geomorphic investigations into sediment movement through landscapes. Recent conceptual and technological advances in sediment budgeting aid interpretations of landform development and responses to anthropogenic disturbance. Hence, sediment budgets are a key conceptual framework in the analysis of landscape systems, allowing researchers and managers to gain critical insights into how landscapes look and operate, aiding spatial prioritization of management applications.

Glacier reconstructions

Definition

Sediment core and glacial environment reconstructions describe the methods used to reconstruct past glacier activity based on sediments deposited in distal glacier-fed lakes (Figure 1). By quantifying physical properties of glacial and extra-glacial sediments deposited in catchments, and in downstream lakes and fjords, it is possible to isolate and identify past glacier activity – size and production rate – that subsequently can be used to reconstruct changing environmental shifts and trends. Moreover, detailed glacier reconstructions can also be used to assess denudation rates, chemical and physical weathering, as well specific glaciological changes.

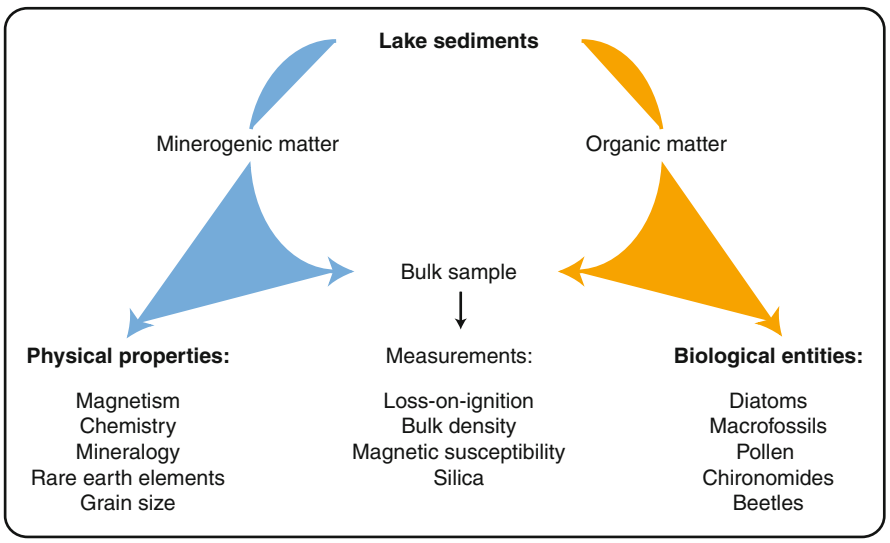
Introduction

Alpine glaciers are often located in remote and high-altitude regions of the world, areas that only rarely are covered by instrumental records. Understanding the behavior of glaciers and linking their activity to climate changes can therefore be challenging, but when successful glacier reconstructions can shed light on past and present climate variability on both shorter and longer time scales.

Few, if any, other proxies have responded in a more unambiguous way to global warming than glaciers, which now are receding in a hitherto unrecognized pattern.

Robust glacier reconstructions can thus be an important source of knowledge for a better understanding of not only natural climate variability, but also change induced by anthropogenic emissions of greenhouse gases. Producing glacier records is not straightforward and is frequently based on a blend of different methods, which occasionally is difficult to reconcile. This can, for instance, be due to the method applied for estimating the equilibrium-line-altitude (ELA) or even the preferred physical parameter that is interpreted to reflect glacier activity.

One major drawback with glacier reconstructions based solely on moraine chronologies – by far the most common – is that due to selective preservation of moraine



Sediment Core and Glacial Environment Reconstruction, Figure 1 Shows a simplified representation of different organic and minerogenic components making up the bulk sediments typically found in records retrieved from distal glacier-fed lakes. It is commonly the physical properties of the sediments that are used for glacier reconstructions.

ridges such records do not exclude the possibility of multiple Holocene glacier advances. This problem is true regardless of whether cosmogenic isotopes or lichenometry have been used to date the moraines, or also radiocarbon dating of mega fossils buried in till or underneath the moraines themselves.

To overcome this problem, Karlén (1976) initially suggested that glacial erosion and the associated production of rock-flour deposited in downstream lakes could provide a continuous record of glacial fluctuations, hence overcoming the problem of temporal incomplete reconstructions. Reading the glacial signal, as preserved in downstream lake sediments, now includes the application of various methods such as measuring the amount of minerogenic versus biologic matter (typically inferred from Loss-on-Ignition (LOI)), grain-size analysis (GSA), magnetic properties (MP), geochemical elements (GE), Rare-Earth Elements (REE), Bulk Sediment Density (BSD), but also other techniques (e.g., Bakke et al., 2009; Guyard et al., 2007; Leeman and Niessen, 1994; Leonard and Reasoner, 1999; Lie et al., 2004; Paasche et al., 2007).

Paleorecords of natural climate variability based on glacier reconstructions are arguably more reliable if separate events, like those that happened to produce individual moraines, can be compared relative to each other. Being able to do so requires knowledge not only about the conditions during the deposition of a single moraine, but also the conditions both prior and after the advance. It is not until such knowledge is made available through continuous glacier reconstructions that changing climate conditions adequately can be evaluated in terms of glacier response. Being able to do so is the main advantage with using sediment cores as basis for glacial environment reconstruction. Here we offer a brief review on prospects and problems associated with the employment of such an approach and also how continuous glacier reconstructions can be used as proxies for past climates.

Methods review

Changes in average sediment evacuation from alpine glaciers are mainly governed by glacier size and the mass turnover gradient, determining the deformation rate at any given time. The amount of solid precipitation (mainly winter accumulation) versus loss due to melting during the ablation-season (mainly summer temperature) determines the mass turnover gradient in either positive or negative direction. In this simplified world, a prevailing positive net balance will lead to higher sedimentation rates and vice versa, which in turn can be recorded in downstream lakes. To retrieve these glacial sediments it is necessary to collect sediment cores from the lake bottom. A range of coring equipment is now available, with different operating mechanisms and different levels of success in core recovery (see Table 1). A number of problems (often overlooked) are encountered during coring operations or during subsequent transport: (1) sediment disturbance/deformation due to coring, (2) cores not capturing all sedimentary units, (3) not enough cores retrieved, and (4) potential onsite pollution of the sediments in the cores.

To optimize the coring effort it is preferable to carry out seismic or similar investigations. New technology has made it possible to do advanced imaging of the soft sediments in glacial lakes using, for instance, Ground Penetrating Radar (GPR) or light-weighted Pinger or Kirp systems (see Moorman, 2001). With these tools it is possible to measure the actual sediment distribution within a basin, which can ensure that the selected coring sites indeed are representative for the overall sediment distribution.

Extra-glacial and also paraglacial sediment sources represent a source of error in glacier lakes because they may influence the way the bulk sediment samples are interpreted. Many are well-known and typically include debris flows, talus cones, dirty snow avalanches, subaquatic slumping, melt-out of permafrost, and so forth.

Sediment Core and Glacial Environment Reconstruction, Table 1 An overview of available coring devices, how they are operated, what maximum water coring depth they are suited for and what the maximum length of the retrieved core is expected to. The last column contains reference to some papers describing these devices

Coring device	Operation	Operating water depth	Core length (m)	References
Piston corers driven by rods (also modified with hammer or percussion)[a]	Hand operated and motorized	<100 m	40 m	(e.g., Livingstone, 1955; Nesje, 1992)
Cable-operated piston corers[a]	Motor, hydraulics	<500 m	40 m	(e.g., Kelts et al., 1986)
Box cores and dredges[a]	Hand operated	<10 m	10–20 cm	(e.g., Murdoch and Azcue, 1995)
Open-barrel and gravity corers[a]	Hand operated	<40–50 m	>1 m	(e.g., Renberg, 1991)
Chamber-type samplers[a]	Hand operated	<15 m	<15 m	(e.g., Russian peat corers, Hiller corers)
Vibracorers[a]	Motorized	<50 m	<15 m	(e.g., Thompson et al., 1991)
Freeze samplers	Hand operated	<50 m	<1 m	(e.g., Lotter et al., 1997)
Modified gravity corers[a]	Motorized for deep water	<500 m	2–4 m	(e.g., Cushing et al., 1997)
Pneumatic corers[a]	Motorized	<30 m	6 m	(e.g., Mackereth, 1969)

[a]Tube diameter varies between 30 and 200 mm

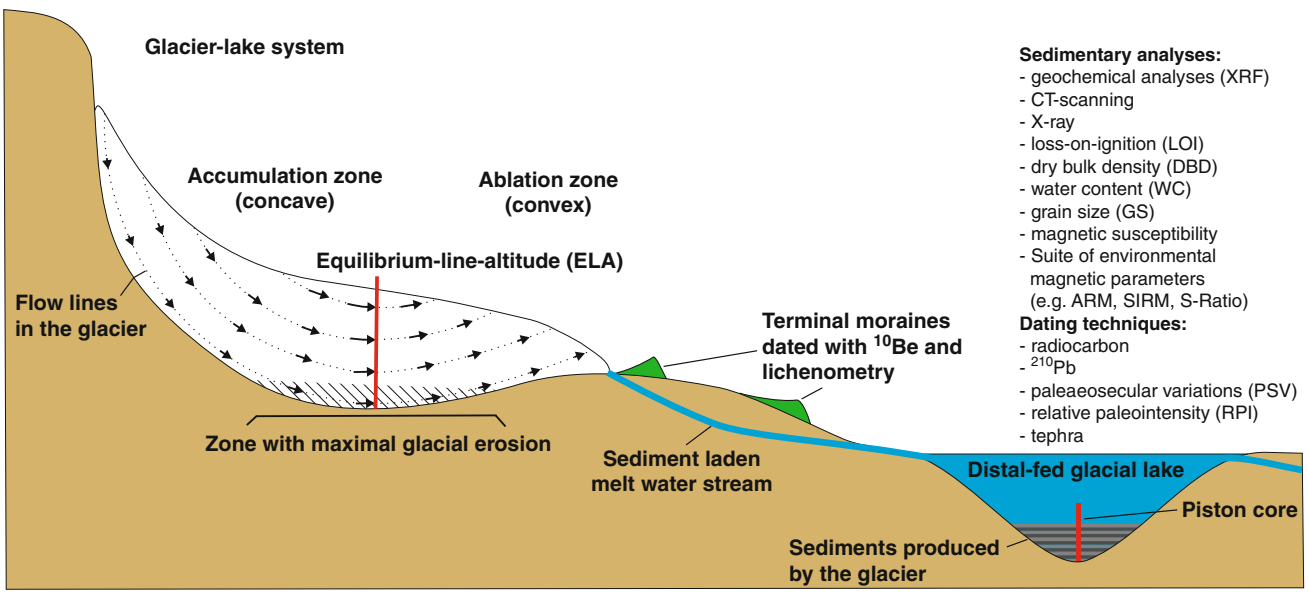
The shortcomings of many lake sediment studies are precisely that they do not distinguish different processes affecting lake sedimentation from each other (Bakke et al., 2005; Snowball and Sandgren, 1996). More recent studies build on multi-proxy approaches (Figure 2), taking advantage of the sediment's different physical qualities, which in due turn allows for the possibility of discriminating glacial flour produced at the sole of the glacier from extra-glacial and paraglacial sediments (Paasche et al., 2007; Rosqvist et al., 2004).

The landscape relief around lakes is also important as gentle slopes reduce the risk of snow avalanches and rock falls, which otherwise might impact the overall sediment budget of the lake (Dahl et al., 2003). Using lacustrine sediments retrieved from downstream glacier-fed lakes to reconstruct past glacier activity requires careful validation of the records in question since several sources of error are present. The bulk sediment composition, as seen from the lake-sedimentary archive, consists of extra-glacial components that need to be identified and isolated, as this would otherwise corrupt the glacier reconstruction. Being able to unmix bulk sediments is the most important research frontier in work dealing with glacial reconstructions based on continuous sedimentary records.

Methods that potentially can be used to distinguish different sedimentary components include rock magnetic properties (magnetic grain size, magnetic mineralogy, signal strength), XRF core scanning, and changes in physical grain-size composition (Bakke et al., 2005, 2010; Guyard et al., 2007; Paasche et al., 2007).

Sedimentary fingerprinting by means of magnetic properties usually requires a suit of measurements, which in sum might allow for a more accurate glacial reconstruction (Paasche et al., 2007; Rosenbaum and Reynolds, 2004). Variations in magnetic mineralogy are, for instance, widely used in environmental magnetism to ascertain contributions from different sediment sources, utilizing variations in provenance when erosion of different lithologies occurs. Not only will magnetic properties yield insight to provenance, it is also possible to identify chemical processes associated with transport and subsequent deposition. Magnetic measurements required to perform such a task typically involve bulk magnetic susceptibility (scrutinizing between paramagnetic susceptibility, diamagnetic susceptibility, and ferromagnetic susceptibility), saturation isothermal magnetization (sIRM), anhysteretic remanent magnetization (ARM), coercivity specters (IRM-H curves), first-order-reversal-curves (FORCS), and hysteresis loops.

XRF count rate of titanium in distal glacier-fed lakes have been employed with some success to detect glacier activity, as observed from lake sediments (Bakke et al., 2009, 2010). Other stable geochemical elements that also can be used – they are present in many lithologies – are Silicon, Potassium, and Rubidium (Guyard et al., 2007). Rubidium can, for instance, be used to monitor the amount of detrital clays (i.e., glacier flour), indicative of glacier erosion (Guyard et al., 2007). The relative new XRF scanning technology provides tools for further unmixing of the lake sediments derived from non-glacial processes.



Sediment Core and Glacial Environment Reconstruction, Figure 2 Shows a conceptual illustration of an alpine glacier in relation to a distal glacial-fed lake that receives sediment-laden meltwater directly from the glacier through the glaciofluvial system. Possible sedimentary analyses that can be performed are listed together with the possible dating techniques that will make it possible to integrate the sedimentary records with, e.g., independently dated terminal moraines. Parts of this methodology have previously been used; however, few studies use all the available methods to validate the sedimentary records in question.

By employing different ratios such as Titanium/Iron and Titanium/Magnesium, which are metals assumed to be redox-sensitive and redox-insensitive, respectively, inferences about slope wash or paraglacial processes can be inferred.

X-rays and CT scanners can also be used to identify any sedimentological signatures that may indicate disturbance in the sedimentary records (e.g., erosional contact, drop stones, bioturbation, etc.).

A complementary approach is to use grain sizes that may reflect transport capacity of meltwater entering a lake. Given that this assumption is valid it may be possible to link variability in the distribution of grain sizes directly to variations in glacier runoff and hence indirectly to size (Bakke et al., 2009, 2010). The critical assumption here is that larger glaciers, on average, release more meltwater than smaller glaciers and that such changes do not also change the potential sediment contribution from other extra-glacial sources. On shorter time scales (annual) large deviations are likely, but on longer timescales (decadal to centennial) this assumption might be valid.

Paleoclimatic reconstructions based on sediment cores

Temperate glaciers respond both to temperature and solid winter precipitation. The importance of these two climatic parameters varies from glacier to glacier, but for maritime glaciers winter precipitation tends to be more important in explaining changes in the overall mass balance budget, whereas for continental glaciers temperature tends to be more important.

The potential of disentangling the climate forcing that plays such a crucial role in most glaciers 'health-state' is precisely the reason for them being sought after as proxies for past and present climate change. By reconstructing maritime glaciers along a certain transect it is, for instance, possible to assess changes of past atmospheric circulation anomalies (cf. Bakke et al., 2008) because such patterns govern the distribution of precipitation.

Over the last 30 years numerous glacial reconstructions based on sediments from distal glacier-fed lakes worldwide are published. They all provide important information about glacier and climate variations from regions often without any other paleoclimatic archives available. It is however critical that each glacier record is seen in the context of both local and regional climate before the results are upscaled.

Many reconstructions during the 1980s and 1990s were based on the pioneer work from Northern Sweden where Karlén (1976) used the organic content of lacustrine sediments (measured by loss-on-ignition, LOI) to quantify glacial erosion and its associated rock-flour production. From North America/Canada and Scandinavia several studies are based on this approach covering the time span from the deglaciation towards present day (e.g., Leonard and Reasoner, 1999). It is especially the Neo-glacial time period that is suited for the methods based on sediments from distal glacier-fed lakes because it is crucial to standardize the sedimentary archives when the boundary conditions are similar to present day. Also in the Alps several glacier reconstructions are based on sediments from distal glacier-fed lakes, such as from Lake Silvaplana (Leeman and Niessen, 1994) and Lake Bramant (Guyard et al., 2007). However, due to few lakes and high sedimentation rates the most important source for information about glacier variability in the Alps still comes from radiocarbon dating of mega fossils as well as historical sources.

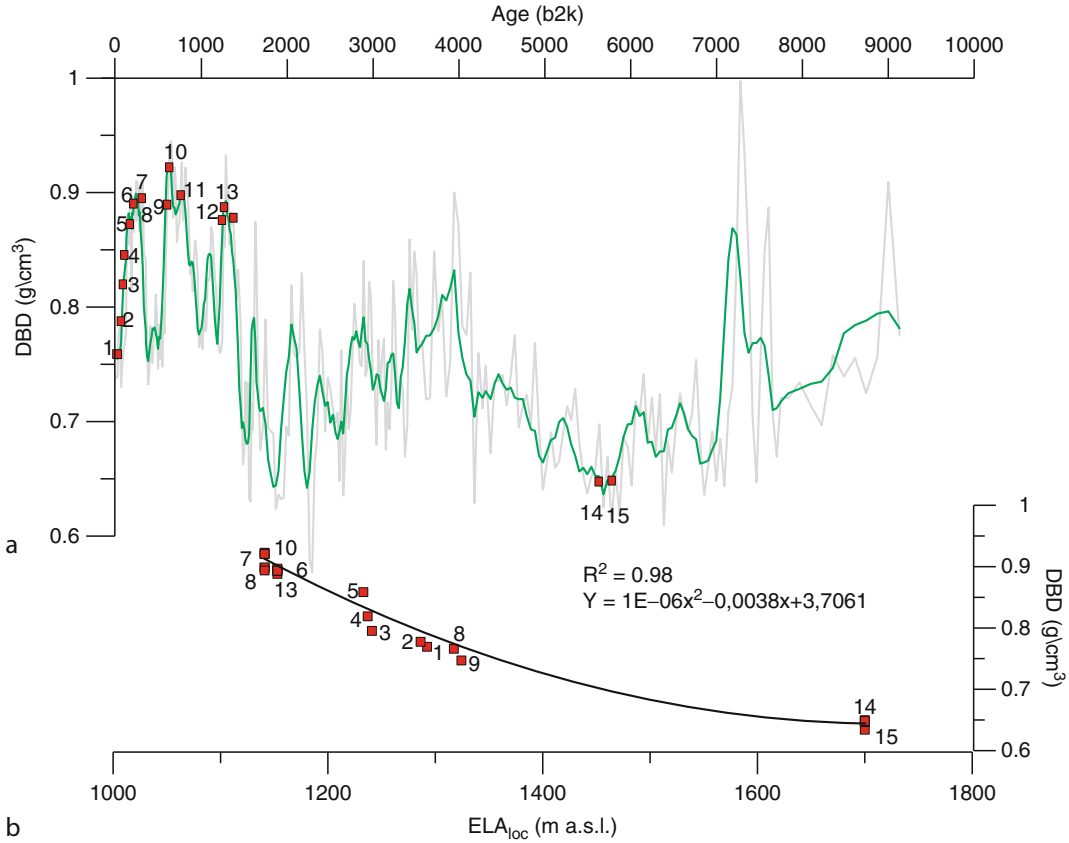
State-of-the-art glacier reconstructions from distal glacier-fed lakes should aim for a quantitative-based reconstruction of the ELA. When sediment records are validated (i.e., intra-core comparison, stacking records, and/or establishing a masterstratigraphy), the next critical step involves connecting the continuous sediment record to corresponding shifts in ELA of the glacier in question. The ELAs (present and past) of dated glacier advances can be reconstructed with established methods such as, for instance, area-altitude balance ratio (AABR) (Osmaston, 2005).

In certain studies dry bulk density (DBD) or SIRM have been used for such a quantification (Bakke et al., 2010; Bakke et al., 2005). First step in this approach is, nevertheless, to integrate an independently dated moraine chronology with an independently dated sedimentary record. As evident from Figure 3, it is possible to establish a statistical relationship between the ELAs calculated from dated moraines and the corresponding sedimentary values obtained from sediment core analysis.

The second step is to use (if available) ^{210}Pb-dated sections in the sedimentary records to correlate sedimentary values to historical documented glacier-front positions recalculated to ELA. Taken together, this allows for a construction of a continuous record of ELA variations, which is based on two independently dated archives (Figure 3). The ELA reconstruction at hand must then be, if necessary, adjusted for potential land uplift before values are used for whatever reason. In Figure 3 the strong statistical relationship between ELA and winter precipitation suggests one area where such an ELA reconstruction can be valuable.

Holocene paleoclimatic trends and future prospects

Alpine glaciers located in the mid- to high latitudes in Northern Hemisphere is small or absent glaciers from 9,000 to 8,000 years BP until ca. 6,000 years BP, which possibly is the most characteristic trend for glacier records during the entire Holocene. After ca. 6,000 years BP the big picture gets more complicated and numerous advances are recorded several places, including South America, North America, Canada, the Alps, and Scandinavia (see Wanner et al., 2008). The major trend in the Holocene glacier variations in the NH seems to be connected to the gradually decreasing summer insolation due to orbital forcing.



Sediment Core and Glacial Environment Reconstruction, Figure 3 (**a**) Diagram illustrating how it is possible to transform a sedimentary proxy into a continuously record of past ELA fluctuation. *Red dots* indicate periods when the ELA is known, either based on historical data, lichenometric data, and/or interpretation of lake sediments. (**b**) Shows the statistical relationship between periods with known ELA (meter above sea level) and dry bulk density (DBD) values. The regression model is used to model a continuous ELA_{loc} for Holocene. (Modified after Bakke et al., 2010).

Besides the 3,000-year period during the early Holocene when glaciers are small or even absent, another common feature for NH-glaciers is that many of them reach Holocene maximum advances during the Little Ice Age (LIA), occurring sometime between AD 1450 and AD 1910.

A challenge for future studies that seek to extract paleoclimatic information from continuous glacier sediment archives is to more actively use Earth System Models, and also modern meteorological observations. Such an approach can allow for positive identification of regions and areas where glaciers are (or are likely to be) most sensitive to changing climate conditions, and also to explore the critical number of glacier reconstructions required in order to adequately represent a particular region or weather system such as the North Atlantic Oscillation (NAO).

Another possibility for future studies is to aim for improving coring techniques by for instance combining the use of short and long cores in order to retrieve pristine sediment stratigraphies from lakes and fjords. Only when in possession of undisturbed top sediments, overlapping with the longer cores, can crucial calibration against modern processes and environment be carried out.

Overlapping time series with glacier mass-balance measurements are important for verifying and quantifying past ELAs. Using modern mass-balance data in combination with simple flow models can shed light on glacier behavior in both long and short perspectives, specifically when it comes to understanding sediment release from glaciers during advance and subsequent retreats.

Modern multi-proxy approaches, partly outlined here, have opened up new avenues for quantifying glacier process in alpine environments and linking them to changing environmental conditions. Furthermore, improving the accuracy of continuous glacier reconstructions hinges on our ability to better decipher lake sediments, i.e., connect the different sedimentary components to their factual source, and also to identify what processes that might have affected them during production, transport, and deposition. Unless we are able to improve the understanding of the glacier-lake system much of the paleoclimatic inferences will be hampered by noise. Distal glacier-fed lakes are, for instance, frequently perturbed by floods, which

can be difficult to recognize in lake-sedimentary cores, but by employing new methods such as XRF and CT scanning it is now possible to generate reconstructions for avalanche and flooding activity from the same lakes that earlier were only used for glacier reconstructions. This represents an optimization of the sediment core–based glacier reconstructions, but it also implies more accurate paleoclimatic reconstructions.

Definition

Sediment entrainment, transfer and deposition explains how debris is incorporated into the base or onto the surface of a glacier, then modified and deformed during glacier flow, and finally deposited beneath or in front of the glacier, including its subsequent reworking.

Introduction

Importance of glacial sediments

Glacial sediments provide a vital legacy for interpreting past climates of the Quaternary and earlier geological periods. Their importance can be gauged from the facts that 30% of the Earth's land surface was under ice during the last ice age, and that even today 10% of the land is still covered by glaciers and ice sheets. During the Quaternary Period, in addition to those that survive in Antarctica and Greenland, vast ice sheets grew over North America, Scandinavia and the British Isles, northern Russia, Tibet, and Patagonia. Smaller icefields grew over the Alps, New Zealand, and central Asian ranges, together with smaller ice masses in many other of the Earth's mountain ranges. Glacier ice has left a complex but often patchy record of deposition on land, but offshore has contributed substantially to the buildup of high-latitude continental shelves.

Glacial transport and deposition is intimately associated with a wide range of other processes, including ice deformational and glaciotectonic, fluvial, mass flowage, aeolian, lacustrine, and marine. The resulting sedimentary facies associations are highly variable, and even with detailed investigation can be interpreted in widely different ways. It is only within the last 4 decades that studies of glacial processes in modern settings have made it possible to develop plausible models of past glacial depositional environments.

Understanding the nature of Quaternary glacial sediments and their associated landforms is crucial in the glaciated areas of North America, Europe, and elsewhere. This is because sand and gravel extraction, notably from glaciofluvial sequences, is essential for construction purposes, as well as informed management of water resources and waste disposal. Some pre-Quaternary glacigenic facies are also economically important in some regions, such as in the Permo-Carboniferous and Neoproterozoic basins of the Middle East and South America, where they constrain the presence of petroleum resources.

Glacial sediments also have an important aesthetic appeal. In mountain regions, they add to the character of impressive glacial erosional landscapes, while in lowland regions they provide a rolling topography of lakes and hills, all of which underpin the tourism business.

The wider implications of focusing on glacial sediments and their associated landforms center on reconstructing past ice sheets. This topic, referred to as paleoglaciology, is of increasing importance as we seek to understand past response of ice masses to climate. Using this concept provides us with constraints on predictions of climate change.

This article is an updated version of that published in the *Encyclopedia of Sediments and Sedimentary Rocks* (Hambrey and Glasser, 2003).

Historical background

It is widely recognized today that the Earth experienced a series of ice ages. However, when the concept was first promoted in the early nineteenth century, it met with fierce opposition. At that time, most of the unconsolidated deposits (so-called drift) that were familiar to geologists were attributed to the biblical Noah's flood. Indeed, the flood concept was used to explain the presence of large boulders displaced from their source bedrock ("erratics") that were deposited from icebergs (Hambrey, 1994, Chap. 1 for review). The Swiss natural historian, Agassiz, became the chief protagonist of the "Ice Age Theory," and when he delivered his ideas in 1837, they had a Europe-wide impact. In the following decades, through Agassiz's influence, geologists in the UK and North America gradually accepted the theory as being also applicable to their regions. In the second half of the nineteenth century, "ancient" glacial deposits (*tillites*) were recognized in many parts of the world. However, even in the second half of the twentieth century, the glacial origin of supposed tillites was challenged, notably those of Neoproterozoic age. It has taken systematic sedimentological investigations, coupled with an appreciation of modern glacial processes, to settle these debates.

Glaciological aspects of debris entrainment and transport

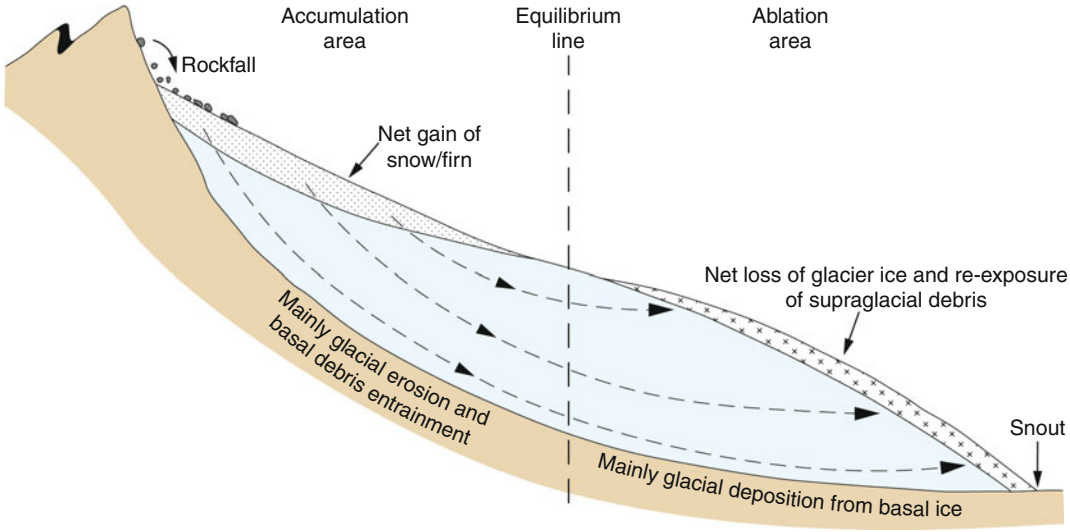
To evaluate the processes whereby sediment is entrained and deposited, we need to understand a number of key glaciological phenomena; several of these are dealt with more thoroughly in this volume (see Section "Cross-references").

Mass balance

The state of health of a glacier and its capacity to carry debris is a reflection of its mass balance, and the supply of debris from surrounding headwalls and from the base. A positive mass balance allows rapid burial of supraglacial debris and transport through an englacial pathway, while a negative mass balance sees the exposure and emergence of greater quantities of debris at the surface. The basal conditions also vary, with a positive mass balance causing the glacier to flow more rapidly and erode the bed more intensely, and a negative mass balance allowing stagnation and rapid deposition of the sediment load (Figure 1).

Glacier dynamics

In order to interpret the origin of glacial sediments and landforms, it is necessary to understand the mechanisms of ice deformation and glacier flow. Glaciers flow by one or more of three main mechanisms: internal deformation, basal sliding, and movement over a soft, deformable bed (Paterson, 1994). In simple terms, *internal deformation* results in the slowest flow occurring at the margins and at the base of a glacier, but large-scale reorganization of preexisting structures, with or without debris, through folding and foliation development is also common. *Basal sliding* is important where rain or meltwater is able to lubricate the bed, and varies according to the season and



Sediment Entrainment, Transport, and Deposition, Figure 1 Longitudinal profile through a valley or cirque glacier, illustrating the relationship between mass balance, particle paths (*arrows*), and debris entrainment processes.

time of day or night. Frictional and geothermal heating may add to the availability of meltwater. All these factors control erosion and regelation at the glacier bed. Many glaciers flow over a *deformable bed* of unconsolidated sediment which, when saturated, can behave as a slurry that enhances the flow of the glacier. Deformable beds exist beneath modern fast-flowing ice streams in Antarctica and Greenland, as well as many ice caps and outlet glaciers. Much of the movement of the Quaternary ice sheets in North America has also been linked to deformation of the bed. The relative importance of these mechanisms is highly variable. In moist temperate regions as much as 80% of glacier flow is from sliding. Cold polar glaciers, which are frozen to their beds, flow almost entirely by internal deformation. Polythermal glaciers (with both cold and warm ice) have a combination of sliding and frozen bed conditions. Debris entrainment commonly occurs where there is a transition between the two modes of flow. Where a deformable bed exists, the bulk of movement may be within the sediment layer beneath the ice, while the sediment itself is transported in conveyor belt–like fashion. In *surge-type glaciers*, flow is unstable, with long periods (often decades) of quiescence punctuated by short bursts (several months to a few years) of high velocity (*surges*). During the most active phase of a surge, the velocity may reach several orders of magnitude above normal, and the glacier may advance rapidly, and redistribute large volumes of sediment.

Glacier structure

Glacier structures are principally the product of internal deformation, and are intimately associated with the transport of debris (Paterson, 1994; Hambrey and Lawson, 2000). Glacier ice is similar to any other type of geological material in that it comprises strata that progressively deform to produce a wide range of structures. Primary structures in glacier ice include stratification derived from snow and superimposed ice, and unconformities. Regelation layering, resulting from pressure melting and refreezing at the base of a glacier, the latter also sometimes being referred to as stratified ice, although not strictly in the geological sense. Secondary structures are the result of deformation, and include both brittle features (crevasses, crevasse traces, faults, and thrusts) and ductile features (foliation, folds, boudinage). All these structures are associated with debris, whether by direct accumulation as rockfall (as in stratification), or by concentration in foliation as in shear zones between two merging flow units. Typically, a glacier reveals a sequential development of structures as in deformed rocks, so that by the time the glacier snout is reached, ice may record several "phases" of deformation. Similarly, the cumulative strain which glacier ice has undergone commonly changes the original geometry of the structure and associated sediment out of all recognition.

Thermal regime

The temperature distribution or *thermal regime* of a glacier is fundamental to glacier flow, meltwater production and routing, and to styles of glacial erosion and deposition. *Temperate* or *warm* glaciers, in which the ice is at the pressure-melting point throughout, tend to slide rapidly on their beds and are highly erosive. These glaciers are typical of alpine regions. *Cold* glaciers are the end member at the opposite temperature extreme, the ice being below the pressure melting point throughout; they occur in high polar regions or at very high altitudes only. These glaciers have long been thought incapable of eroding their

bed, although evidence from Antarctica indicates that this is not strictly true. An intermediate type of glacier, found especially in the high Arctic, is referred to as *polythermal*. In such glaciers, it is typical for the snout, margins and surface layer of the glacier to be below the pressure-melting point, whereas thicker, higher-level ice is warm based.

Glacier hydrology

Glacial erosion and sediment transport would be much less effective were it not for the presence of meltwater within, beneath, and beyond the glacier. Water, derived from melting snow and ice, flows in supraglacial rills, channels, and canyons cut into the glacier surface. If structural weaknesses exist, the meltstreams commonly plunge into the interior or bed of the glacier via moulins, before emerging at the snout. Drainage routes, and therefore sediment transport paths, differ according to the thermal regime of the glacier. In cold and polythermal glaciers, meltwater tends to be forced toward the glacier margins, as subzero ice prevents surface water penetrating far below the glacier surface. In contrast, water flows in discrete channels at the bed in temperate glaciers, often emerging from the glacier at a single portal. Glaciers act as natural storage reservoirs, retaining water and sediment in winter and releasing them in summer. Thus discharge is markedly seasonal and diurnal. On a typical braided outwash plain, beyond the glacier, marked fluctuations in discharge result in rapid, continuous channel shifts, and deposition of both suspended and bed-load sediment. Meltwater and sediment also accumulates in ice-constrained lakes, including ice-dammed, proglacial, supraglacial, and subglacial types. Many of these are ephemeral, and those dammed by ice, which are most commonly associated with polythermal glaciers, are particularly prone to catastrophic failure, resulting in outburst floods called *jökulhlaups*. Moraine-dammed lakes, which typically grow behind Little Ice Age moraines are also prone to catastrophic failure, notably in the Andes and the Himalaya. Glacial meltwater is not only a powerful erosive agent, but is also responsible for among the most important sedimentary facies in glacierized regions.

Morphological controls on sediment transport

As documented elsewhere in this volume, glaciers range in size from ice masses only a few hundred meters across to the huge ice sheets that cover Antarctica and Greenland, and there are thus many different morphological types (Hambrey, 1994; Bennett and Glasser, 2009; Benn and Evans, 2010). Ice sheets and ice caps carry most of their sediment load in the bed, where regelation processes have entrained the debris. Conversely, they carry little supraglacial debris, other than dust, or where compressive flow causes upward movement of basal debris in the terminal region. Valley and cirque glaciers carry much more supraglacial debris as a result of rockfall, induced by freeze-thaw processes, especially in high-relief temperate zones. Dealing with the past record, one of the key roles of the glacial sedimentologist is to reconstruct the morphological characteristics of former ice masses, in order to constrain the interpretation of past climates and sea-level response.

Glacial erosion

The processes whereby a glacier or ice sheet picks up and transports rock fragments and sediment, and transfers this material to another location are referred to as glacial erosion. In summary, glacial erosion occurs by means of four main processes: *glacial abrasion*, *glacial plucking* (or *quarrying*), *glacial meltwater erosion*, and *subglacial sediment deformation*, and gives rise to a wide range of spectacular landforms (Figure 2). Since glacial erosion is the starting point for debris entrainment and transport by glaciers and ice sheets, an understanding of this topic is essential if we are to understand the sedimentary products of ice masses.

Glacial abrasion is the process by which particles entrained in the basal layer of a glacier are dragged across the subglacial surface. The scratching and polishing associated with glacial abrasion tends to create smoothed rock surfaces, commonly with striations or grooves.

Glacial quarrying (or *plucking*) is the process whereby a glacier removes and entrains large fragments of its bed. The processes of rock fracture are controlled by the density, spacing, and depth of preexisting joints in bedrock, together with the stresses applied by the glacier. Fracturing of bedrock is also aided by the presence of meltwater beneath the glacier, where bedrock is loosened by subglacial water-pressure fluctuations. Material ranging from quarried blocks to fine material is then entrained in basal ice by freezing-on (*regelation*), when surrounded by flowing ice, or when incorporated along thrusts. Entrainment is most pronounced in polythermal glaciers, especially where there is a transition from sliding-bed to frozen-bed conditions, and a complex layer several meters thick may develop (Figure 3a). In contrast, the abundance of meltwater precludes substantial entrainment of debris in temperate glaciers, and the basal debris layer may be less than a meter thick (Figure 3b). Although not noted for being erosional agents, cold glaciers can entrain blocks of frozen subglacial sediment and bedrock as a result of shear at the ice/substrate contact (Figure 3c).

Glacial meltwater erosion involves both mechanical and chemical processes. Mechanical erosion occurs primarily through fluvial abrasion by the transport of suspended sediment and bedload within meltwater at the base of the glacier. Locally, fluvial *cavitation* (the sudden collapse of bubbles within turbulent meltwater under high pressure) may also be important. In subglacial channels, chemical erosion involves the removal of rock and rock debris in solution, especially in areas of carbonate bedrock. Rates of chemical erosion beneath ice masses are high because of high flushing rates, the availability of large amounts of chemically reactive rock flour, and the enhanced solubility of CO_2 at low temperatures.

Sediment Entrainment, Transport, and Deposition, Figure 2 Glacially sculpted peaks of Piz Morteratsch and Piz Bernina, Graubünden, Switzerland, with the glacier Vadret da Tschierva in the center. The huge lateral moraines on either side of the valley and the hummocky moraine in the foreground date from the Little Ice Age.

Subglacial sediment deformation is a relatively new concept, and is believed to be a major component of glacier flow beneath ice streams and valley glaciers (Boulton, 1996). The process involves net removal of wet sediment in conveyor belt–like fashion and can contribute to the progradation of sediment aprons or wedges where there is a sharp break in slope, for example, at the edge of a continental shelf or in a lake.

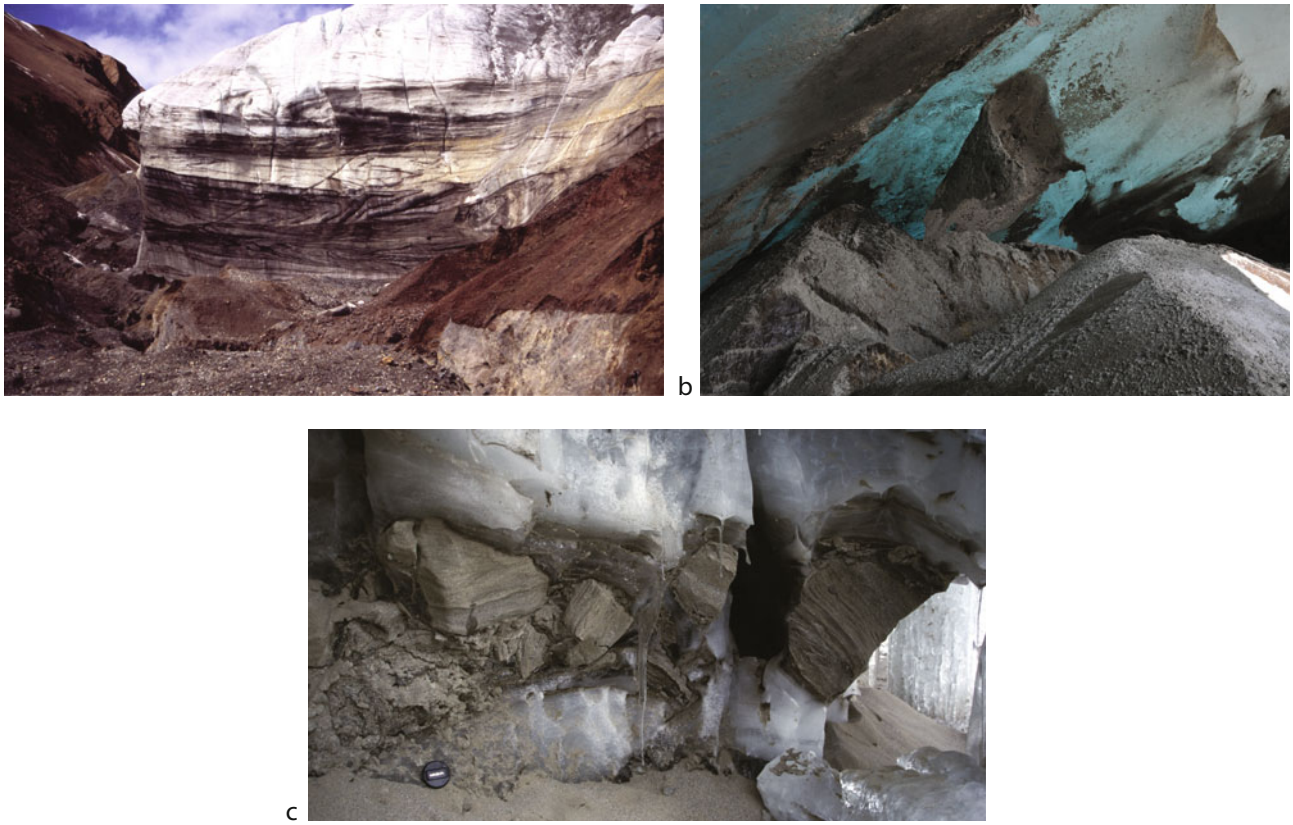
Debris entrainment and transport

Debris is entrained within a glacier both at the bed as basal glacial debris and at the surface as supraglacial debris. In addition, there is transfer of debris from low to high level and vice versa by means of a range of processes related to deformation of the ice (Figure 4). The following discussion considers both low- and high-level transport and stages in between, but in effect entrainment is a continuum of processes at different levels within the glacier. Transport paths and textural character of glacial sediments are related to the dynamic and thermal characteristics of the glacier. Broadly speaking, polythermal glaciers tend to carry a high basal debris load (Figure 3a), and the surface rarely has a substantial cover of debris. In contrast, temperate glaciers, especially those in high-relief regions, normally carry relatively little basal debris (Figure 3b), but the surface commonly has an extensive cover of supraglacial debris. The resulting sedimentary products can thus be used to infer the thermal and topographic regimes of a former glacier regime.

Low-level debris entrainment and transport

Debris is entrained at the bed by a combination of pressure melting and refreezing (regelation). Freezing to the base of the glacier occurs when the 0°C isotherm migrates into the substrate, sometimes even allowing sediment or bedrock to be entrained en masse. The thickness of the basal ice layer can be increased by folding and thrusting, or concentration around obstacles. These complex processes create a basal debris layer that comprises a wide range of ice types (or facies), involving frozen meteoric water, glacier ice, different concentrations of debris, and even solid sediment (Knight, 1997; Hubbard et al., 2009), as is well known from studies of both temperate and polythermal glacier margins (Figure 5). Basally derived debris is subject to abrasion, fracturing, and crushing at the ice/bedrock interface. The resulting entrained sediment is dominated by clasts up to boulder-size, with subangular and subrounded shapes, faceted surfaces, and striations (if the lithologies are fine grained) (Figure 6). In addition, much clay- or silt-grade sediment is produced by abrasion. Together, on deposition, the resulting sediment is poorly sorted with a wide range of clast shapes and sizes.

A second mechanism of debris entrainment at the glacier bed, discovered in recent years at a temperate glacier in Alaska, is associated with glaciohydraulic supercooling. This involves sediment-laden supercooled water refreezing to the glacier sole on the upslope side of an overdeepening in the glacier bed. The process preferentially selects finer-grained sediment, and can lead to the buildup of a several-meters-thick basal ice layer.

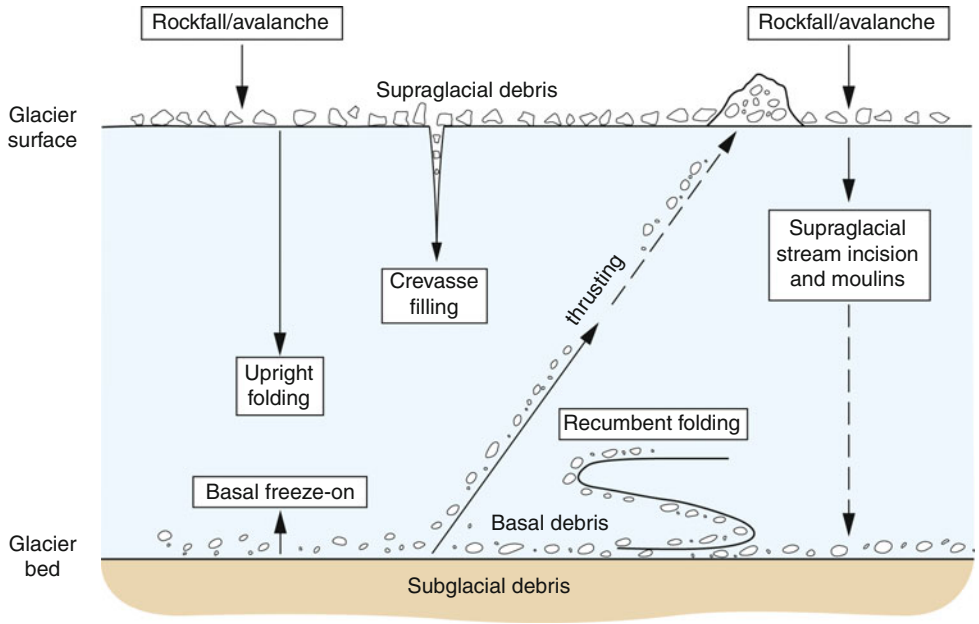


Sediment Entrainment, Transport, and Deposition, Figure 3 Debris entrainment compared in the base of thermally contrasting glaciers. (**a**) Several-meters-thick basal debris layer, repeated by folding in polythermal Trapridge Glacier, Yukon; the cliff is c. 10 m in height. (**b**) Minimal basal debris in a cave at the snout of temperate Rhonegletscher, Switzerland; a thin film of granitic sand mantles the bedrock, while a 1-m-wide folded layer of debris hangs from the roof. (**c**) Solid frozen blocks of glaciofluvial sand incorporated, boudinaged, and rotated in the base of cold Wright Lower Glacier, Dry Valleys, Antarctica.

High-level debris entrainment and transport

In high-relief areas, freeze-thaw processes on exposed bedrock in the accumulation area of a glacier result in rockfall onto the snowpack below, where it is buried as the layer of stratified snow, firn, and ice buildups. Similarly, along the flanks of the glacier in the ablation zone, rockfall allows debris to drape large areas of the glacier surface, sometimes covering it completely to a depth of several meters (Figure 7). Debris falling high in the accumulation area tends to take an englacial path and emerge near the snout, following the flow lines through the glacier, whereas debris falling close to the equilibrium line will follow a shallow englacial path and emerge a short distance down glacier (Figure 1). However, superimposed on this simple pattern are the complexities of folding, as discussed below. Supraglacial debris is generally dominated by gravel (pebble to boulder-sized) material, with few fines, and clast shapes are typically angular and very angular (Figure 7).

Debris on the surface of a glacier is commonly concentrated into flow-parallel ridges of debris, referred to as medial moraines, of which there are two types: *flow-unit interaction moraines* (also confusingly referred to as ice-stream interaction moraines) and *ablation-dominant moraines*. An understanding of structural glaciology is necessary to infer which is the correct mechanism involved. Flow-unit interaction moraines are formed by the confluence of two lateral moraines at the junction of two glacier flow units (Figure 8). The medial moraine consists of a debris-covered ridge that represents the surface expression of a vertical debris septum that may extend down to the bed of the glacier. The internal structure of the septum may be complex, consisting, for example, of anastomosing shears and isoclinal folding. Texturally, these moraines are highly variable; some consist of angular supraglacial debris, but others are mixed with sediment reworked at the ice/bed interface and so comprises more rounded material. *Ablation-dominant moraines* form



Sediment Entrainment, Transport, and Deposition, Figure 4 Schematic longitudinal cross section through a glacier, summarizing the various processes whereby debris is entrained and transported.

Sediment Entrainment, Transport, and Deposition, Figure 5 Deformed basal ice layer in a cave at the snout of Glacier de Tsanfleuron, Valais, Switzerland. The glaciologist (Bryn Hubbard) is standing on striated limestone bedrock, and there is a folded multilayered basal ice sequence to his right.

where ridges of englacial debris emerge from the ice surface in the ablation zone and extend to the snout. This type of moraine may form in two ways:

1. From a point source between two flow units in the accumulation area where the debris is initially buried and then takes an englacial path through the glacier. Structurally, these are similar to flow-unit interaction moraines.
2. Incorporation of angular rockfall material within the stratified sequence of snow and firn (Figure 9).

This debris takes an englacial path through the glacier, and becomes folded, especially in zones of lateral compression, such as where multiple accumulation basins feed into a narrow tongue. Fold styles range from the broad open "similar" type to isoclinal folds (with parallel limbs). In the ablation area, the debris emerges at the surface on the flow-parallel hinges and upper limbs of the folds, producing medial moraines that merge toward the snout. The resulting lines of debris are deposited on the proglacial area in the form of regular trains of angular debris, as the glacier recedes. This process has been inferred from several small valley glaciers in Svalbard and the Alps (Hambrey et al., 1999).

Sediment Entrainment, Transport, and Deposition, Figure 6 Striated and faceted clast of limestone on the proglacial basal till surface of Austre Lovenbreen, Svalbard.

The above mechanisms result in typical flow-parallel medial moraines than can be tracked long distances downglacier. However, perturbations in flow resulting from surging can distort the moraines into folds and loops (Figure 10). These contortions allow surge-type glaciers to be identified even when there is no historical record of a surge having taken place. Another situation where folded moraines develop is where narrow tongues spread out into piedmont lobes. In this case, the folds generate axes normal to the maximum compression that is parallel to the ice margin.

Debris transfer between low and high levels

An understanding of glacier structure is once again vital to appreciate how debris is redistributed within the glacier, especially where basal debris is uplifted to a higher-level position. In this context, glacier ice behaves no differently from any other geological material deforming where the Earth's crust is subject to lateral stresses. Debris in glaciers is transferred from the bed to an englacial and even a supraglacial position by three main glaciotectonic processes: thrusting, basal crevasse-filling, and incorporation within longitudinal foliation. Of these, the role of thrusting versus crevasse-filling has been much debated, and certainty of the mechanism cannot always be achieved.

Thrusts, typically inclined upglacier at angles ranging from a few to c. 40°, develop under longitudinal

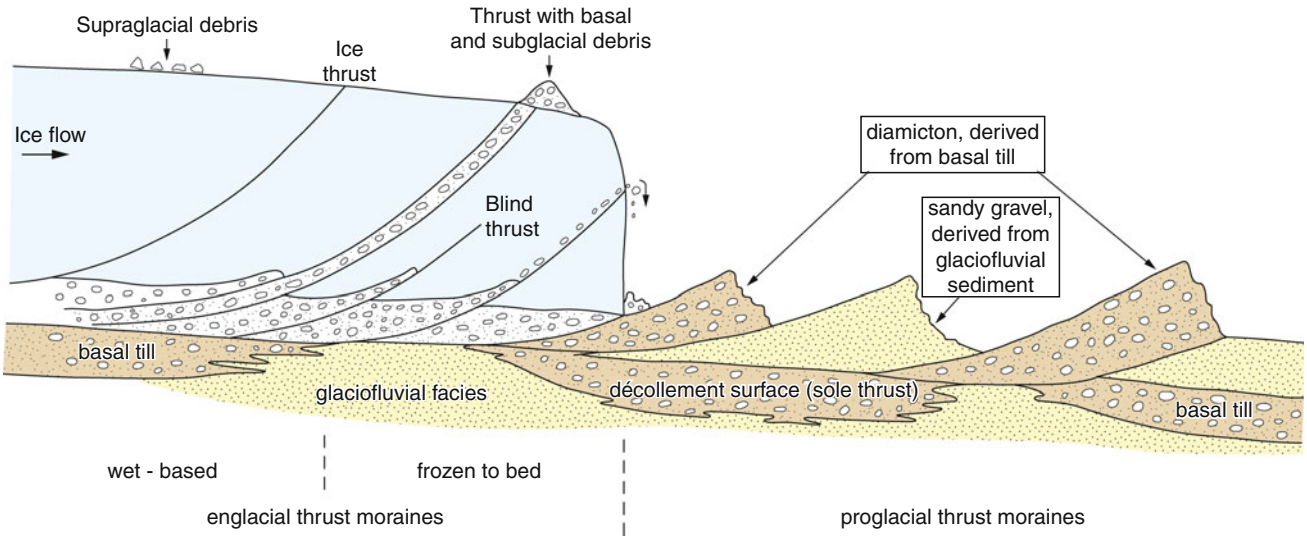
compression in three main situations: (1) where there is a downstream transition from a sliding to a frozen bed, as in polythermal glacier; (2) where ice flows against a reverse bedrock or sediment slope; and (3) in surging glaciers as the strongly compressive surge front moves down glacier. Thrusts carrying abundant debris are a feature of many polythermal and cold glaciers, but they also occur to a limited extent in temperate glaciers. Specifically, debris-rich basal ice (including regelation ice) and rafts of subglacial sediments are uplifted into an englacial position, sometimes emerging at the ice surface (Figure 11). This material is more varied than rockfall debris, and reflects the substrate lithologies: typically poorly sorted sediment (diamicton) with striated clasts (inferred to be basal till), sandy gravel (glaciofluvial sediment, and even laminated or stratified mud and sand (glaciolacustrine or glaciomarine sediment). The thrusts may extend upward to the ice surface and be associated with recumbent folding with lower limbs being sheared off at the thrust surface. Other so-called blind thrusts may terminate within the ice mass. As thrusts melt out at the glacier surface, groups of roughly aligned, commonly arcuate ridges and hummocks of basally derived sediment are formed.

Flowage of subglacial sediment into basal crevasses, followed by rotation during glacier flow, has also been inferred to explain the emergence of debris on inclined planes at the glacier surface. There are few direct sightings of basal crevasses, but such fractures are thought to occur especially when a glacier surges over a soft deformable bed of till. Once they attain a moderate angle, they resemble thrusts, and discrimination between the two processes relies on whether the feature is associated with basal ice, in which case the thrusting mechanism is most likely. The sedimentary product of incorporation of debris into basal crevasses is a suite of meter-scale landforms referred to as crevasse-fill ridges.

A third mechanism involves incorporation of debris of both supraglacial and basal character within longitudinal foliation. This process is particularly evident at the glacier margins and at flow-unit boundaries where the folding is commonly isoclinal. The folding has an axial planar relationship with the foliation. At depth, it is inferred (but not so far observed) that the lateral compressive regime that produces high-level folding, also induces folding is soft subglacial and basal sediments of the same geometry (Figure 9). As these features melt out, low (meter-scale) longitudinal ridges form that are similar to, but genetically different from, flutes; these are referred to as "foliation-parallel ridges."

Debris transfer between high and intermediate levels

In addition to burial and folding of supraglacial debris, described above, debris can enter an englacial position via crevasses. Crevasses generally do not penetrate to the bed, and in temperate glaciers are theoretically no more than 30 meters deep unless water filled. Structures commonly influence the pattern of supraglacial and englacial drainage. For example, a moulin that captures a supraglacial stream may form along a crevasse trace, which acts as a plane of weakness in the ice. Supraglacial sediment washed into the stream may tumble into the moulin and enter an englacial position or even reach the bed.



Sediment Entrainment, Transport, and Deposition, Figure 11 Simplified model of thrusting as exemplified by an advancing polythermal glacier, with thrusts propagating beyond the ice margin into frozen ground of the forefield.

Glacial depositional processes and facies

Glacial sedimentation involves the direct release of debris that has been transported on or within glacier ice. Debris is modified during transport primarily by basal processes (e.g., abrasion, crushing, and quarrying during intra-clast collision, subglacial sediment deformation), and by water in subglacial, englacial, and supraglacial stream channels. Debris that follows a passive transport path (supraglacially or englacially) tends to retain its primary characteristics.

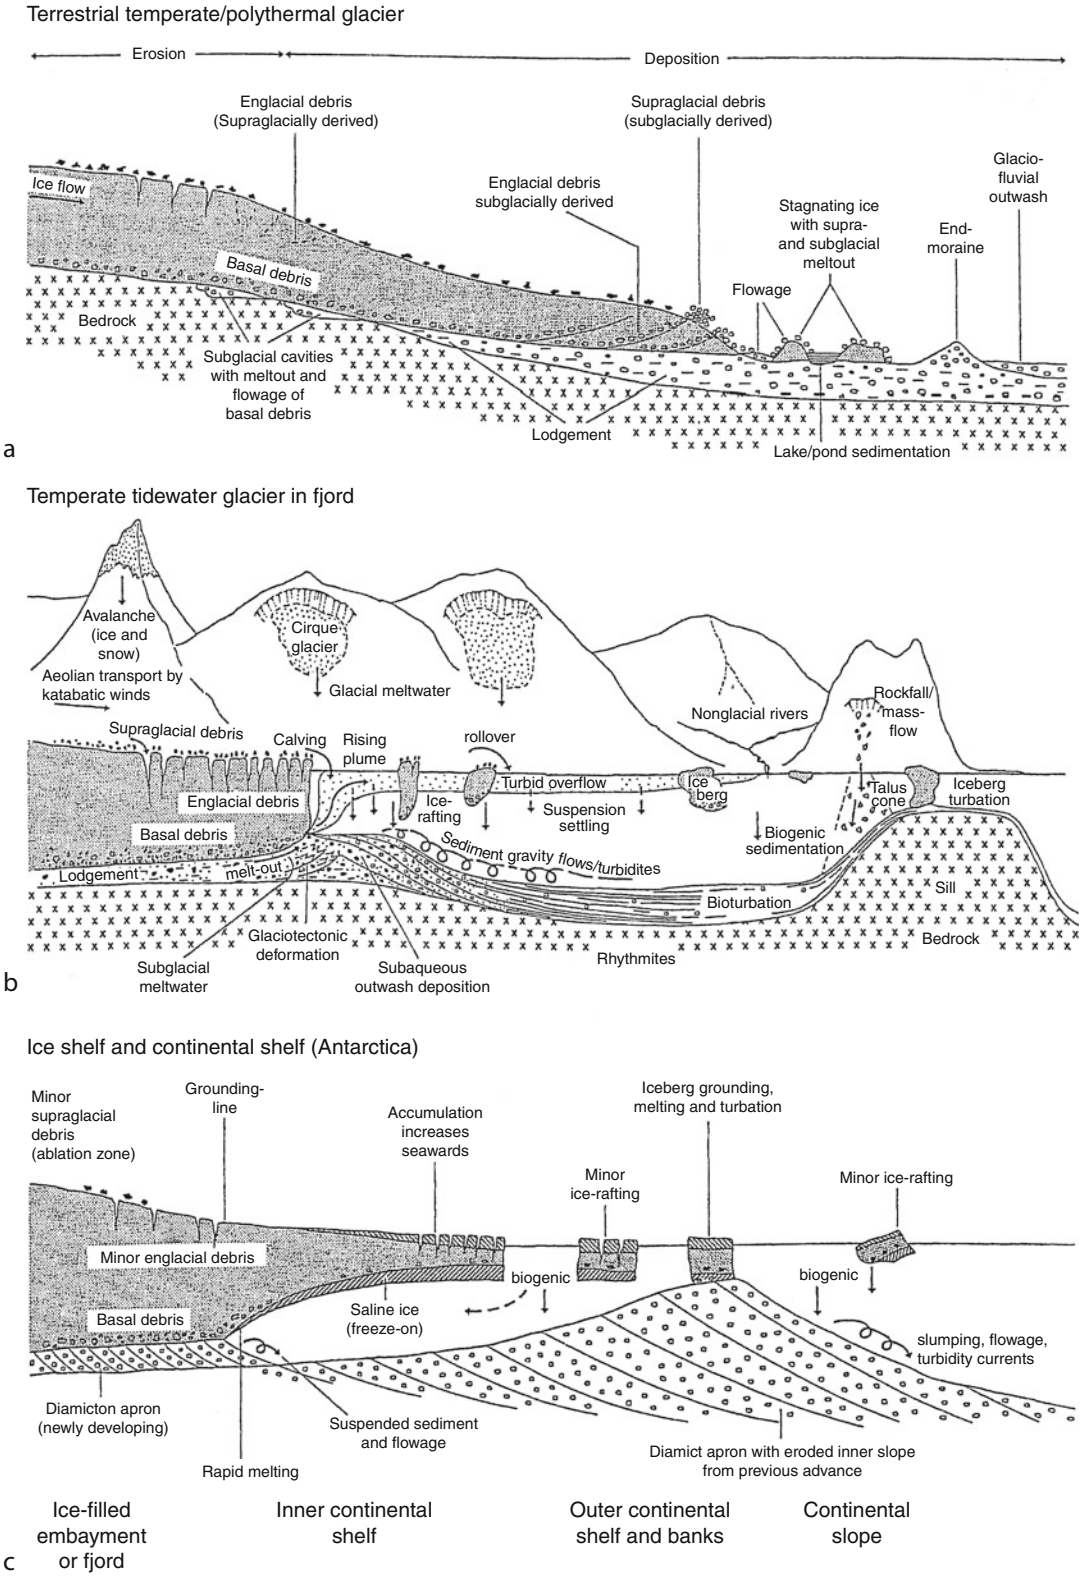
Sediment may be deposited directly beneath the glacier or at its margins, or it can be transported significant distances from the glacier itself by other agents such as rivers or by iceberg calving. During release from the ice, numerous glacier-related processes, including reworking in marginal streams and lakes, debris flows, and aeolian activity, may modify sediment. Many glacigenic sediments may be related to specific glacial environments. For example, the temperate terrestrial glacier system is commonly regarded as being dominated by a mixture of basal (actively transported) and supraglacial (passively transported) sediment, with a strong element of glaciofluvial modification upon release (Figure 12a). Glaciers terminating in fjords produce a suite of sediments that is also dependent on thermal regime. Temperate and polythermal glaciers, such as those in Alaska and Greenland, respectively (Figure 12b), not only provide basal and supraglacial debris inputs, but also sediments released from subglacial streams emanating at or below water level close to the ice margin, sediment released from suspension over the whole depositional basin, and iceberg-rafted debris. The resulting sediment associations reflect thermal regime, which primarily controls the balance between direct glacial deposition and fluvial inputs. For the coldest glaciers, terminating as ice shelves on the continental shelf, as in Antarctica today, direct glacial deposition is restricted to the grounding line, while the volume of meltwater sediments is limited. Rather, biogenic sedimentation in the form of diatom ooze may become dominant (Figure 12c). Indeed, rather than releasing sediments, some ice shelves accrete saline ice at their base, trapping sediment, which is released only when the tabular icebergs, calved from the ice shelf, disintegrate.

Glaciotectonism

Glaciotectonic deformation is now recognized as a widespread phenomenon (Maltman et al., 2000). Commonly visible at the scale of entire moraine complexes (Figure 13), it is also widely recognized at the microscopic level and recent years have seen substantial advances in understanding the role played by deformation in the character of glacial sediments. Not only is deformation associated with internal processes, such as folding and thrusting, as noted above, but it is also transmitted subglacially and proglacially. Glaciotectonic deformation operates in any topographic setting, both during advancing and recessional phases, and involves all types of material, including frozen, saturated, and dry unconsolidated sediments, as well as bedrock. Deformation may detach blocks of rock and sediment, occasionally hundreds of meters across, incorporating them into the ice by thrusting or pushing them in front of the glacier. Faults and brecciated zones are common in such materials. Sediments may also be deformed in ductile fashion, especially if wet and fine grained. Beneath ice sheets, deformation may affect sediment and bedrock to depths of several hundred meters.

Reworking of glacigenic sediments

Glacigenic sediments are typically subject to syn-depositional and postdepositional modification by fluvial, mass-movement, and aeolian processes. In terrestrial settings, fluvial modification by proglacial streams is



Sediment Entrainment, Transport, and Deposition, Figure 12 Depositional processes and products in a selection of glacial environments: (**a**) terrestrial, (**b**) fjord with temperate tidewater glacier, and (**c**) ice shelf on the Antarctic continental margin. Sediment Entrainment, Transport, and Deposition, Figure 13 Glaciotectonic deformation exemplified by the push moraine complex at Dinas Dinlle, North Wales. The section is exposed in a coastal cliff and the subsurface geometry was revealed by a seismic survey. (Modified from Harris et al., 1997.)

particularly important in temperate climates, and many temperate glaciers terminate at the head of large *outwash* or *sandur* plains composed almost entirely of reworked glacial sediments. Resedimentation by mass-movement processes is common in ice-cored terrain where water, released by the melting of buried glacier ice or permafrost, mixes with sediment to create *glacigenic sediment flows*. Modification by wind, especially in cold arid environments such as Antarctica, involves the redistribution of sand and silt, creating *deflation surfaces* and *ventifacts*. The extent to which each of these processes operates is controlled to a great extent by the local topographic, meteorological, and climatological conditions. Resedimentation by subaqueous gravity flows is also important in glaciomarine and glaciolacustrine environments, where large volumes of sediment may accumulate on relatively steep ice-contact slopes that become unstable during recession.

Terminology of terrestrial glacigenic sediments

The terminology used to describe glacigenic sediment has always been in a state of flux, and the evolution of terms may be linked to progressive improvement of understanding glacial processes. For an objective study of glacigenic sediments, a nongenetic classification of poorly sorted sediments is required. The use of process-focused terms such as "till" should only follow from careful description of a wide range of attributes, including texture, clast-shape and surface characteristics, bed-geometry, and boundary relationships.

The terms *diamicton* (unlithified), *diamictite* (lithified), and *diamict* (both) are now well established for "a nonsorted or poorly sorted terrigenous sediment that contains a wide range of particle sizes" (Flint et al., 1960). However, this definition hides a vast range of textures, and the literature abounds with conflicting ideas about what constitutes a "diamicton." A textural classification, based on the relative proportions of sand and gravel, has subsequently been developed (Hambrey and Glasser, 2003) (Table 1).

The genetic terminology is perhaps even more confused. First, we need to define some widely used general terms:

Glacigenic sediment: "of glacial origin"; the term is used in the broad sense to embrace sediments that have been influenced by glacier ice.

Glacial debris: material being transported by a glacier and thus in contact with glacier ice.

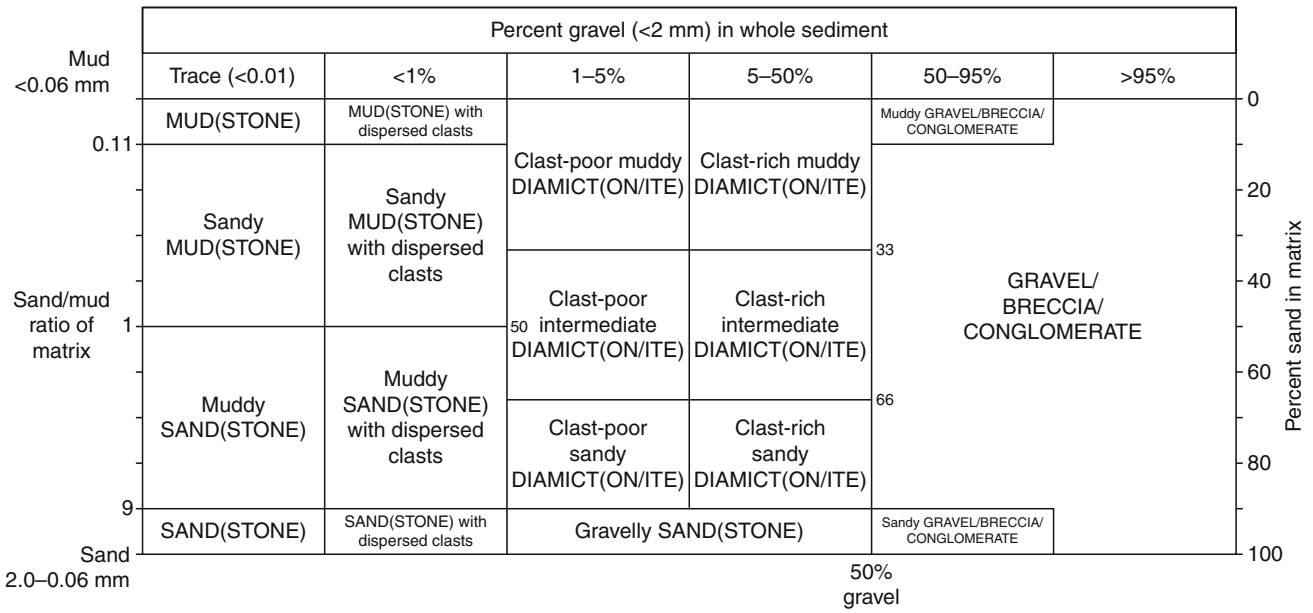
Glacial drift: a general term embracing all rock material in transport by glacier ice, all deposits released by glaciers, and all deposits predominantly of glacial origin deposited in the sea by icebergs, or from glacial meltwater.

Till: sediment deposited directly by glacier ice that has not been subsequently disaggregated by flow or gravity. There are several subcategories of till, which are explained below.

Subglacial sedimentary processes

It is evident from the general nature of the above terms that texturally glacigenic sediments are exceedingly variable, and therefore a lack of consensus as to their appearance is apparent in the literature. Nevertheless, there are several processes which have been identified by which debris in transport is deposited: lodgement, meltout, flow, subglacial deformation, and sublimation. All these processes give rise to subcategories of till, and all are widespread except sublimation till, which is confined to the cold arid environment of Antarctica. This classification of till has traditionally been widely used and adopted by the International Quaternary Association (Dreimanis, 1989; Hambrey, 1994), but these distinctions have been challenged over the past decade following the development of microstructural (micromorphological) analysis of till in thin section. Indeed, most "tills" form by a combination of processes, especially in the subglacial environment, and they are thought by some to be the product of deformation rather than depositional processes; hence the new term *tectomict* (Bennett and Glasser, 2009 give an up-to-date synthesis of this issue).

Sediment Entrainment, Transport, and Deposition, Table 1 Textural classification of poorly sorted sediments (From Hambrey, 1994; modified from Moncrieff 1989). In order to derive sediment name, percent of gravel is first estimated (horizontal axis) and then the proportion or percent of sand in the matrix (vertical axis)



Supraglacial sedimentary processes

Debris on the glacier surface includes material that has fallen on the surface via rockfalls and passively transported as well as basally derived debris that originates where flow units combine, or where glaciotectonic processes have lifted basal sediments from the bed. This debris accumulates as a result of melting under the influence of solar radiation. A thin cover of debris will enhance melting, but as the debris accumulates, it retards melting, so debris-covered areas tend to be elevated compared with surrounding ice surfaces. Debris is concentrated into mounds and ridges, and as slopes increase in angle by the differential melting, it is prone to constant movement by sliding and slumping. Sediment thus accumulates in hollows which, when sufficiently thick, retards ablation so gradually becoming a new high point – a process known as topographic inversion.

Glaciomarine (or glacimarine) sedimentation

Glaciomarine sediments are much less studied than terrestrial glacigenic sediments, but nevertheless considerable strides in understanding have been made in recent years. Sediments are released into the ocean via several processes, giving rise to a distinctive suite of attributes that are subtly different from their terrestrial counterparts.

Ice-proximal glaciomarine sediment comprises debris that is released either from floating basal glacier ice or by continuous rain-out from icebergs, without subsequent winnowing by currents and waves.

Ice-distal glaciomarine sediment is debris that is released from icebergs, but in this case subject to winnowing and admixing with other marine sediment, including biogenic components. Texturally, this facies is sandy mud or muddy sand with dispersed clasts, and in modern environments is often rich in diatoms.

Iceberg turbate is sediment deposited on the sea floor that is subsequently reworked by grounded icebergs. The end product is commonly a massive diamicton with a heavily grooved upper surface.

Cyclopels (silt/mud couplets) and *cyclopsams* (graded sand/mud couplets) are rhythmically laminated sediments derived from turbid overflow plumes originating from subglacial discharge, especially in fjords, typically producing two couplets a day according to the tidal cycle.

Subaqueous sediment flows are the product of remobilization of all of the above sediment types. They range from massive uniform diamicton, resulting from down-slope creep or mobile flow, as on land, to well-graded beds of mud, sand and gravel where disaggregated in a turbidity flow.

Glaciolacustrine (or glacilacustrine) sedimentation

Glaciolacustrine sediments are similar to those in glaciomarine environments. In addition, lakes commonly have rhythmically laminated sand and mud called *varves*. They are similar to cyclopsams and cyclopels, but each couplet forms over 1 year.

Facies analysis of glacigenic sediments

The facies approach

For objective treatment of glacial sediments, and following other branches of sedimentology, the facies approach must be used. The first step is to describe the *lithofacies* (types of sediment) found in a vertical section or core, using a wide range of criteria (texture, sedimentary structures, bed geometry and boundary relations, clast characteristics), and avoiding genetic terms such as "till." Some authors use a formal lithofacies code (Eyles et al., 1983) which has been widely adopted, but this is thought by others (e.g., Hambrey, 1994; Miller, 1996) to be too inflexible and not totally objective as it includes interpretative elements.

The next step is to group the lithofacies into *facies associations* that contain a set of attributes that will allow the depositional setting to be determined, such as glacioterrestrial or glaciomarine. On a regional scale, given sufficient three-dimensional exposure on land, or extensive seismic and borehole stratigraphy offshore, derivation of the *facies architecture* is a desirable aim, allowing one to address larger issues, such as basin evolution, ice sheet–scale fluctuations and sea-level changes. Representative facies associations from terrestrial, lacustrine, and glaciomarine settings are illustrated in Figure 14.

Glacial sediment/landform associations

The concept of *glacial sediment/landform associations* (the "*landsystem*" approach) rests on the assumption that, at the large scale, it is possible to identify areas of land with common attributes, distinct from the surrounding areas, that can be related to the processes involved in their development (Benn and Evans, 2010; Evans, 2003). The landsystem approach was pioneered for glaciated terrain in an attempt to identify tracts of land created by similar till-forming processes and therefore of similar geotechnical properties. The *glacial landsystem* concept was then applied to former ice-sheet beds. Originally, three distinct landsystems were defined: (1) the *subglacial landsystem*, in which the dominant glacial sediment/landform associations are formed at the glacier bed; (2) the *supraglacial landsystem*, in which the dominant glacial sediment/landform associations are largely composed of a drape of supraglacial debris; and (3) the *glaciated valley landsystem*, in which the dominant glacial sediment/landform association is that formed by mountain glaciation.

As the concept has developed, other landsystems have been added to this simple list (Evans, 2003). These include landsystems formed in proglacial and glaciomarine environments, as well as those found in settings where surge-type glaciers are common. It is also possible to define landsystems according to glacier thermal regime. Thus we can identify landsystems related to warm-based ("temperate"), polythermal, and cold-based ("polar") glacier margins. A criticism of the landsystems approach is that it takes little account of spatial patterns of ice-sheet erosion and deposition, and how these vary during ice-sheet growth and decay.

Glacial depositional landforms

Glaciers and ice sheets produce a huge variety of depositional landforms that are commonly grouped according to their origin into ice-marginal and subglacial types (Hambrey, 1994; Menzies, 1995, 1996; Bennett and Glasser, 2009; Benn and Evans, 2010). Distinguishing between the different types of moraine is important for reconstructing the size, morphology, and dynamics of former ice masses.

Ice-marginal landforms. Ice-marginal landforms can be produced by advancing, stationary, or receding ice margins, as well as during seasonal fluctuations of the glacier terminus. These landforms include *glaciotectonic moraines, push moraines, dump moraines*, and *thrust-block moraines* (Figure 11).

Ablation moraines (sometimes referred to as *ice-cored moraines*) form wherever ice-melt is retarded beneath a cover of supraglacial debris (Figure 12). If the cover of insulating debris is irregular, irregular ridges and mounds of debris, referred to as *hummocky moraines* or *moraine-mound complexes*, will develop.

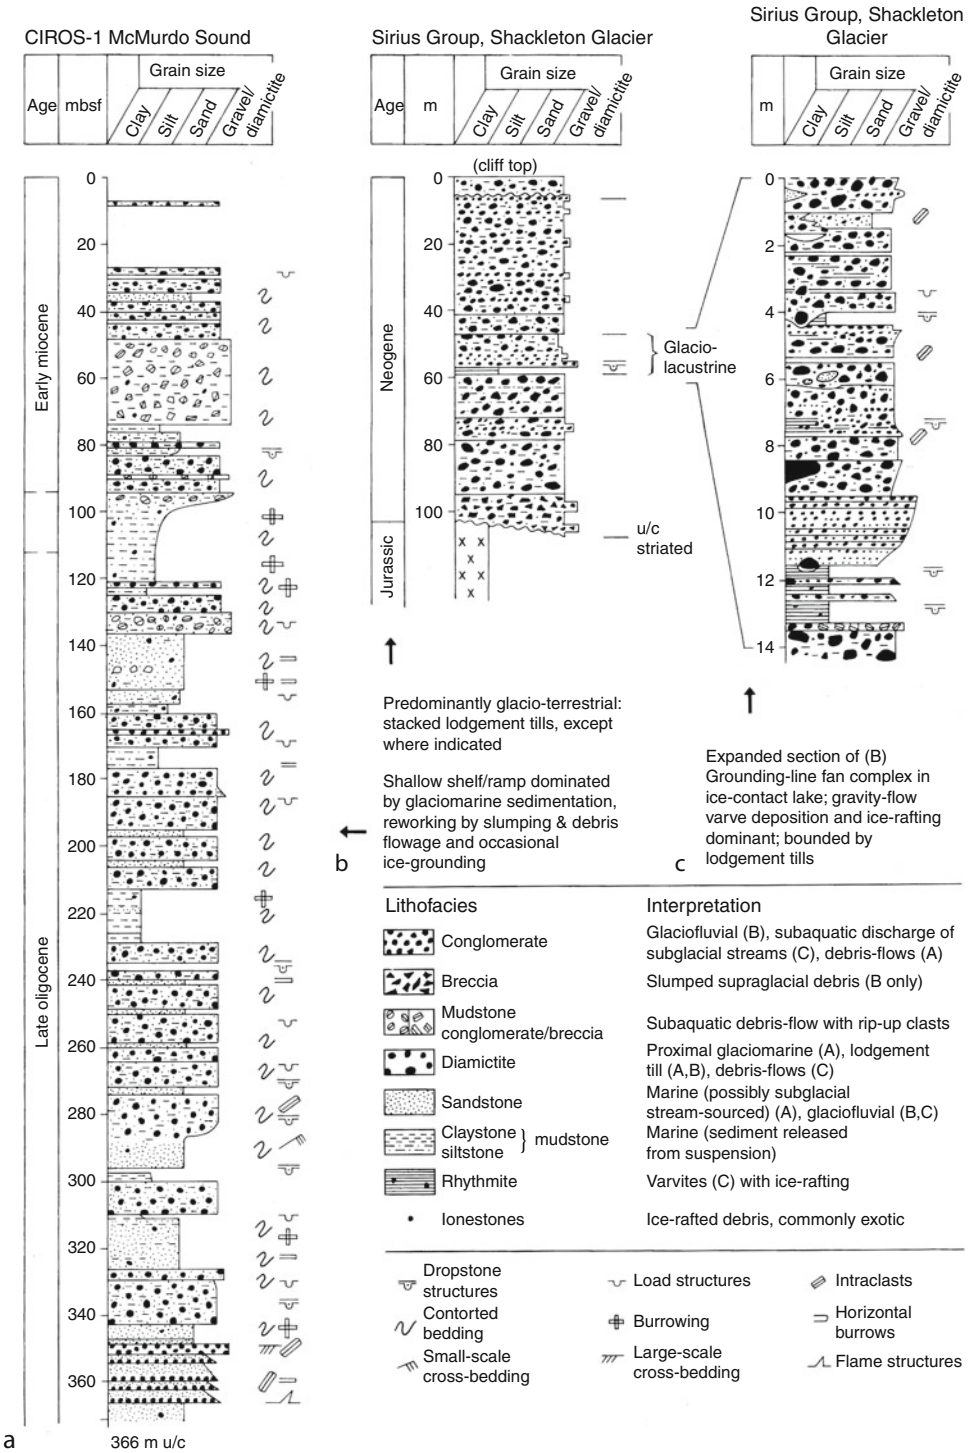
Subglacial landforms (sometimes referred to as *subglacial bedforms*) are produced beneath actively flowing ice. They provide information about former subglacial conditions, including ice-flow directions, thermal regime, and paleohydrology. The most common of these is a family of ice-molded landforms, all of which are parallel to ice flow. This includes *flutes, megaflutes, mega-scale glacial lineations*, and *drumlins.*

Ribbed moraines (also known as *Rogen moraines*) are large, regularly and closely spaced moraine ridges consisting of glacigenic sediment.

Geometric ridge networks and *crevasse-fill ridges* are subglacial landforms that are not generally ice-molded. They form by the squeezing of subglacial material into basal crevasses or former subglacial tunnels, commonly during surges, or beneath glaciers as a result of the intersection of foliation-parallel ridges and englacial thrusts.

Eskers are glaciofluvial landforms created by the flow of meltwater in subglacial, englacial, or supraglacial channels. *Concertina eskers* are deformed eskers, created by compression beneath overriding ice.

Outwash fans and *outwash plains* (or *sandar*, plural; *sandur*, singular) are formed as glacial meltwater emerges from the glacier and sediment is deposited at or beyond the ice margin. Outwash fans form at stationary ice margins where meltwater is concentrated at a particular point for a length of time. Outwash plains are much larger features, formed where individual fans coalesce away from the glacier to create a braided-river facies association. Characteristics of the glaciofluvial environment are braided river channels with rapidly migrating bars, terraces, frequent channel avulsions, and the formation of *kettle holes* where sediment is deposited over buried ice.



Sediment Entrainment, Transport, and Deposition, Figure 14 Characteristic glacigenic facies associations from marine and terrestrial settings in Antarctica. (**a**) Late Oligocene – Early Miocene proximal continental shelf facies association, upper part of CIROS-1 drill-core, McMurdo Sound, illustrating deposition in a subsiding rift-basin, with occasional ice-grounding events (after Barrett, 1989). (**b**) A terrestrial glacigenic facies association dominated by repeated lodgement till deposition, represented by stacked diamictites, but with a lacustrine phase of sedimentation in midsection: Sirius Group (Neogene), Shackleton Glacier, Transantarctic Mountains. (**c**) Enlargement of the glaciolacustrine facies association in B illustrating ice-proximal deposition dominated by slumping and debris flowage of rain-out diamictite and varve-sedimentation. (From Middleton, 2003 published with permission of Kluwer Publishers, Dordrecht.)

Kame terraces are formed when sediment is deposited by meltwater flowing laterally along an ice margin. *Kames* are more fragmentary features, formed in a similar manner, but often in ice-walled tunnels and against steep valley sides. *Kame-and-kettle topography* is the term used to describe the landform-sediment assemblage often found on glacier forefields where there was formerly a high proportion of buried ice.

Bathymetric forms resulting from glacial processes

Erosional forms

Various erosional phenomena, mainly associated with grounded ice or subglacial meltwater are found in marine settings. The larger-scale forms are filled by sediment and may be recognizable in seismic profiles (e.g., Anderson, 1999). *Submarine troughs* are found on continental shelves, and are genetically equivalent to fjords and other glacial troughs, but are generally much broader. Formed by ice streams, the largest occur in Antarctica where they attain dimensions of over 400 km in length, 200 km in width, and 1,100 m in depth. Where two ice streams merge, an *ice-stream boundary ridge* is formed. Steep-sided channels a few kilometers wide, carved out by subglacial meltwater and subsequently filled by sediment are known as *tunnel valleys*. These are well known from the NW European continental shelf around Britain, the Scotian Shelf off Canada, and in Antarctica. Icebergs can also cause considerable erosion as they become grounded on the sea floor. Large tabular bergs can scour the bed of the sea for several tens of kilometers, leaving impressions up to 100 m wide and several meters deep. *Slope valleys* are groups of gullies forming a dendritic pattern that develop just beyond the ice margin, on the continental slope, as a result of erosion by sediment gravity flows that emanate from sediment accumulation at the ice margin. On continental shelf areas, where the ice repeatedly becomes grounded, and then releases a large amount of rain-out sediment, alternations of diamicton and *boulder pavements* may be observed. The pavements build up by accretion of boulders around an obstacle, by subglacial erosion, or they represent a lag deposit from winnowing by bottom currents.

Depositional forms

The morphology and sediment composition of subaquatic features, particularly in fjords and on continental shelves are less well known than their terrestrial counterparts, but major strides have been made in identifying such features in the last 3 decades. As on land, depositional assemblages reflect the interaction of a wide range of processes and they comprise a diverse range of sediments.

Ice-contact features form when a glacier terminus remains almost stationary in water, particularly in fjords (Powell and Cooper, 2002). *Morainal banks* form by a combination of meltout from basal ice, dumping of englacial and supraglacial debris, push and squeeze processes, combined with glaciofluvial discharge. The end product is an assemblage of poorly sorted deposits with some evidence of glaciotectonically disturbed stratification (Figure 15). *Grounding-line fans* extend from a subglacial tunnel that discharges meltwater and sediment into the sea, and are typically composed of sand and gravel. A series of such fans may develop if glacier recession is interrupted. Developing out of grounding-line fans are *ice-contact deltas* that form when the terminus remains stable long enough for sediment to build up to the surface of the fjord. Where a glacier becomes disconnected from the water body, alluvial sediments may prograde to form *fluviodeltaic complexes*, which comprise sand and gravel. In addition to these large-scale forms (measured in hundreds of meters), there are small-scale features (measured in meters or less), found particularly on beaches, such as iceberg tool-marks, ridges, depressions from melting of buried ice, bounce-marks, chattermarks, and roll-marks. Icebergs can also churn up submarine sediment, particularly on shoals, producing *iceberg turbates*.

Depositional forms on continental shelves are best known from a combination of deep drilling and seismic profiling. Some, as in Alaska, are simply larger-scale analogues of fjordal features, such as delta-fan complexes, but others form under floating tongues that are typical of the colder ice of the polar regions. These include subglacial deltas, till tongues, diamicton aprons, and the immense (up to 400 km wide) trough-mouth fans, all of which are commonly associated with ice streams. Other features are similar to those on land, including shelf moraines, flutes, mega-scale glacial lineations, and transverse ridges.

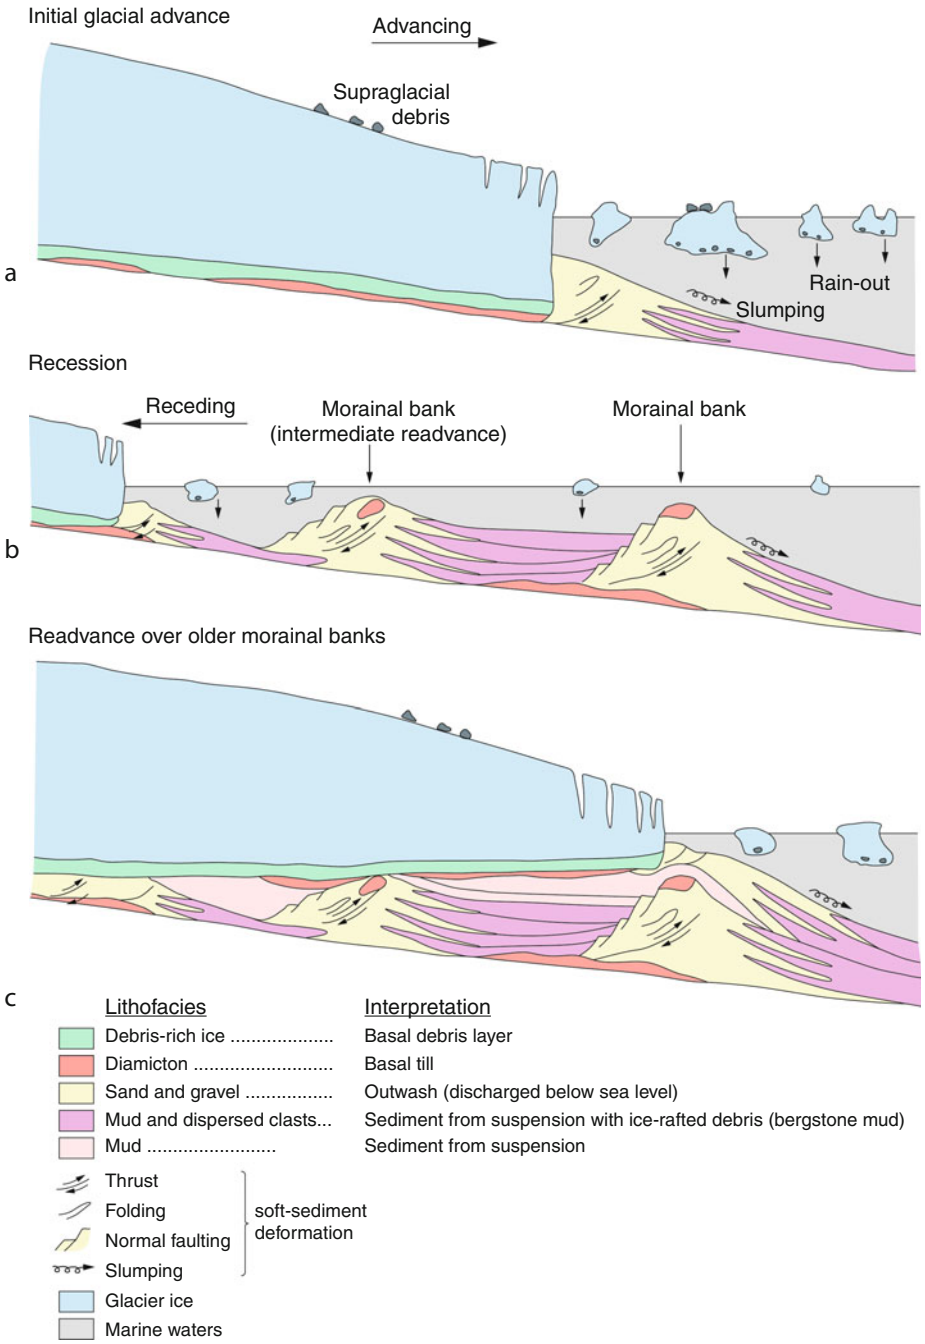
Glacial sediments in the geological record

Identification of glaciation in the geological record

The recognition of glacigenic sediments and landforms in the rock record is of fundamental importance to the emerging field of paleoglaciology, which embraces paleoclimatological and paleoenvironmental reconstructions. Even where exposure is good, evidence for glaciation may be equivocal as, for example, in alpine regions where mass-movement and fluvial processes may overprint direct evidence for glacial deposition, or in those areas where tectonic deformation has overprinted depositional features. However, detailed analysis may yield sufficient criteria that, taken together, could form the basis of a glacial interpretation.

Preservation potential of glacigenic successions

Tectonic setting is the principal control on whether a glacial succession is preserved. Eyles (1993) provided a detailed review of the wide range of tectonic settings suitable for preservation. Intracratonic basins, rifts, forearc and backarc basins, and subsiding continental shelves are particularly suitable receptacles for accumulation and preservation of glacial sediments, especially if those sites are first buried and later uplifted and exposed. Except for deposits of Quaternary age, land areas are less likely to preserve glacial sediment, as continued erosion tends to



Sediment Entrainment, Transport, and Deposition, Figure 15 Conceptual model for the development of the morainal bank facies association, as exemplified by the succession recovered by the Cape Roberts Drilling Project, western McMurdo Sound, Antarctica. (Simplified from Powell and Cooper, 2002.)

remove traces of glaciation. There are, however, notable exceptions in the geological record.

Earth's glacial record

Far more is known about the Quaternary glaciations than all previous glaciations put together, even though some of those earlier events were equally dramatic in terms of scale. Since the International Geological Correlation Programme compiled an inventory of all known pre-Quaternary glacigenic sequences (Hambrey and Harland, 1981), several syntheses have been undertaken (e.g., Eyles, 1993; Deynoux et al., 1994; Crowell, 1999). For the Quaternary Period there is a vast literature from which to choose.

The oldest known glacigenic sediments are of late Archaean age (2,600–3,100 Ma) from South Africa. Extensive Paleoproterozoic (2,500–2,000 Ma) tillites are known from South Africa, Australia, and Finland. The most prolonged and globally extensive glacial era took place in Neoproterozoic time (1,000–550 Ma). Evidence for glaciation occurs on all continents, leading to the "snowball earth" hypothesis that envisages the Earth being totally ice covered, although this concept has proved highly controversial (Allen and Etienne, 2008). Sporadic Early Paleozoic glacial events are best represented by the late Ordovician to early Silurian deposits and erosional features of the supercontinent of Gondwana, notably in Africa. The most prolonged and extensive phase of glaciation during the Phanerozoic Eon spanned about 90 Ma of the Carboniferous and Permian Periods, affecting all Gondwana continents. Finally, after a phase of global warmth, with little evidence of ice on Earth, the Cenozoic glaciations began in Antarctica at the Eocene/Oligocene transition (c. 34 Ma). Northern Hemisphere glaciation followed, with minor ice-rafting events recorded in the North Atlantic from late Miocene time, until full-scale glaciations began in late Pliocene time (2.4 Ma) and continued through the Quaternary to the present day.

Summary

Sediment entrainment, transport, and deposition are important in understanding the legacy of former glaciers and ice sheets. The entrainment and transport processes depend primarily on glacier mass balance, dynamics, structure, thermal regime, hydrology, and morphology. Sediment entrainment takes place at the bed and the surface of a glacier, and there are transfers between both zones. Structural evolution plays a key role in defining the distribution of sediment through a glacier. Structural processes are also evident in the depositional environment, especially in terms of glaciotectonic deformation of sediments and landforms, for example, through folding and thrusting. Systematic analysis of the sedimentary record following deposition, through the facies approach, allows inferences to be made about the environments of deposition and paleoclimates, and approach which is valid not only for understanding the Quaternary record, but also that of ancient glaciations.

Definition

Erosion (mobilization), transport (transfer), and deposition (accumulation, storage) of sediment within a defined area (landscape unit).

Introduction

Geomorphologic processes, responsible for transferring sediments and affecting landform change, are highly dependent on climate, and it is anticipated that climate change will have a major impact on the behavior of Earth surface systems. Research on sedimentary fluxes from source to sink in a variety of different climatic environments is very well documented in the literature. Studies on source-to-sink fluxes generally refer to the development of sediment budgets. A sediment budget is an accounting of the sources and disposition of sediment as it travels from its point of origin to its eventual exit from a defined landscape unit like a drainage basin (e.g., Reid and Dunne, 1996). Accordingly, the development of a sediment budget necessitates the identification of processes of erosion, transport, and deposition within a defined area, and their rates and controls (Reid and Dunne, 1996; Slaymaker, 2000; Beylich and Warburton, 2007). The fundamental concept underpinning source-to-sink sediment flux and sediment budget studies is the basic sediment mass balance equation:

$$I = O + -\Delta S$$

where inputs (I) equal outputs (O) plus changes in net storage of sediment (ΔS). Source-to-sink study allows quantification of the transport and storage of sediment in a system. A thorough understanding of the current sediment production and flux regime within a system is fundamental to predict likely effects of changes to the system, whether climatic induced or human influenced. Source-to-sink sediment flux and sediment budget research therefore enables the prediction of changes to erosion and sedimentation rates, knowledge of where sediment will be deposited, how long it will be stored, and how much sediment will be remobilized (Gurnell and Clark, 1987; Reid and Dunne, 1996; Beylich and Warburton, 2007).

Sediment sources

Sediments are eroded and mobilized in source areas. Sediment sources are diverse and subject to variation in response to climate change. Global warming leads to the loss of glacial ice, which in turn increases slope instability caused by glacial de-buttressing, and flooding from glacial and moraine-dammed lakes (Evans and Clague, 1994; Ballantyne, 2002). All these processes redistribute sediments and operate at different rates as a result of change to the system. Glaciers and ice sheets exert strong controls on the supply of sediments. For example, Knight et al. (2002) identify the basal ice layer of a section of the Greenland ice sheet as the dominant source of sediment production. There is, however, only limited knowledge of debris fluxes from ice sheets and glaciers, and its variability. The main mechanisms of sediment production in source areas can be described in terms of contemporary environmental conditions. However, in order to fully understand sediment supply, a longer-term perspective is needed. Over the Quaternary, glacier fluctuations have had profound influences in depositing extensive mantles of sediments. More-widely, periglacial activity has altered the landscape under non-glacial cold climate conditions. The obvious imprint of this legacy is often reflected in contemporary sediment transfer rates where preexisting deposits are eroded by present-day processes (Ballantyne, 2002; Warburton, 2007).

Sediment transfers

Sediment transfers move eroded sediments from their source area to an area of temporal storage or long-term deposition in sinks. Rates of sediment transfer are not only conditioned by competence of geomorphic processes but

also by the availability of sediment for transport. Accordingly, in assessing sediment transfer, we need to quantify the forces that drive transport processes but equally account for the factors that control sediment supply (Warburton, 2007). Glacial fluxes are arguably the most significant processes for contemporary sediment flux (Harbor and Warburton, 1992). Small-scale process studies very often focus on sedimentary fluxes from areas of weathering and erosion to areas of storage within defined landscape units like drainage basins, whereas large-scale sediment systems couple headwaters to oceanic sinks. For example, Gordeev (2006), applying models developed by Morehead et al. (2003), estimates the increase in sediment load in Arctic rivers in response to a rise in surface temperature of the drainage basins. Based on this model, increases in river discharge lead to an increase in the sediment flux of the six largest Arctic rivers, predicted to range from 30% to 122% by the year 2100.

Sediment stores/sinks

The identification of storage elements and sinks is critical to the effective study and understanding of source-to-sink sedimentary fluxes (Reid and Dunne, 1996). The setting of a particular drainage basin defines the boundary conditions for storage within that landscape unit. In a defined landscape unit like a drainage basin, the slope and valley infill elements constitute the key storage units and storage volumes are important for addressing time-dependent sediment budget dynamics. Dating of storage in sedimentary source-to-sink flux studies is applied to determine or estimate the age and chronology of the storage components within the system. An understanding of the nature of primary stores, secondary stores, and the potential storage capacities of different types of drainage basins is important along with knowledge of sediment residence times. Of growing importance is the development of innovative field methods, such as geophysical techniques for estimating sediment storage volumes (Schrott et al., 2003; Sass, 2005; Hansen et al., 2009). Within large-scale sediment systems, oceanic sinks are most important and provide the opportunity to estimate rates of sediment production and delivery at long-term temporal as well as continental spatial scales (Rise et al., 2005; Dowdeswell et al., 2006).

Summary

Studies on sedimentary fluxes from source to sink are an accounting of the sources and deposition of sediment as it travels from its point of origin to its eventual exit from a defined area. The connected development of a sediment budget necessitates the identification of processes of erosion, transport, and deposition within this defined area, and their rates and controls. Within the scope of climate change research, knowledge on the contemporary sediment production and flux regime within a system enables the prediction of possible future changes to erosion and sedimentation rates. In addition, improved knowledge of where sediment will be deposited, how long it will be stored and how much sediment will be remobilized can be achieved. The main mechanisms of sediment production in source areas can be described in terms of contemporary environmental conditions. However, in order to fully understand sediment supply also a long-term perspective is required. Sediment transfers move eroded sediments from their source area to an area of temporal storage or long-term deposition in sinks, with glacial fluxes being arguably the most significant processes for sediment flux. An understanding of the nature of primary stores, secondary stores, and the potential storage capacities of different types of drainage basins is important along with knowledge of residence times. Within large-scale sediment systems oceanic sinks are most important and provide the opportunity to estimate rates of sediment production and delivery at large temporal and spatial (continental) scales.

SEDIMENT GRAVITY FLOW

George Postma
Faculty of Geosciences, EUROTANK Laboratories, TA Utrecht, The Netherlands

Density currents; Gravity currents; Mass flows; Sediment flows

Definition

Sediment gravity flows are mixtures of water and sediment particles where the gravity acting on the sediment particles moves the fluid, in contrast to rivers, where the fluid moves the particles.

Introduction

Sediment gravity flows are catastrophic subaerial and subaqueous events that occur at various frequencies. An event can originate from sliding of unstable sediment mass on a slope, in which case the trigger is often by storm, tidal wave, seismic shock, or heavy rainfall. It can also originate from flood wave in a river that debouches onto the delta slope, where it, if denser than the basin water, first plunges down as hyperpycnal flow and continues as sediment gravity flow.

Sediment gravity flows have the ability to transport large masses of coarse-grained sediment into places, where otherwise only fines are deposited from suspension. Their deposits have been found in oceanic basins at 5 km depth at more than 2,000 km away from the continental slope, but also occur almost everywhere on land and in shallow seas and lakes and occur also in present-day glacial environments.

Since the rheology of sediment gravity flows varies and has great impact on the type of deposits, first an overview is given of this variation, which is followed by an impression of how rheology and flow characteristics (density, velocity) is reflected in the deposits. Finally, their occurrence in the glacial environments is highlighted.

Rheology of sediment gravity flows

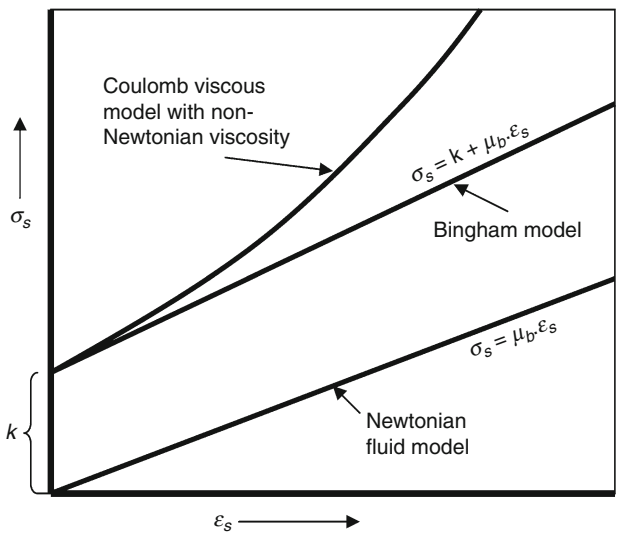
The rheology of sediment gravity flows falls into two main classes of flow behavior that are fundamentally different and which difference is often reflected in the final deposit. The first class is characterized by fluidal behavior similar to Newtonian fluid, where shear stress is linearly related to strain according to

$$\sigma_s = \mu \,.\, \varepsilon_s \quad \left[\mathrm{N/m^2}\right] \tag{1}$$

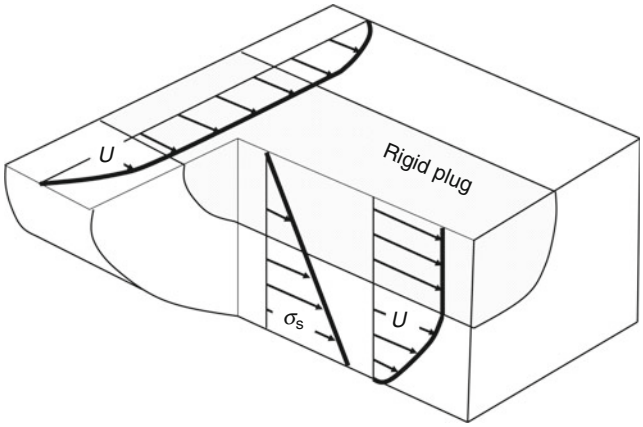
where σ_s is the shear stress, μ is the apparent viscosity, and ε_s is rate of shear strain. In a fluid the shear strain is measured by the velocity gradient, hence dU/dz, where U is velocity at height z in the flow. Characteristic for waning, fluidal flow is that deposition occurs from the bed upward. Such depositional behavior is in sharp contrast with the second class of sediment gravity flow with plastic-viscous flow behavior. Such flows exhibit strength, while above the yield point viscous deformation occurs. Their rheology is described by the Coulomb-viscous model (Johnson, 1970, Figure 1):

$$\sigma_s = k + \mu_b.\varepsilon_s \quad \left[\mathrm{N/m^2}\right] \tag{2}$$

where k is the yield strength, μ_b is the Bingham viscosity, and ε_s rate of shear strain. The expression tells us that above the yield strength k the flow behaves viscous and has a linear viscosity called the Bingham or plastic viscosity. The apparent viscosity may be shear stress related and deformation above the yield strength is in such case non-Newtonian. Flow of plastic-viscous sediment mass is characterized by a nondeforming rigid plug which is riding on a viscously deforming basal layer, a behavior that



Sediment Gravity Flow, Figure 1 Diagram showing the Bingham rheological model: If strength $k = 0$, the flow experiences only Newtonian viscous deformation. In case of nonlinear viscous deformation, the viscosity is stress depended and non-Newtonian.



Sediment Gravity Flow, Figure 2 Plastic-viscous flow characterized by the formation of a rigid plug if the shear stress σ_s is equal or less than the shear strength k (see Eq. 2). The velocity gradient in the plug is zero.

is exemplified by the flow of concrete cement (Figure 2). The plug exists for $\sigma_s \leq k$.

The strength k within a debris flow mass is a function of the effective normal stress (σ') through the relationship

$$k = c' + \sigma \tan \Phi \quad [\mathrm{N/m^2}] \tag{3}$$

where c' is the effective cohesion and Φ' is the effective angle of internal friction (Rodine and Johnson, 1976). Extreme poor sorting reduces the internal friction; whereas the normal stress is reduced by

$$\sigma' = \sigma - p \quad [\mathrm{N/m^2}] \tag{4}$$

where σ is the total normal stress (the total weight of the debris and p is the pore pressure, which if positive (excess pressure) reduces the normal stress. Hence the excess pore pressure may locally (in most cases it is maximal at the base of the flow) significantly reduce the strength (up to 100%). The ability of the flow to trap pore pressure depends on the particle-size distribution (Rodine and Johnson, 1976). Very poorly sorted fabrics can maintain high excess pore pressure, because the narrow passageways (pore necks) hinder the fluid to escape upward. The presence of minimum amount of silt and clay (as little as 5%) appears to be important trapping the pore fluid and hinders draining of the flow, which greatly enhances its mobility.

Flow transformations

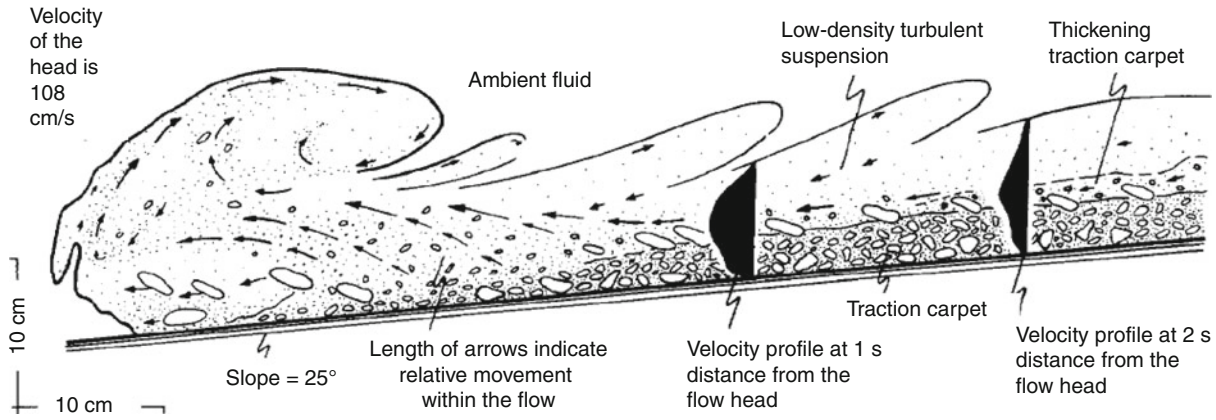
If a flow accelerates or decelerates, its behavior may change due to dilution or to deposition. Four types of flow transformations are feasible (Fisher, 1983): Body transformation, when the flow changes between laminar and turbulent; Gravity transformation, when initial turbulent, particle charged flows become gravitationally segregated into a 2-phase flow with a high-concentrated lower and a low-concentrated upper suspension layer; Surface transformation, when fluid becomes mixed or lost at flow boundaries resulting in dilution; Fluidization transformation, which develops by upward-moving fluids from the substrate or at the head of the flow also diluting the sediment gravity flow.

All types of transformations may play a role during the lifetime of a sediment gravity flow. Upon failure of a sediment mass on a slope, fluidization can make entire sediment slice on a slope unstable and initiate movement of the slice due to failure of, what can be, a thin weak layer where pore pressure could build up sufficiently to reduce its strength (e.g., Brunsden and Prior, 1984). At low rates of shear clast concentrations over 35–58 vol% still form a supporting framework of clasts in contact with each other (Rodine and Johnson, 1976) in which strength derives from both frictional resistance and cohesion. Hence, the slice can start to move as a rigid body riding on a thin shear zone behaving essentially as a plastic body, i.e., if its movement stops its original internal structure is still intact. If the slice accelerates it dilates by water intake from below (fluidization transformation), and from above (surface transformation). This may enhance body transformation, causing the sediment mass to move in either plastic-viscous or fluidal fashion depending on the remaining strength.

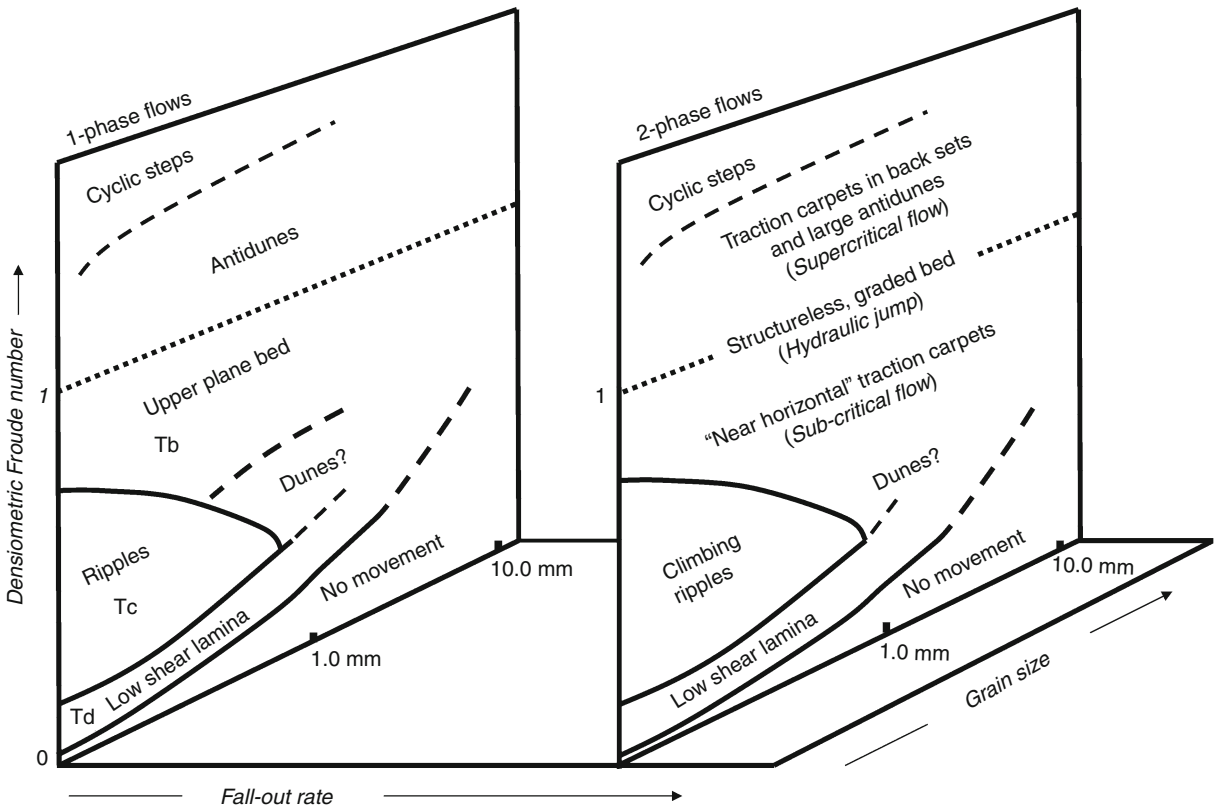
Experiments show that sustained, quasi-steady fluidal flows can have concentrations of up to 35 vol% (see Baas et al., 2004). In such highly concentrated fluidal flows, grains are held in suspension mainly by grain-to-grain collisions that cause an upward directed dispersive pressure (Bagnold, 1954). At concentrations less than 9 vol%, grains can be fully supported by turbulence of the fluid (Bagnold, 1954; Sohn, 1997). Flume experiments on high-concentration sandy to gravelly turbulent suspensions by Postma et al. (1988; Figure 3) show how behind the fully turbulent head of the flow the coarsest particles separated out into a highly concentrated basal layer by gravity transformation. The experiments reveal the presence of so-called traction carpets that are overridden by a low-concentrated turbulent suspension (2-phase suspension flows, see Postma et al., 2009).

Deposits of sediment gravity flows

Middleton and Hampton (1973) were the first to summarize a range of sediment gravity flow deposits based on sediment support mechanisms during flow. Later, Lowe (1982), Nemec and Steel (1984), Postma (1986), Nemec (1990), Mutti (1992), Kneller and Branney (1995), Sohn (1997), Russell and Arnott (2003), Postma et al. (2009), and many others addressed in detail the variety of deposits that stems from plastic-viscous and fluidal flow behavior of sediment mixtures. Although some controversies about whether to relate some structureless poorly sorted, coarse-grained deposits to plastic-viscous or to fluidal flow behavior still exist to date (and the just cited papers give a fair insight into these controversies), a fair overview of flow rheology and related deposits can be given, without



Sediment Gravity Flow, Figure 3 An initial high-concentration turbulent flow transforms by gravity transformation as observed through time (head of flow passes observer at 0 s). The passing head of the current is a fully turbulent 1-phase suspension flow and just before 1 s has passed, a density interface has developed separating the high-concentration traction carpet from the low concentration overriding suspension flow (2-phase flow). The drawing is traced from photographs with a high-speed film camera (70 frames per second (Slightly modified from Postma et al., 1988).



Sediment Gravity Flow, Figure 4 Three-dimensional bed-form stability diagram for 1- and 2-phase suspension flows. To illustrate the position of the hydraulic jump, the stability fields of the various bed forms are given relative to critical flow conditions ($Fr' = 1$). Hence, the boundaries of the stability feeds are only approximate (From Postma et al., 2009).

discussing extensively the right or wrong of certain interpretations.

Deposits of plastic-viscous sediment gravity flow

The deposit of a plastic-viscous flow is called debris flow deposit, or debrite. The basal layer of such deposit is often finer grained than its body and could have a "ropy" appearance representing the original shear zone underlying the rigid plug: The latter is often structureless and nongraded, with large clasts floating in a matrix (similar to *diamicton*). The strength of the debris flow is measured by its largest clast size (Hampton, 1975), and a good correlation between max particle size and bed thickness has been demonstrated in studies of Nemec and Steel (1984).

Deposits of fluidal sediment gravity flow

To fully understand the deposits of fluidal sediment gravity flows it is imperative to realize that deposition can take place under both supercritical, critical, and subcritical flow conditions as defined by the densimetric Froude number. The densiometric Froude number is determined by

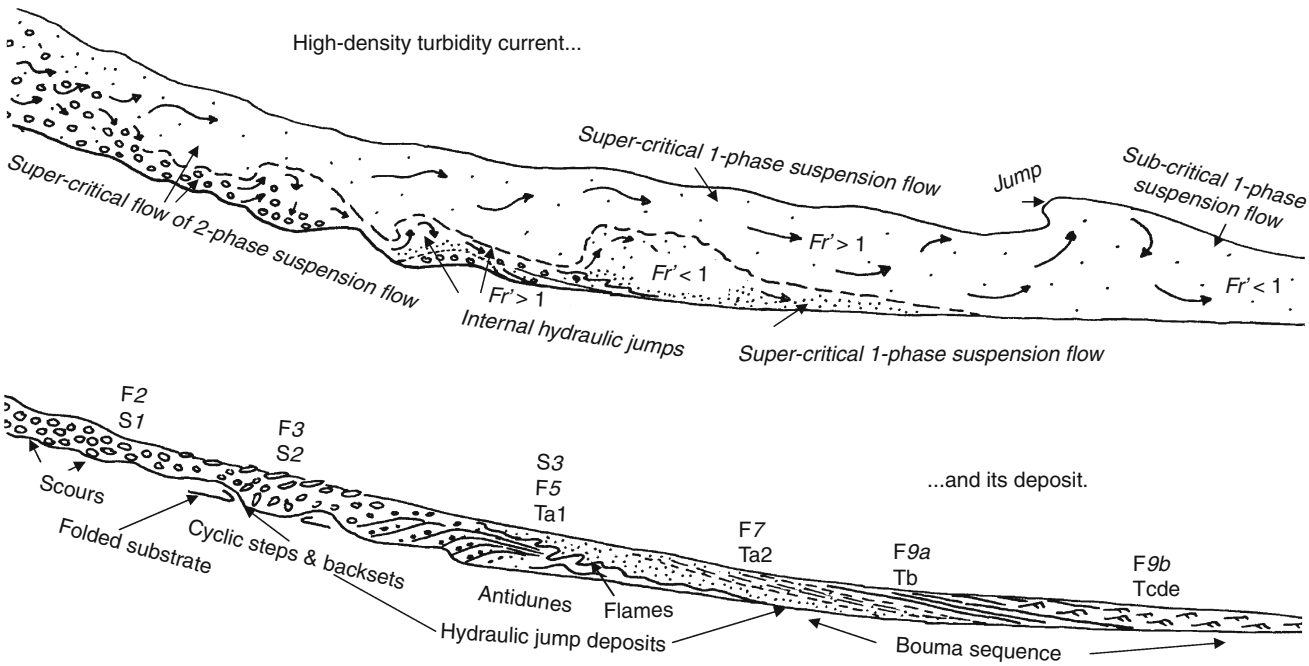
$$\mathrm{Fr}' = \frac{U}{\sqrt{g' h}} \quad [-] \tag{5}$$

where U is the flow velocity, h is the flow thickness, and g' is the reduced gravity

$$g' = g\,\frac{\rho_{\mathrm{mix}} - \rho}{\rho} \quad \left[\mathrm{m/s^2}\right] \tag{6}$$

and where ρ_{mix} is the density of the flow, ρ is the density of the ambient water, and g is the gravity constant. For $\mathrm{Fr}' < 1$, the turbidity current is called subcritical, for $\mathrm{Fr}' > 1$ the flow is supercritical, and when $\mathrm{Fr}' \approx 1$ it is critical. When a supercritical flow switches to a subcritical flow it passes the hydraulic jump. Most fluidal sediment gravity flows are already supercritical on slopes of 0.001.

The various bed forms that may develop from a fluidal sediment gravity flow are depicted in the diagram of Figure 4, which illustrates that bed forms are different for 1-phase and 2-phase suspension flows. In 1-phase flows, suspension concentration is below 9 vol% criterion. In such flows fallout rate is low and bed-load transport is dominant, a flow behavior very similar to unidirectional water flow. In 2-phase suspension flows the fallout rate is sufficiently high to form traction carpets (gravity transformation). Various styles of traction-carpet deposits have been recognized as a function of the varying rheology of the layer during its deposition, as was discussed by Sohn (1997). Field and flume evidence indicate that traction



Sediment Gravity Flow, Figure 5 Flow transformation from supercritical to subcritical, with an internal hydraulic jump that leads to the development of Bouma Ta_1 (structureless coarse-tail graded gravelly sand) with flame structures at the base of the unit. In the supercritical region traction carpets deposit in back sets and large wavelength antidunes, whose deposits can be truncated by Bouma Ta_1. In the subcritical region, down slope of the internal jump, weakly stratified Bouma Ta_2 may develop truncated by Bouma Tbcd units of the subcritical flow regime.

carpets can form under both super and subcritical flows, as long as the required fallout rate is achieved.

The evolution of a decelerating high-concentration sediment gravity flow is depicted in Figure 5, together with the resultant deposits, a sketch inspired by Mutti (1992). The F numbers refer to detailed descriptions and illustrations of deposits by Mutti (1992), the S numbers refer to deposits described by Lowe (1982) and the T numbers refer to deposits described by Bouma (1962). The number addition for Ta1 and Ta2 gives the difference between structureless and weakly stratified deposits in the Bouma Ta unit (Postma et al., 2009).

Traction carpets formed under supercritical condition are deposited as large backsets, long-wave (>30 m) antidunes, and large sand and gravel waves (cyclic steps). Backsets and long-wave antidunes have been described from Gilbert-type deltas (see review by Nemec, 1990) and from ice-marginal lakes in deposits formed by subaqueous water jets occurring at the outlet of subaqueous tunnel valleys (e.g., Russell and Arnott, 2003). Traction carpets formed under subcritical conditions are straight and tabular often deposited in association with plane bed lamination (Bouma Tb) and climbing ripple sets (Bouma Tc, see Postma et al., 1983). The deposit of a waning, low concentration turbidity current is described in detail by the Bouma Ta–e sequence with coarse-tail graded basal unit (Ta) followed by plane bed lamination (Tb), small-scale ripple sets (Tc), and silt lamina formed by low shear and suspension fall out (Tde).

Sediment gravity deposits in the various glacigenic environments

Sediment gravity flows and their deposits occur in many present-day glacial environments, and have, for instance, been encountered in fjords in association with deltas (e.g., Bornhold and Prior, 1990), in glacial lakes (e.g., Postma et al., 1983; Gilbert and Crookshanks, 2008), and in many subaerial and subaqueous ice-contact environments. In the latter case, deposits are not necessarily from sediment gravity flows *sensu stricto*, because the high-concentration suspension is for great part driven by the subaqueous jet efflux originating from subglacial melt water drainage systems (tunnel valleys). Yet, their deposits show many close similarities with those of sediment gravity flows (Postma et al., 1983; Russell and Arnott, 2003; Hornung et al., 2007). At the terminus of glaciers, subaerial sediment gravity flows originate where sediment overlies the ice. The ablation of ice disaggregates the overlying sediment and mixes it with the melt water resulting in watery debris slurries. A beautiful example of debris flow deposits has been studied on James Ross Island (Antarctica). The debris flow deposits attain thicknesses of up to 150 m and extend over 4 km laterally. The high volume of glacigenic sediment delivery implicit in the James Ross Island successions indicates that a series of dynamic ice fronts crossed the region during the late Miocene and Pliocene epochs (Nelson et al., 2009). The highly fossiliferous glacigenic debris flows are well dated and signify episodes of ice expansion during relatively warm periods (interglacials).

Summary

The deposits of sediment gravity flows are common in both subaerial and subaqueous glacial environments. They are strongly related to the rheology of the suspension carrying flow and flow characteristics such as speed, densiometric Froude number, and particle concentration and size. The deposits of fluidal sediment gravity flow class are varied and have been organized here in a bedform stability diagram and a longitudinal cross-section.

SEDIMENT ROUTING

Subhajit Sinha
DBS College, Dehradun, Uttarakhand, India

Sediment is transported from areas of uplift and erosion into adjacent sedimentary basins. The relationship between transport processes and storage sites of the sediments is sediment routing. From its generation to its reaching the depozones, the position a sediment particle occupies, depends on its location at the time of deposition. Large sediment routing systems are among the largest geological features on earth, commonly spanning ocean–continent boundaries and occasionally crossing plate boundaries.

Basin models conventionally involve modeling of the filling of sedimentary basins is dependent on incorporating surface processes of weathering, sediment release and dispersal, and long-term burial in the basin. This integrated process system from source to sink is the sediment routing system. Tectonics and sediment routing systems are closely coupled. Dispersal of a mixed sediment supply into a basin with a certain spatial pattern of tectonic subsidence also controls the regional slope and downstream granulometric fining of the depositional system, the positioning of discontinuities such as the gravel front, and gross depositional facies. This offers the possibility that certain basin types may be occupied by particular styles of sediment routing system.

SEDIMENT TRANSFER MODELING

Richard Hodgkins

Sediment transport modeling

Definition

Simulation of rates of suspended-sediment transport in glacial meltwaters, by statistical or physical methods.

Introduction

Models of suspended-sediment transfer in glacially fed rivers have been developed in order to forecast sediment yields for engineering purposes (e.g., Bezinge et al., 1989; Bogen, 1989), to predict erosion rates for geomorphological purposes (e.g., Swift et al., 2002, 2005), to investigate fluvial processes (e.g., Church and Gilbert, 1975; Gurnell and Fenn, 1984), and to identify and interpret seasonal changes in suspended-sediment transfer from glacierized catchments (e.g., Gurnell et al., 1992, 1994; Hodgkins, 1996). Although sophisticated, computational fluid dynamics approaches are well established in hydraulic engineering, the modeling of sediment transfer in glacial environments is typically restricted by the perennial difficulties of acquiring continuous, high-quality hydrometric and sediment transport data at fine spatial and temporal resolutions, in unstable proglacial and inaccessible subglacial environments. Parameterizations of complex models require detailed data such as precise fluvial network topology, bed characteristics and velocity profiles that are usually impractical to obtain in proglacial locations, and even less so in subglacial ones.

Rating-curve approaches

Because of the difficulties of parameterizing physical models, statistical approaches to sediment transfer modeling are much more widespread. By far the most common model is a rating curve derived from linear regression of Suspended-Sediment Concentration (SSC), or sometimes (spuriously, from a statistical point of view) Suspended-Sediment Load (SSL), on discharge (e.g., Repp, 1988). Swift et al. (2005) used residuals from linear regressions of daily SSL on discharge to highlight important changes in the seasonal efficiency of sediment transfer, which were investigated further at a sub-seasonal scale using SSC as

the dependent variable. The popularity of the rating curve stems from its simplicity of construction and interpretation, with SSC deterministically predicted from discharge. However, the discharge-SSC relationship is far from simple in reality, and the performance of rating curves is frequently poor. For instance, Parks and Madison (1984) derived rating curves for glacierized basins in Alaska that had standard errors ranging from −50% to +100%, while Fenn (1989) found that rating curves developed for one season's data from the Glacier de Tsidjiore Nouve (Switzerland) predicted suspended loads from 34% to 278% of measured values when applied beyond that season. Such limitations arise because the bivariate discharge-SSC relationship is unstable over a range of temporal scales. Fenn et al. (1985) summarized the effects that limit the performance of sediment rating curves as follows:

1. Variations in sediment supply at the seasonal scale, such as from early-season flushing (Liestøl, 1967; Collins, 1989), late-season exhaustion (Østrem, 1975; Gurnell et al., 1992), or changing sediment sources (Gurnell et al., 1994; Hodgkins, 1996).
2. Variations in sediment supply at the diurnal scale, between the rising and falling limbs of the hydrograph, leading to diurnal hysteresis (Bogen, 1980; Hodgkins, 1996). This is a particular problem for forecasting SSC from discharge alone, since there are distinct, rising- and falling-limb values of SSC for any one value of discharge.
3. Transient SSC pulses, which are independent of discharge (Gurnell, 1982; Gurnell and Warburton, 1990).
4. Variable entrainment and deposition of sediment in the proglacial region (Maizels, 1979; Warburton, 1990; Hodgkins et al., 2003).
5. Variations in sediment supply associated with rainfall-induced events (Church, 1972; Richards, 1984).

Time-series (stochastic) approaches

The limitations of the rating curve are usually reflected in the presence of autocorrelation in the residual series. *Quasi-autocorrelation* results from shortcomings in the formulation of the model: nonlinearity, omission of relevant independent variables, the presence of response lags/leads, and hysteresis at different time scales (Fenn et al., 1985). *True-autocorrelation*, however, indicates that the SSC series is generated not through a linear dependence on discharge, but by a stochastic process in which the present value of SSC is not independent of previous values of SSC, but a probabilistic function of them and of present and previous random disturbances (Richards, 1979).

Gurnell and Fenn (1984) took advantage of true-autocorrelation, estimating a Box-Jenkins transfer function (Box and Jenkins, 1976) between discharge and SSC series from Glacier de Tsidjiore Nouve. AutoRegressive Integrated Moving-Average (ARIMA) stochastic time-series models of discharge and SSC series were developed for an estimation period, and the transfer function used to bring them into phase and apply a scaling factor. Predictions from the transfer-function model were far superior to those from rating curves, such that Gurnell and Fenn (1984) recommended a similar approach be used whenever possible. Fenn (1989) found that a transfer-function model gave predictions of SSL from 96% to 105% of measured values at Glacier de Tsidjiore Nouve, even when applied beyond the season in which it was developed. Nevertheless, despite the advantages of the transfer-function approach, it has not been widely adopted, because: (1) it requires an unbroken series of uniformly spaced observations for estimation, (2) it is sometimes difficult to place physical interpretations on the ARIMA parameters (Swift et al., 2005).

Simpler implementations of time-series approaches are available, however. Linear regression models for successive subperiods of an SSC time series acquired at Scott Turnerbreen (Svalbard), using discharge as the independent variable, accounted for between none (when not significant) and about 52% of the variance in SSC (Hodgkins, 1996). However, *autoregression* models, incorporating both discharge, Q, and an ARIMA (1,0,0) component ($SSC_t = aQ_t + bSSC_{t-1} + \varepsilon_t + c$, where a and b are regression coefficients, c the regression intercept, and ε is a random disturbance), indicate that the latter dominates the regression relationship, and is relatively constant with a value close to unity, throughout the melt season (Hodgkins, 1999). Likewise, Gurnell et al. (1994) found that a first-order autoregressive ARIMA model was largely sufficient to describe an SSC time series obtained at Austre Brøggerbreen (Svalbard), although a second-order autoregressive, or sometimes also a diurnal moving-average, model was required for series obtained at Haut Glacier d'Arolla (Switzerland): this is a temperate glacier with a seasonally evolving, multi-reservoired, subglacial drainage network (Gurnell et al., 1992) of greater complexity than the largely sub-serial networks of the essentially non-temperate Svalbard examples. Inferring the structure of the glacial drainage system was an early motivation of sediment transfer modeling, and remains important. For example, Swift et al. (2005) noted increasing sediment availability through a strong relationship between daily SSL and discharge amplitude at Haut Glacier d'Arolla, and inferred that increasing subglacial water pressure variation as a consequence of increasingly peaked diurnal run-off cycles was likely to have increased access to basal sediment, by encouraging extra-channel flow excursions and/or enhancing basal sediment deformation.

Subdivision of time series

Other attempts to improve rating-curve performance have involved subdividing the discharge and SSC series into shorter intervals of more uniform response, for which a linear relationship may be more valid. Collins (1979) estimated rating curves for individual rising and falling limbs of the diurnal hydrograph at Gornergletscher

(Switzerland). Hammer and Smith (1983) derived early- and late-season rating curves for Hilda Glacier (Canada). Richards (1984) obtained separate rating curves for periods of meltwater runoff and storm runoff at Storbreen (Norway). Gurnell et al. (1992) divided discharge and SSC series from Haut Glacier d'Arolla into five subperiods on the basis of variations in diurnal maximum and minimum discharge, prior to estimating regression and ARIMA models. Statistical hydrograph classification has also been used as a tool to trace the seasonal evolution of subglacial drainage configuration, which has in turn been used to define periods of consistent run-off sediment transfer response for further statistical analysis, e.g., Orwin and Smart (2004) and Swift et al. (2005) used principal components and hierarchical clustering analyses to classify hydrographs on the basis of shape and magnitude at Small River Glacier (Canada) and Haut Glacier d'Arolla, respectively. Orwin and Smart (2004) also applied these analyses to diurnal suspended-sediment cycles, and compared the resulting classes with discharge and meteorological data to analyze sediment transfer patterns. This approach showed that relatively low SSC and clear diurnal cycling were the norm, but that about 70% of the total seasonal sediment load occurred in "irregular," relatively high-SSC events associated with rainfall and enhanced snowmelt: the proglacial area was the source for up to 80% of the sediment yield of the glacier basin. Proglacial storage effects are particularly relevant to the modeling of sediment transfer in glacierized catchments, and careful field experimental design is required to distinguish the glacial sediment transfer signal from the proglacially modulated one, though it is not always possible to achieve this in intractable glacial locations.

Multivariate approaches

A further approach has been to develop multivariate rating curves incorporating additional explanatory variables, which may represent components of variability at different temporal scales. Richards (1984) introduced the *rate of change of discharge per hour*, positive during rising and negative during falling stages, to represent diurnal hysteresis. It was found that this variable was the main control on SSC variation during periods of meltwater runoff. Willis et al. (1996) found that the variables *discharge*, *rate of change of discharge,* and *days since discharge was equalled or exceeded* were all significant in a multivariate rating curve from Midtdalsbreen (Norway), although the improvement over a rating curve using discharge alone was slight, and the residuals were autocorrelated. Likewise, Swift et al. (2005) found that the variables *days since discharge was equalled or exceeded*, *rate of change of discharge* and *rainfall* were significant in multivariate regression models at Haut Glacier d'Arolla; again, autocorrelation, though reduced compared with bivariate models, was not removed. However, autocorrelation was absent from models that included the variable SSC_{t-1}, indicating true-autocorrelation arising either from a dependence of the current value of SSC on recent values of SSC (denoting sediment availability), from the settling velocity of fine particles being lower than that required for their entrainment (Hodson and Ferguson, 1999), or from some combination of these factors. In all models, SSC_{t-1} became the most significant explanatory variable at the expense of Q. Note that lagging an independent variable in a regression is not the same process as building an ARIMA (1,0,0) model: the former still uses the least-squares approach to estimate its parameters, while the latter takes a maximum-likelihood approach (Akaike, 1974). However, both methods can reduce autocorrelation. Hodgkins (1999) earlier noted that the dependence of SSC on the magnitude of discharge in time series from Scott Turnerbreen was weak and highly variable, whereas the dependence of current SSC on recent values of SSC, revealed through an ARIMA(1,0,0) term, was strong (an order of magnitude greater than Q) and relatively constant. The dominant control on SSC was therefore short-term sediment availability: a corollary of this is that forecasting becomes problematic in the absence of recent SSC data. The challenge is therefore presented of identifying and modeling processes that control sediment *availability.*

Physical approaches

Physical models of sediment transfer are far less developed than statistical ones. A notable contribution is that of Clarke (1996), who developed a lumped-element model of the subglacial hydraulic system. He related the sediment flux from the bed into suspension (erosion), $F_S^{\uparrow}$, to the porosity of the bed, n, the sediment density, ρ_S, and the bed shear stress, τ_0:

$$F_S^{\uparrow} = \rho_S(1-n)k_E(\tau_0 - \tau^*)^N \quad \tau_0 > \tau^*$$

where k_E is a constant relating to the character of the flow and the bed surface, τ^* is a threshold boundary shear stress for erosion and N is an experimentally derived constant. Clarke (1996) assumed an unlimited sediment supply, but this is not a necessary assumption of the model. τ^* depends on grain size, and can be approximately zero for silt particles. Assuming that Stokes' Law governs the processes of sedimentation, the sediment flux from suspension into the bed (deposition), $F_S^{\downarrow}$, can be written

$$F_S^{\downarrow} = c_S v_S = c_S \frac{(\rho_S - \rho)gD_P^2}{18\mu}$$

where c_S is SSC (essentially supplied from upstream), v_S is the settling velocity of grains of diameter D_P, and density ρ_S from a fluid of density ρ and viscosity μ. Mass conservation requires the flux of sediment per unit time from a drainage element of volume V and bed surface A to be equal to the flux in, plus erosion, minus deposition. Therefore a sediment balance can be written:

$$\frac{dc_S}{dt} = \frac{1}{V}\left[-c_S\frac{dV}{dt} + c_S^{in}Q^{in} - C_S^{out}Q^{out} = A\left[\rho_S(1-n)k_E(\tau_0-\tau^*)^N - \frac{c_S(\rho_S-\rho)gD_P^2}{18\mu}\right]\right]$$

Clarke (1996) notes astutely that the main limitations on subglacial hydraulic modeling are not in the mathematical treatment, but in our poor knowledge of drainage configurations and of sediment sources and sinks.

Jones and Arnold (1999) applied Clarke's (1996) equations to a subglacial water routing model (Arnold et al., 1998) and obtained reasonable results for the period when conduits were well established in the mid-to-late melt season, though not before. An observed reduction in peak diurnal SSCs toward very end of melt season was not seen in modeled data, which suggested it was not caused by any reduction in water discharge or velocity. Instead, it was suggested that sediment exhaustion was occurring, as at that point of the melt season the conduits had been established for some 30 days, with little headward expansion, and therefore without potential access to fresh sediment sources (though note Swift et al.'s (2005) interpretations, above). The diurnal range of SSC was more sensitive than the mean SSC to changing parameter values, and diurnal SSC maxima and minima tended to increase/decrease together. This suggested that, to improve model performance, it would probably be necessary to include additional physical processes, such as sediment exhaustion, hiding of grains, and the exposure of fine particles if and when larger particles become entrained. This is to reiterate the point that sediment availability is probably the key control of sediment transfer, and that while variations in availability can be identified by statistical analysis of SSC/SSL time series, there are currently no effective means to model it.

Summary

Sediment transfer rates in glacial meltwaters have so far mainly been modeled by statistical means, and the rating-curve approach has been the most important of these. However, while it can be improved by subdividing time series and incorporating independent variables other than runoff, the rating curve is essentially simplistic and fails to account for the true-autocorrelation that is pervasive in sediment transfer series. Stochastic methods, such as ARIMA, can model autocorrelation explicitly, but are more complex to estimate, more demanding of data, and more difficult to interpret. Autocorrelation at short lags shows that sediment availability is probably the key control of sediment transfer rates. An expanding range of statistical approaches, including the classification of hydrographs and sedigraphs by principal components and clustering analyses, have shed valuable light on temporal patterns of sediment availability, but a really effective means to model the availability of sediment in a predictive manner remains elusive. Physical models of sediment transfer are underdeveloped by comparison with statistical approaches, but they may become more widely adopted as our ability to parameterize complex hydrological processes improves.

Annual sediment yield; Integrated sediment flux

Definition

Sediment yield: Total quantity of sediment, expressed in units of mass (or volume) per unit time. In the case of glacial or fluvial environments, sediment yield is typically the volume of sediment transported from a drainage basin over a given time period.
Annual sediment yield: Total quantity of sediment fluxed from a basin during an entire year, expressed in units of mass or volume per annum.

Introduction

Sediment yield is broadly understood in earth surface processes to mean the total volume or mass of sediment evacuated, transported, or deposited from a drainage basin. As the term yield implies, the amount of sediment removed is estimated or measured over a known period of time. Yield is then reported as mass per year (typically tons/year) or volume per year. Sediment yield refers to the inorganic fraction of sediment, ignoring organic material frequently in transport in fluvial systems.

Source of sediment in glacierized basins

Measurements of sediment yield are typically difficult to make, in part because of the large distribution in grain size produced by glacial processes. Accurate measurements of sediment yield consider the coarse-grained fraction (from headwall processes and subglacial quarrying) and the finer-grained material (produced during subglacial abrasion). Fine-grained sediments (silts and clays) are often carried to proglacial lakes and fjords in streams, while coarser material is transported more slowly and over shorter distances. The production of sediment is either subglacial (subglacial abrasion and quarrying) and therefore impossible to observe directly, or sourced from the valley walls but incorporated into glacier ice in the accumulation zone or from rockfall into the bergschrund or

crevasses. Some rockfall from the valley walls either falls or emerges in the ablation zone; this material is eventually moved to the proglacial zone and deposited in the form of moraines. While there may be a contribution of subglacial or proglacial fluvial bedrock erosion contributing to sediment yield, this is typically assumed to be many orders of magnitude less than the glacial contribution of sediment.

Measurement of sediment yield in glacierized basins

The variety of methods for quantifying sediment yield fall into three general categories: measurement of active suspended sediment and bedload flux in proglacial streams and ice proximal marine settings; mapping terrestrial deposits and landforms; and bathymetric, ground-penetrating radar, and/or coring studies of subaqueous sedimentary deposits.

A key study of sediment yield using measurements of sediment flux from an active glacier is Humphrey and Raymond (1994). Using measurements of suspended sediment at Variegated Glacier in Alaska, the authors constrained sediment yield from the glacier over a wide range of measured ice velocities. The techniques used to measure sediment flux in proglacial streams are well documented (e.g., Ostrem, 1975; Gurnell, 1987; Bogen, 1989). Measurement of the bedload fraction is difficult to constrain; examples of studies that have successfully quantified bedload contributions to sediment yield include Pearce et al. (2003) and Riihimaki et al. (2005). In addition to measuring sediment concentration and flux in proglacial streams, some studies of active glaciers utilize sediment traps to assess yield. Direct measurements of settling sediment in lakes have been used (e.g., Hunter, 1994); uncertainties can be high over daily to seasonal timescales.

Terrestrial measurements of moraine volume and debris cover have been used to estimate basin-wide sediment yield (e.g., Reheis, 1976; Heimsath and McGlynn, 2008). Calculations of sediment yield are made using mapping and estimates of moraine density. An important uncertainty with this technique is constraining the timescales over which the deposits were formed. The use of cosmogenic radionuclides (CRN) to determine sediment yield in non-glacierized basins has been used with good success (e.g., Blanckenburg, 2005; Kirchner et al., 2002), and is beginning to be used in alpine settings to constrain the timescales over which sediment accumulates on moraines (e.g., Heimsath and McGlynn, 2008). An important challenge for utilizing CRN in glacierized basins is the shielding of subglacial sediment and rock with ice and snow, as well as the extremely steep angles of valley walls, both of which complicate the estimated exposure and inheritance of basin surfaces (discussed in Bierman and Nichols, 2004).

Measurements of total sediment volume deposited in well-defined traps such as proglacial lakes, fjords, and debris fans in subaqueous ocean environments have been used with some good success (in addition to the summary provided in Hallet et al. (1996), Koppes and Hallet (2002) provide a new methodology for determining the time series of sediment yield from a retreating tidewater glacier). Ground-penetrating radar and bathymetric measurements have been used to image and constrain sediment volume and density in these areas. Lake coring has also been used to constrain sediment yields from glacierized basins; sediment accumulation rates from cores are converted to volume by averaging across the surface area of the lake (Foster et al., 1990) or an averaging technique using multiple cores (e.g., O'Hara et al., 1993; Evans and Church, 2000). Loso et al. (2004) quantified sediment yield by measuring the accumulation of fine and coarse-grained sediment in an ice-dammed lake that had drained. This work highlighted the uncertainties associated with measuring only suspended sediment yield as a proxy for total sediment flux.

Sediment yield is frequently converted to basin-averaged (or glacier-averaged) erosion rate. The effective erosion rate is simply the sediment yield divided by the basin area or glacier footprint. A key assumption in these calculations is that subglacial storage of sediment is either zero (i.e., the bed beneath the glacier is bare bedrock) or storage of sediment is steady (input of sediment into the glacier is equal to sediment output). It is difficult to assess the validity of this assumption in subglacial settings.

Sediment yields from glacierized basins

An excellent summary of sediment yield from glacierized basins can be found in Hallet et al. (1996). Typically, sediment yield is converted to basin-averaged erosion rate and reported in mm a^{-1}. Hallet et al. (1996) reported rates of erosion in glacierized basins exceed those in fluvial settings by an order of magnitude or more, with sediment yields increasing with greater ice cover. Sediment yields converted to erosion rates vary from 0.01 mm a^{-1} for polar glaciers, to 10–100 mm a^{-1} beneath fast-moving temperate glaciers (Hallet et al., 1996). Koppes and Hallet (2002) document variability in sediment yield and, therefore, erosion rate in Alaskan tidewater glaciers. Their work suggests the extremely high modern rates of erosion (greater than 30 mm a^{-1} in this region) are about five times greater than long-term erosion rates because of rapid ice motion and calving resulting from warming since the Little Ice Age.

Summary

Sediment yield from glacierized basins is a key measurement for constraining rates of glacial erosion. Models of exhumation and range-scale evolution are sensitive to the timing and distribution of rock removal, and quantifying sediment yield is an important aspect of constraining these models and their predictions. While measurements of sediment yield are difficult to make, they offer insight into basin-wide erosional dynamics in arctic and alpine systems.

SEM ANALYSIS OF GLACIAL SEDIMENTS

William C. Mahaney
Quaternary Surveys, Thornhill, ON, Canada

Definition

Microtextures studied by SEM are found on quartz and other mineral grains from different sedimentary environments, and these along with grains from bedrock release, are transported by glaciers which inflict the most extensive array of fracture and abrasion microfeatures. Anywhere from 10% to 20% of grains in glaciers may escape contact with other grains, and hence sojourn in the ice without suffering physical damage. The other 80–90% of glacial grains will exit the system with fractured and abraded surfaces some of which are diagnostic of the glacial environment. These grains record damage that, to a large extent, depends on the thickness of the ice and the distance of transport with temperatures close to pressure-melting (p-melting). While the distance of transport is nearly impossible to compute with total accuracy, it would seem that long-distance transport close to p-melting will yield a triangular faceted quartz grain totally reformed from its original shape and size, and with the greatest damage inflicted on it. No other geological agent is capable of this transformation and none have the damaging effect that glaciers can inflict on quartz and other minerals entrained in the ice.

SEM analysis of glacial sediments

Sand grain surface microtexture analysis, using the Scanning Electron Microscope (SEM), was initiated by Dave Krinsley and John Doornkamp (1973), who introduced the subject to sedimentology. The original atlas became a repository of sand grain imagery and provided the first attempt to collate microtextures on sands, specifically quartz sands, linking them to specific geologic agents and/or sedimentary environments. After five decades of research on sand grain morphometry/fractography, it is now known that only a few microtextures are unique to specific environments, or geologic processes. Many microtextures, previously believed to be unique signatures of a particular environment, are now known on sands emplaced by different geologic/geomorphic processes. Thus, microtextures ranging across many environments perfectly illustrate the *Principle of Equifinality*, that is, in open systems a given end state can be reached by many potential means (Mahaney, 2002). Beyond this, investigators need the power of a representative population of grains to definitively identify the conditions under which grains are sourced, transported, and emplaced. The initiation of SEM analysis of sediments was pioneered by Biederman (1962), Porter (1962), and Krinsley and Takahashi (1962), and has since undergone several modifications as equipment has evolved into the digital age. During the inception of SEM

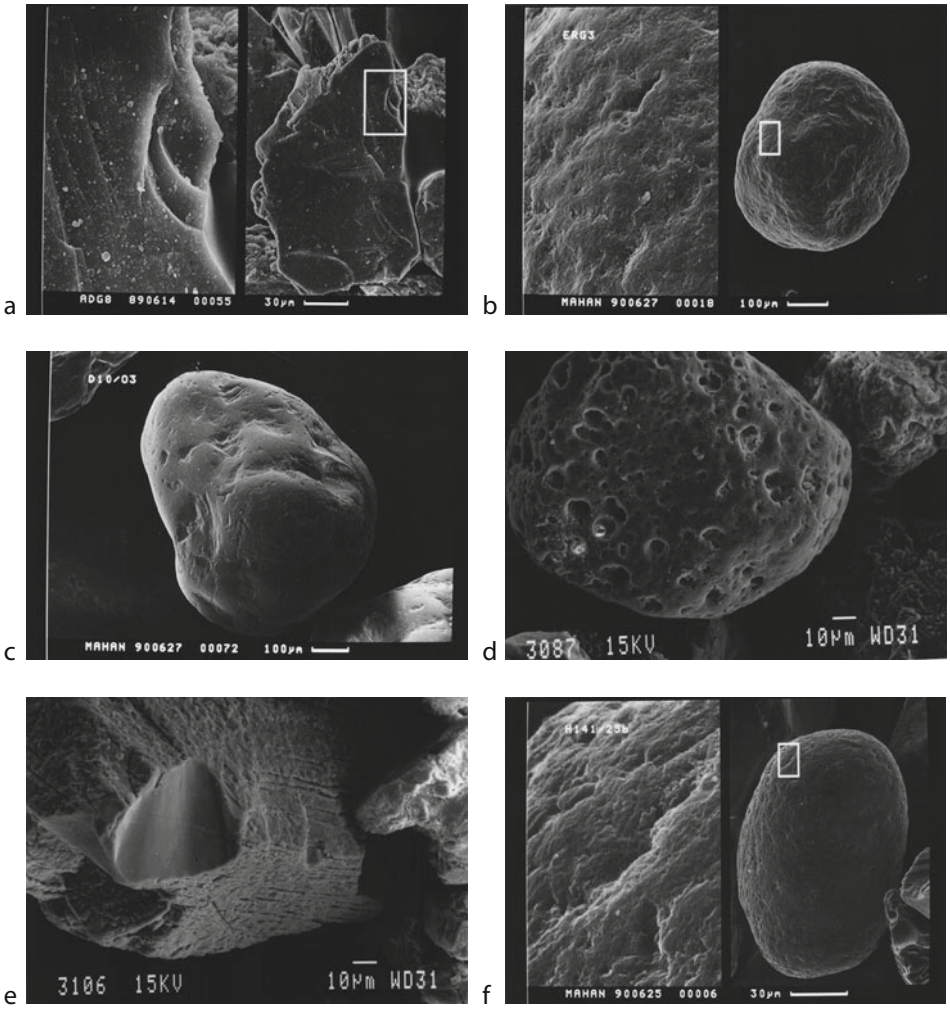
investigations in the early 1960s, research emphasis focused on sedimentological and mineralogical applications. However, increasingly over the years, the method has been applied to other fields where SEM-EDS (Energy Dispersive Spectrometry) methods can be employed to build a database of microtextures, microstructures, and chemical spectra that help to answer questions related to weathering in paleoenvironments as well as generate new ones. For example, standard databases on precipitates and coatings, information lacking in the Krinsley and Doornkamp (1973) volume, are now frequently used to help solve questions related to weathering of glacial grains (Mahaney, 2002), the coating chemistry offering new insight into wetting depths and paleoleaching in paleosols (Mahaney, 1990a), all of which may provide valuable information on preweathering prior to glacial transport (Mahaney et al., 1991) and relative dating of sediments (Mahaney et al., 2009).

The 1973 volume on glacial grain surface microtextures, although long out of date, remains a basic reference for researchers interested in the application of the technique since that time. Additional work by Whalley (1978) and Marshall (1987) has added numerous case studies in the microtexture field since that time. The new SEM atlas by Mahaney (2002) contains additional case studies intended to complement and expand upon these earlier reference works; however, the intent here is to bring the reader up to date on current techniques used and the range of microtextures now recognized on sands from glacial environments. From the evidence discussed by Mahaney (2002), it is possible, for example, to separate till from glaciolacustrine and glaciofluvial grains within the glacial sedimentary environment. Similarly, while it has proved difficult to separate tills genetically (Mahaney et al., 2001), it is possible to generate information related to glacial thickness and differences between warm and cold-based ice (Mahaney et al., 1988), as well as the relative amount of water transport within the glacier system.

In general terms, the pathway of grains from initial bedrock release (Figure 1a; quarrying process) leads to the production of *fracture faces* (Mahaney, 2002), the one common, but by no means the only, microtexture resulting from mechanical weathering. The fracture face is undeniably the common microtexture found on grains entering alpine glacial systems (Mahaney et al., 1991) and one that is soon overridden by a complex of new signatures comprised of subparallel linear fractures, conchoidal fractures, arc-shaped steps, uplifted plates, deep grooves, and microstriations, the latter being the one unique glacial microtexture, just as striations can be taken as evidence of glacial movement. Hence, glacial signatures can only be assessed from individual samples of till if the ice responsible attained a minimum thickness (~50–100 m) and applied a minimum force (Mahaney et al., 1988). Indeed, SEM microtexture imagery of α-quartz grains grown in an ice column and subjected to uniaxial stress under controlled conditions has indicated the importance of greatly increased glacial crushing that occurs along a transition from cold-based to warm-based ice with a minimum thickness in excess of ~100 m. At temperatures close to p-melting, and with cryostatic pressures equal to 1- and 2-km thick ice sheets, stick–slip motions appear to induce an array of microtextures on quartz sand grains that closely resemble microtextures observed on grains in tills deposited by the thickest Pleistocene glaciers of Canada, Europe, and the Antarctic. Aside from striated surfaces, it is not the presence of individual microfeatures that identifies the mechanism of glaciation, but the range of microtextures associated with varying degrees of glacial crushing. With decreasing ice thickness the range of microfeatures diminishes until, with thin cirque ice, little damage appears on grains transported from source to end moraines (Mahaney et al., 1988).

Grains subjected to aeolian processes (Figure 1b) produce bulbous edges, rounding and frosting on larger grains due to abrasion, along with occasional upturned plates and the presence of numerous craters of variable geometry (abrasion fatigue). Aeolian grains may be subject to multiple turbulent collisions during transport and later subjected to glacial transport which adds a whole new array of microtextures. The very fact that aeolian and glacial grains were differentiated in an analysis of Saharan ergs (Mahaney and Andres, 1996), without any previous knowledge of sedimentary processes on the part of the SEM operator, should convince skeptics that there is, indeed, an advantage in using SEM imagery in sedimentological analyses of various kinds. Aeolian microtextures are generally limited to superficial "skin" disruption and damage to individual grains which distinguishes them from deeper, more linear oriented "Wallner lines" produced by glaciation (Mahaney, 1991, 2002). Grains subjected to aeolian transport may retain their windblown signatures after transport in glacial systems but most often deeply embedded glacial crushing microfeatures may completely obliterate the aeolian source markings.

The fluvial environment, like the aeolian one, produces an array of superficial fractures and abrasion microfeatures often superficially disrupting the surfaces of grains, all of which are fine-tuned in the glacial environment. However, for the most part, fluvial transport tends to produce severe rounding and abrasion correlated with the discharge and turbulence of river or tsunami wave flow, the latter with optimal geomorphological parameters often results in resurfacing of quartz with a high count of v-shaped percussion scars (Mahaney et al., 2010b). Overprinting of fluvial grains brings forceful grain collisions that produce v-shaped percussion scars (Figure 1c), the one microtexture exclusive to the fluvial and geothermal environments. Interpretive difficulties arise because similar microfeatures are also produced by meltwater transport within glaciers, as for instance, in moulin systems or in fast moving, turbulent subglacial and englacial meltwater channels. If such grains are fluvially overprinted upon leaving the glacial system, the origin of the grain may be difficult or impossible to decipher. Of course, in nonglacial areas, streams leave an indelible record of water transport on quartz and other mineral



SEM Analysis of Glacial Sediments, Figure 1 (**a**) Mass wasted quartz grain, Adishy Glacier Area, Caucasus Mountains, Russia. The fracture face on the grain is typical of bedrock release accompanied by deep conchoidal fractures. The reverse side appears to be partly etched and covered with coating. Close up of the fractues is ×5. (**b**). Round quartz from Saharan ergs shows slight bulbous microfeatures (*right and top left facets*) and minor abrasion fatigue, a type of disrupted lattice formed from dry grinding. The disrupted lattice consists of broken surface structures of mm or micron size made up of small cracks, dislocations. The elongate depressions shown in the enlargement (×10) produce microrelief not seen with hand lens and probably result from saltation. (**c**), Aeolian grain with bulbous edges overprinted with v-shaped percussion cracks from transport in the Nile River; (**d**), Subround shock melted quartz with interconnecting melt cavities from Clear Creek, Colorado (K/T ejecta); (**e**), Shock lamellae on partially melted quartz, partially melted and annealed (From Mahaney, 2002, courtesy Oxford University Press). (**f**), Round quartz from lacustrine sand in the Thorncliffe Formation, Middle Wisconsinan age, Little Rouge Creek, Ontario, Canada. A plethora of v-shaped percussion scars attest to continual movement in Upper Flow Regime water masses (lacustrine or fluvial) prior to the ingress of Last Glacial Maximum ice in Southern Ontario.

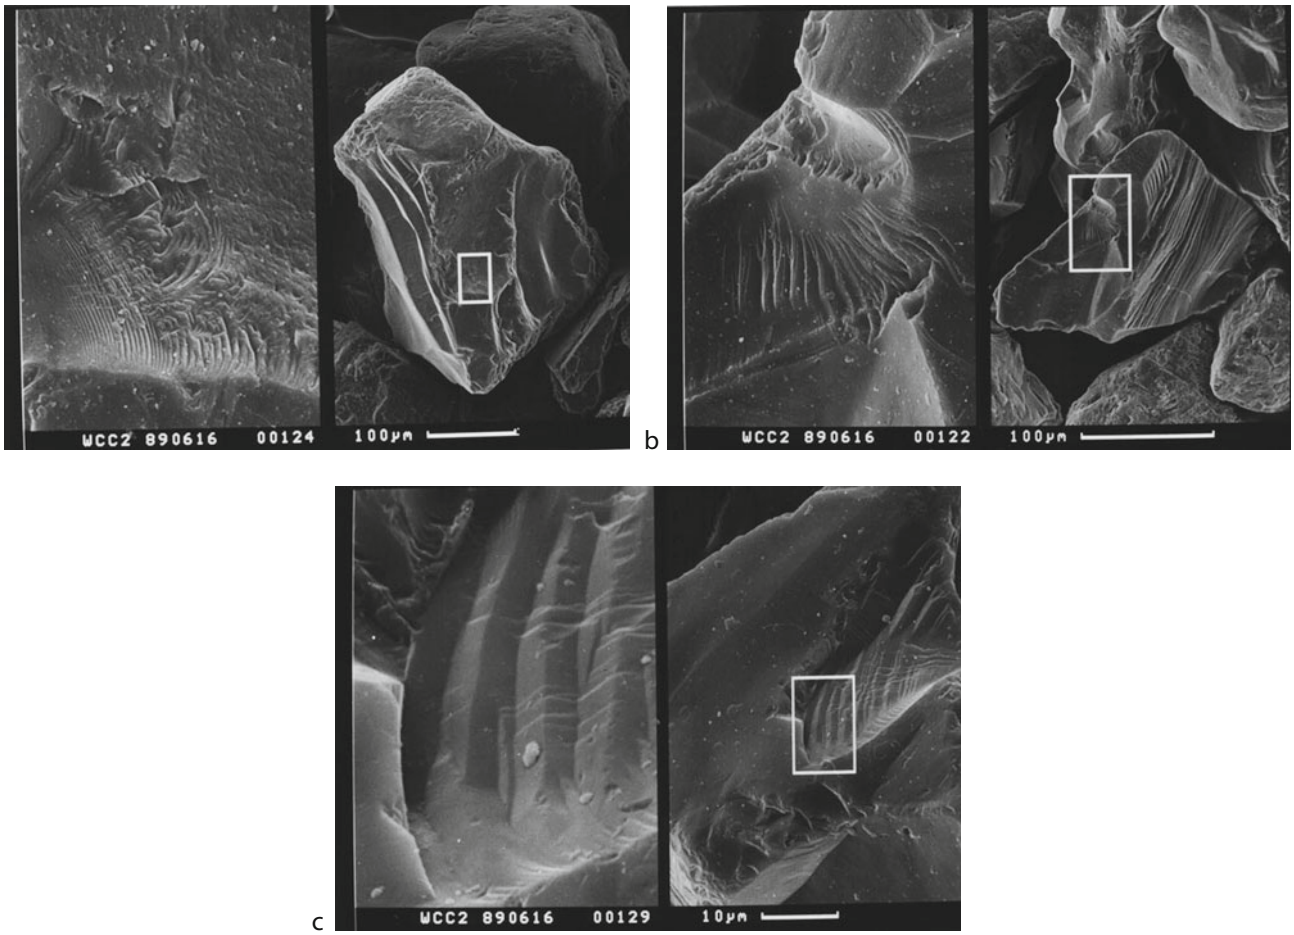
fragments. Mass wasting, a neglected geologic agent in microtextural studies (Bull et al., 1987), initially leaves a record of bedrock release on grains just as in the glacial environment; however, fast or slow movement in gravitationally induced systems leads to the generation of new microtextures that involve grain packing and slickensides, microfeatures that are quickly erased in later glacial transport. The most distinctive microtexture in mass wasted sediments is the fracture face, a relatively clean break on the grain surface, often surrounded by varying degrees of chemical dissolution, microfeatures that survive transport in alpine glaciers, but are usually obliterated with long-distance transport in continental ice sheets. Thus, SEM investigations offer the chance to reconstruct source microtextures, followed by glacial, aeolian, and fluvial transport.

Some researchers (Oberbeck et al., 1993) consider that bolide (asteroid) impacts provide a plausible explanation for the occurrence of some tillites (ancient glacial deposits), characterized mainly by fragmented and

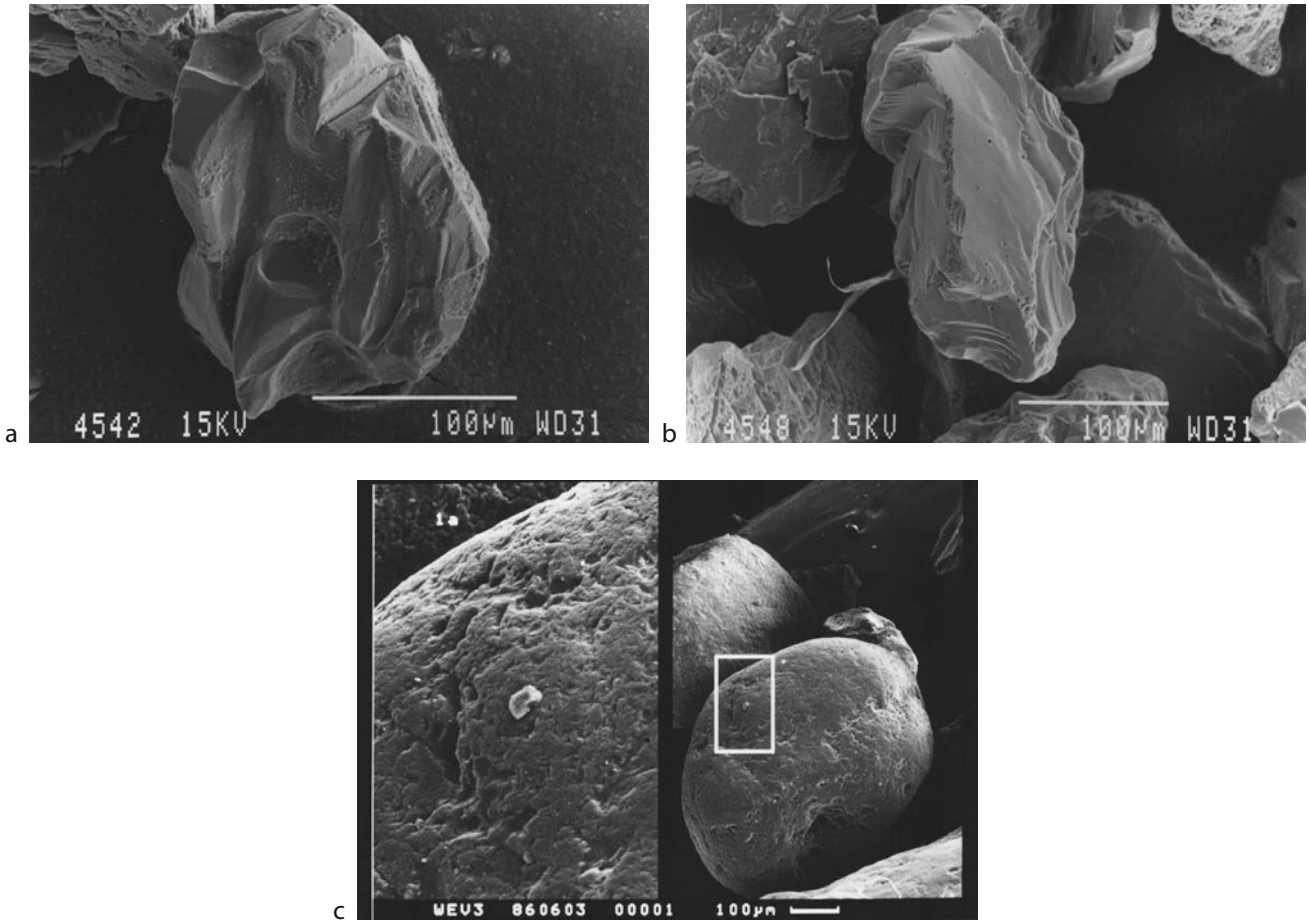
fractured quartz particles (Figures 1d and e). The tillites in question, however, are lacking in shock-melted quartz and planar deformation features (pdfs) which are the main product of extreme high-energy impacts ([15–25 km/s] [Boggs et al., 2001; Kennett et al., 2009; Firestone et al., 2007; Mahaney et al., 2010b]). Additional investigations of tillites are needed to determine if shock-melted quartz can be located in sufficient quantity to support the impact theory.

Glacial grains (Figures 2a–c and 3a–b) probably carry the greatest range of deeply embedded microtextures when compared with grains affected by other geologic agents. This includes the full range of fractures (Figures 2a–c and 3a–b), grooves, and abrasion microfeatures listed in Mahaney (2002), as well as solution-precipitation microfeatures and other coatings that may predate or postdate a glacial episode. Moreover, some grains (perhaps as many as 1 in 5) make the "glacial trip" unscathed by their sojourn in the ice and carry only microtextures related to previous environments. These fragments may carry a record of release from bedrock with unremarkable fracture faces, without the usual grain-to-grain contact in glacial systems that produce triangular faceted, sharp-edged grains with moderate to high relief, the latter usually well abraded with a multitude of fractures, grooves, and well-worn abrasion microfeatures.

As recorded in most studies, quartz is the ubiquitous and well-studied recorder of glaciation in many environmental settings (Krinsley and Doornkamp, 1973; Helland and Diffendal, 1993), major mineral suites, including all the plagioclase and orthoclase minerals, as well as many heavy minerals and gold, may also be analyzed to determine the degree of damage inflicted during glacial transport (Mahaney, 2002). This discussion, however, concentrates on quartz as the prime environmental recorder.



SEM Analysis of Glacial Sediments, Figure 2 (**a**), Deep troughs in subangular quartz from basal till, Wildcat Creek, Indiana. Linear troughs to left, curved troughs to right. Pseudo-chattermarks terminate on an upper ridge. See Folk (1975) for similar microfeatures on garnet. Upper grain is subrounded quartz and carries numerous v-shaped percussion scars from transport in meltwater. Crossed fractures, like crossed striae, depict typical high frequency younger fractures overprinting low frequency, higher wavelength microfeatures to the right in the enlargement (×10). (**b**), Quartz, heavily abraded and fractured; (**c**), Quartz with deep striations.



SEM Analysis of Glacial Sediments, Figure 3 (**a**) Angular quartz with partial abraded edges in Weichselian Till from sample TAR 3/3, Estonia. The sample shows deep grooves, multiple striations, deep cavities, well-abraded facets, and minor preweathering as indicated by minor etching; (**b**) from the same section, angular quartz with wavy, smoothed top and multiple grooves, striations and conchoidal fractures along the *c*-axis; (**c**) Two subround quartz grains with numerous v-shaped percussion cracks in the lowermost till, WEV3 Section, Wellsch Valley, Saskatchewan, Canada. The number of round grains with fluvial transport signatures depends on whether the till has a warm- or cold-based history. These grains have a warm-based history that becomes depleted up-section.

The relative hardness of quartz (7.0 on Mohs hardness scale) and its widespread occurrence in nearly every environment make it an ideal candidate for microtextural study. Grains are often unblemished, existing as colorless, hexagonal crystals, although sometimes colored by impurities. With an absence of cleavage, especially in the coarse fractions (2,000–50 µm), it is composed exclusively of silica-oxygen tetrahedra with oxygen atoms joined with silicon into a strong geometrical network (Frondel, 1962). Unlike weaker minerals, quartz is capable of transiting the glacier system many times and it is possible to examine complex quartz grains that have undergone many trips in the ice. Because quartz is subject to slow dissolution and precipitation, it is also an ideal mineral to record subaerial and diagenetic weathering events; moreover, it is possible to observe preweathered microfeatures overprinted with the fresh scars of glacial transport, followed by more recent weathering events. Hence, a single grain may carry evidence of several transport/weathering episodes (Mahaney, 2002).

Load

The load transported by ice ranges from clay to boulder and block sized material. It also includes a minor amount of aeolian-delivered grains as well as mass wasted material derived from nunataks and high-cirque walls. The supraglacial load may be light to heavy, depending on the nature of the source rocks and the climatic setting (tropical mountains to Arctic or Antarctic environments), and consist of material delivered by airfall influx and gravity to the glacier surface. There must be grain-to-grain contact even at pressures close to 1–2 atm to achieve sufficient stress in the basal ice to comminute mineral

material. The englacial environment, however, is relatively free of clastic load, although subsurface channels may move large volumes of meltwater that may occasionally carry clastic load. In these turbulent sluiceways grains may suffer heavy abrasion, giving overprints partially masking previously inherited weathering (e.g., preweathering) and other fractures and/or abrasion inflicted during the initial stage of ice transport.

The basal ice, containing the bulk of the clastic load in a glacier, together with variable amounts of water, provides the environment with the highest probability of grain-to-grain contact. Increasing water content tends to create hydrostatic pressures close to one bar and nearly equal in all directions. With decreasing water content, shear stress rises somewhat but falls far below the pressures that result from stick–slip processes (up to ~200 bars) where sudden slippage generates vibrations, the sudden convergence of kinetic energy to elastic energy. The vibrations produced by glacier movement are manifest in the array of fractures seen in great numbers on glacial grains. No other geologic agent can generate the strong vibrations, cones of energy that produce deeply embedded microfeatures in clasts nicely demonstrated by the multitude of fracture microfeatures often observed on glacial grains.

Of the many pathways by which clasts may enter, move through, and exit a glacier, grains of any description may: (a) sink into the ice from the glacial surface, (b) be carried by surface and subsurface meltwater streams to exit the terminal areas, (c) be forced to the surface by thrusting, and/or (d) be entrained from contact with underlying bedrock and/or till. This raises the question as to where to sample till, and whether it is best to concentrate on subglacial deposits where glacial grinding is apt to be at a maximum, or alternatively sample end or lateral moraines, which might likely contain a mix of material deposited directly in contact with ice or from meltwater.

Unlike aeolian and fluvial grains, glacial grains are generally held in bondage by the ice, or by other grains in rigid suspension, so that the ultimate amount of grinding occurs with movement down glacier. Aeolian and fluvial grains, as previously discussed, are capable of considerable turbulent random movement, and while they are capable of high-energy collisions, they are not subjected to the sustained and concentrated high-energy fields inflicted on glacial grains. While aeolian grains may produce scars somewhat reflecting microfeatures resulting from glaciation, the damage is far less deeply imbedded in the former grain surfaces.

As suggested by Barcilon and MacAyeal (1993) and Mahaney (1995, 2002) stick–slip motions at the base of glaciers tend to fracture and abrade particles in ice. Particle surface microtextures are governed partly by bedrock release (mechanical weathering), preweathering, resultant transport by different geologic agents and diagenesis/pedogenesis in a depositional environment. Within the ice body, quartz grains form inhomogeneous elastic inclusions with different strengths depending on preweathered states and these respond to variable stresses by forming fracture and abrasion microfeatures. If the particles are already weakened by chemical preweathering, and if they have fracture faces (Mahaney, 1995) derived from frost riving (Mahaney et al., 1991), they may easily comminute into smaller particles. This is particularly the case if they come into contact with one another in the basal ice layer where stick–slip processes produce high basal shear stresses and high strain rates (Barcilon and MacAyeal, 1993). Basal till, with meltwater lubrication, glides over bedrock and occasionally surges, subjecting particles carried as load to high fracture and abrasive stress, engendering low velocity impacts which impart microtextures onto quartz sand surfaces. While there are similar shallow, conchoidal and linear fractures on quartz from aeolian (Mahaney and Andres, 1996) and fluvial environments, the angular shape, deep entrenchment of conchoidal and linear fractures, and frequent directionality of troughs and grooves (striations) are unique to grains emplaced by glacial transport. As shown by Sweet and Soreghan (2010), Soreghan et al. (2008) and Strand et al. (2003) glacial microtextures may remain in the rock record for tens of millions of years.

Microtexture recognition

Almost all the microfeatures listed and discussed in Mahaney (2002) can be found on glacial grains. All dissolution and weathering microfeatures resulting from subaerial weathering and or diagenesis are presumably inherited from interstadial or interglacial climates having survived the damages inflicted on a large proportion of grains moving through glaciers.

Taking the array of microtextures as possible candidates for microfeatures likely observed on glacial grains, the researcher is faced with the question of how many grains to analyze and at what resolution. All microtextures should be logged by their frequency of occurrence, and it is necessary to analyze several samples and several fractions of each sample in order to arrive at a meaningful interpretation. A quick overview of each sample can be obtained by analysis of the fine and very fine sand fraction taking into account that angularity is often extreme in the finer fractions. This should be followed by analysis of at least 20 grains in the medium sand fraction (500–250 μm) and 20 grains in the coarse to very coarse fractions (2,000–500 μm). These grains should be collected as randomly as possible and studied under the light microscope prior to using the SEM.

The degree of relief is one of the first assessments to make when analyzing a sample suite. Because of heavy fracturing and abrasion, high relief often dominates on glacial grains. This needs to be assessed and given a percent frequency of occurrence. Next, among the population of grains studied, the degree of angularity, edge rounding, and all fracture and abrasion microfeatures need to be identified and frequency of occurrence tabulated. Last, all weathering, precipitation, and dissolution

features should be assessed in a similar fashion. Glacial grains should be compared and contrasted with grains resulting from the action of other geological agents, perhaps in the same section or between sections.

Continental glaciation

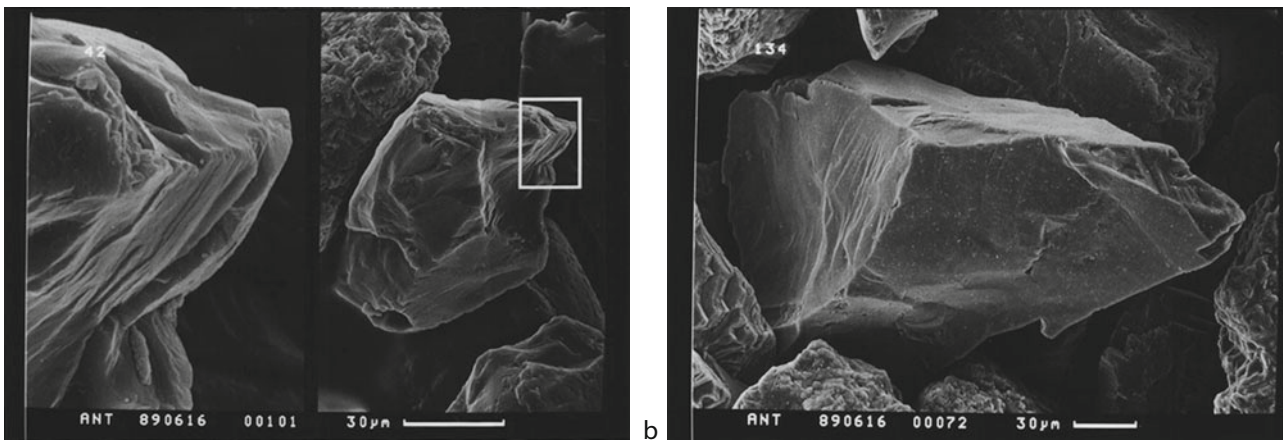
Wisconsinan and pre-Wisconsinan tills provide a wealth of information on glacial processes and preweathering that occurred prior to glacial entrainment (Mahaney, 1990a). One of the most striking microfeatures on grains from thick and extensive valley glaciers and continental glaciers are curved grooves, striations similar to those forms on bedrock or on pebble, and cobble clasts residing in tills (Figure 3a, b). Linear grooves may be glacial but they may also result from fault movement although with tectonic origins there is usually lattice distortion, very high abrasion, and uplifted surfaces that allow differentiation from glacial processes. Curvilinear grooves are unidirectional features that are as much an indisputable proof of the glacial environment as striations on rock. Whether these grains are frozen into the ice and dragged along the surface or affected by ice drag on particles, which eventually break off from bedrock; they are clearly the product of ice contact similar to macrofeatures that have been invoked to prove glaciation for nearly two centuries since the advent of the Glacial Theory proposed by Louis Agassiz.

Another microfeature typically observed on glacial grains is the v-shaped percussion crack (Figure 3c) that indicates the effect of water transport, presumably in this case, meltwater flow. Also with attrition along the edge of the grain some rounding appears to have been in progress when these grains were incorporated into till. Edge rounded grains, nearly equant, often carry surface scars of meltwater transport in somewhat greater abundance than is usual in fluvial systems. Often they are associated with grains showing directional grooves, steplike features, cirque-like amphitheater, overprinted with superficial radiating fractures less deeply inscribed and uplifted surface plates that have been lifted out leaving the amphitheater-like feature, the radiating fractures of which indicate plate removal may have come from a high-stress collision.

Antarctic tills

Grains in polar environments show heavily damaged surfaces representative of tills emplaced by continental ice. Often refashioned into triangular-shaped particles (Figure 4a–b), they exhibit deep fractures, upturned plate along the bottom of the grain, somewhat curved directional trough from top to mid region and steplike features on top right; much of the grain is extensively abraded. Considered to be the product of high stress fields, such microfeatures might be expected in thick continental ice with low water content where high local stick–slip motion might produce pressure capable of starting to dislocate the lattice. Polar grains display grains with high degrees of abrasion and directional troughs. While adhering particles are rather scarce on most of the sands shown here, they are more prevalent on the abraded grains.

The most intense crushing comes from the thickest ice as indicated by observations made by Mahaney et al. (1988) following a thorough examination of samples from Mount Kenya and southern Canada. Quartz sand grains in thick ice, such as the Antarctic Ice Sheet, are presumably subjected to transport over long distances with maximum stress generated by stick–slip mechanisms at the base of the ice.



SEM Analysis of Glacial Sediments, Figure 4 (**a**) Angular quartz from till 42 (Mahaney et al., 1996) exhibiting multiple fractures, deposited by the Inland Ice Sheet, Antarctica. Edge of fractured quartz lower right; preweathered plagioclase in upper left; (**b**) Angular quartz with multiple fractures and minor preweathered etching in upper left surrounded by preweathered calcite and plagioclase.

Alpine glaciation

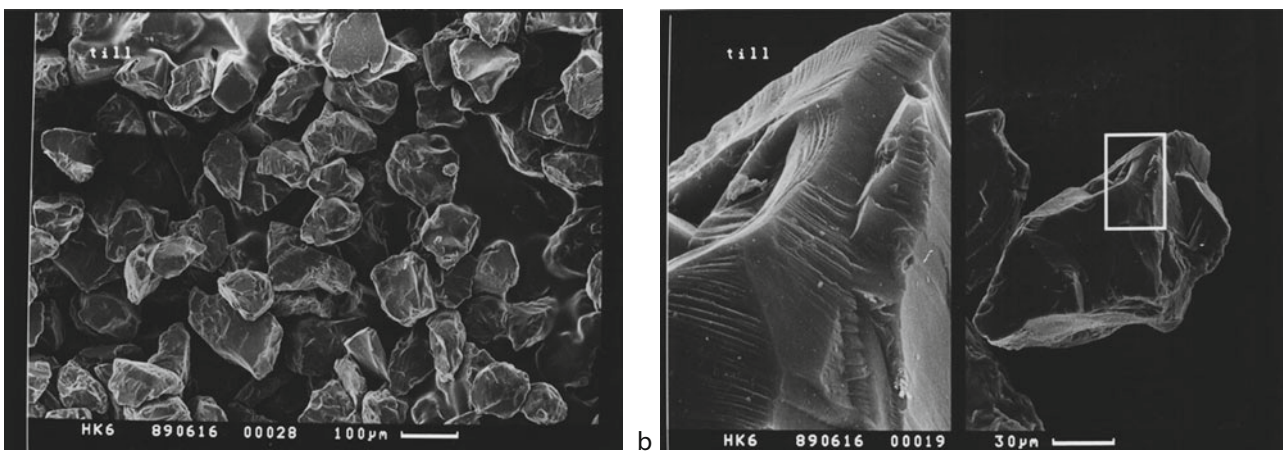
Quartz and other mineral grains, recovered from various tropical and middle latitude alpine areas (Figure 5a, b), show ranges of fracture microfeatures, striations, and abrasion that appear to be related to ice thickness and distance of transport (see Mahaney, 2002). Quartz and other minerals surviving transport in alpine ice carry a range of fractured and abraded preweathered grains showing varying degrees of *minor* subparallel linear fractures, conchoidal fractures, and abrasion that suggest low shear stress, low stress field conditions for stick–slip occurrences, and, of course, minimum transport distance. As previously discussed, many alpine subglacial tills are well lubricated with water giving them very low shear stress and high pore water pressure making it difficult to fracture grains carried as basal load. This condition must also affect stick–slip processes (Barcilon and MacAyeal, 1993; Mahaney, 1995) creating a situation where, even if stick–slip were to occur, the resulting shear stress would not overcome the shear resistance of the grain.

Reworking of grains from other environments through the glacial system is evidenced from several suites of samples from African massifs, the Andes, Tibet, Rocky Mountains, and the European Alps. The greatest ratio of preweathered to fresh grains is often observed in alpine areas for both Neoglacial and late Pleistocene tills studied to date. For example, the imagery indicates glacially crushed grains may carry extensive dissolution features, overprinted with a glacial signature followed by younger weathering and re-entrainment in an active glacier.

Experimental fractography

The theory of brittle and ductile fracture, the central canon of microtexture theory, requires the fracturing of quartz and other minerals to result from increasing stress until strain produces slow to catastrophic crack propagation. The resulting fractures may open along preexisting flaws in minerals (Griffith cracks) and/or generate new flaws extending across mineral surfaces, either as shallow or deeply embedded cracks. These fractures are predetermined by the stress–strain energy field, much as vibrational energy is released through the grain (Mahaney, 1995). In a glacier, large sand grains of very coarse to coarse (2,000–500 μm) grade size require less stress to fracture than smaller ones (500–50 μm), but much depends on the applied stress field, strength of the minerals undergoing strain, and particularly their weathered state. In general smaller grains require, on average, higher stress fields to induce failure leading to crack propagation. Put another way, the probability of fracture by breaking the weakest mineral increases with increasing size of fragments. Particularly susceptible are mineral intergrowths, as for example, quartz and biotite, with the latter mineral prone to rupture. Analysis of different grade sizes of glacial sands (Mahaney, 2002) within the same till sample reveals that coarse fractions exhibit about the same range of glacial microtextures as fine ones.

Analysis of different fragment grade sizes of sands in glacial sediment has shown that repeated fracturing results in increased fragmentation. Increased fragmentation, and hence smaller size material, requires increased stress to achieve continual fracturing as particle size diminishes from sand to silt. Small silt-size fragments (<50 μm) continually fragmented/comminuted and/or liberated from larger grains by grinding at the base of the ice lie at the end of their size reduction run (Dreimanis and Vagners, 1971), and are apt to be preserved intact in till after their sojourn in the ice. These smaller grains may carry the final range of microtextures from glacial crushing, the end product of a long series of grinding and fragmentation from very coarse sand to silt. Other small fragments of



SEM Analysis of Glacial Sediments, Figure 5 (**a**) General frame showing angular and subangular grains, a mix of plagioclase, orthoclase, minor biotite, and quartz in till from section HK6, Zillertal Alps, Austria; (**b**) Angular quartz with multiple fractures and deep grooves.

the same size, subjected to low pressure mechanical action by either mass wasting, aeolian, and/or fluvial agencies long before they are added as load to a glacier, are likely to be little modified by the mechanical forces of an active glacier although they may be overprinted with a glacial signature. This is why fine sand–silt fractions are important to study with the objective of cataloging the range of microtextures at close to the final stage of comminution. Therefore, depending on grain-to-grain contact within the ice some of the grains in the fine and medium silt fractions may have a microtexture record entirely unrelated to travel in the ice; that is, some grains make the glacial trip in isolation, without contact with other grains.

Fractography, that is the identification and interpretation of fractures on particle surfaces (Krinsley and Donahue, 1968; Krinsley and Doornkamp, 1973; Margolis and Krinsley, 1974; Mahaney et al., 1988; Mahaney, 1990a, b, 1995; Marshall, 1987), has been pursued with the objective of analyzing individual fracture markings, and their frequency of occurrence, as a means to gain insight into glacial grain history. All attempts to target certain microtextures as "glacial" have made it necessary to pose several important questions: (1) Do characteristic mechanical damage microfeatures reside on grains subjected to glacial transport? (2) If glacial microfeatures exist, are they related to glacial dynamics? (3) If unique glacial microtextures exist, is it possible to deduce distance of transport and ice thickness from the fractography?

Many different minerals have been used to study crack propagation in glacial grains but quartz is the usual material selected as test material for stress–strain relationship tests because it is abundant in glacial deposits and its hardness ensures it to be an excellent long-lived recorder of damage inflicted on it. As a test, amorphous silica glass spheres have been utilized: (1) as an analog of quartz that could be subjected to low stress in a confined space, (2) using a spherical shaped object makes it possible to compare with crushed mineral grains, and (3) to determine the shape and number of fractured particles.

Since several previous fractographic studies were performed on till particles in the 50–500 μm range (Krinsley and Donahue, 1968), and on larger particles of 16–26.5 mm diameter (Iverson, 1990), it seemed logical to carry out laboratory experiments using quartz of a similar size. In the first three tests, particles were selected from fragments of a large single piece of optically translucent α-quartz (from Brazil), crushed by low velocity impact. After separating the particles into three size categories of 50–500 μm sizes, they were subjected to compression in a cylindrical volume of ice at 2,000 psi capacity (see Mahaney, 2002). Compression was achieved in a piston cylinder that contained a cooling agent maintained at a constant low-test temperature.

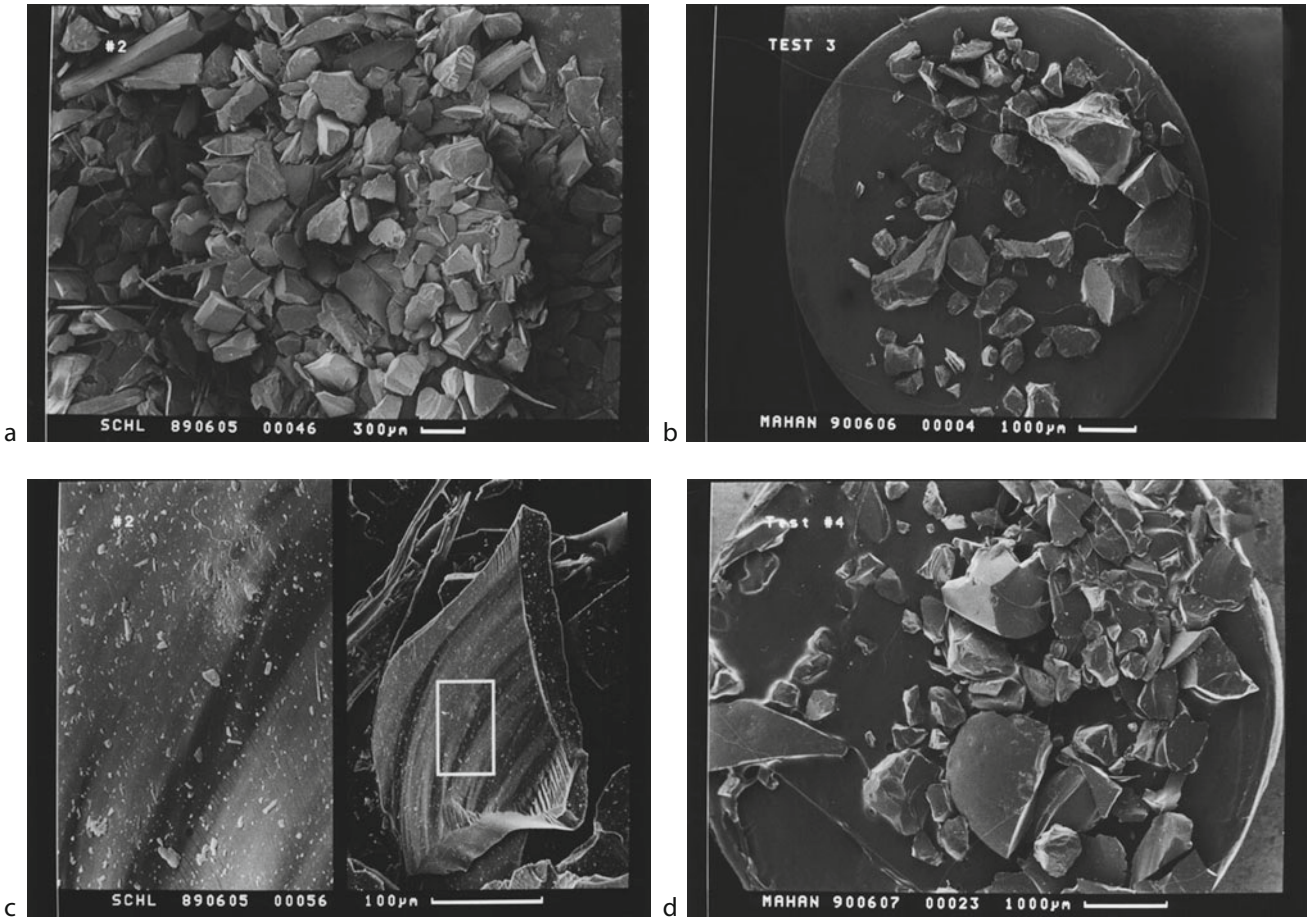
Mineral fragments were sprinkled widely on ice, which was grown by layer to insure particle segregation. Each layer was periodically subjected to a low vacuum of ~1 Torr to eliminate as much air as possible. The first three tests were run on quartz fragments. In Test 1 the ice temperature was below −10°C, thus similar to a cold glacier. Tests 2 and 3 were carried out using quartz (2) and silica glass (3) and with the temperature raised to p-melting simulating warm glacier conditions. The objective of the experiment was to determine the amount of fracturing that occurred in the charge before and after compression in ice.

Test 1 (Figure 6a) used the *fine* sand fraction (125–250 μm), selected as load with a maximum pressure of 2,000 psi or 17.5 Mpa on the ice cylinder, as before equating to an ice thickness of 1.98 km, applied for 30 min. Recovered grains showed several new fragments with sizes finer than the starting size. Original fragments with protrusions were subjected to considerable edge rounding and several flaky particles were likely due to physically induced spalling probably from lattice disruption.

In Test 2 (Figure 6b), the grain size and cylinder pressure were approximately the same as in Test 1. In this experiment, grains were subjected to similar pressure as in Test 2 for 40 min while temperature was brought up to p-melting. The imagery of the resultant charge shows considerable change in particle size and distribution. Here, several small fragments and fine fragments cling to larger ones, which survived compression. P-melting conditions in the test cylinder led to formation of meltwater; ice bridges melted, allowing particles to join. Particles at the base of the brass cylinder were subjected to high hydraulic pressure causing some quartz to become embedded in the brass base. In this third test, quartz grains were fractured into numerous particles brought into mutual contact under high load. These particles exhibited unmistakable arc-shaped steps with numerous and deeply imbedded conchoidal and subparallel linear fractures, with a sizable population of fine adhering particles.

Test 3 (Figures 6c and d), the concluding test in this series, was designed to study the effect of compression on a population of well-isolated, untouched, and perfectly spherical silica glass spheres. These were situated to represent inhomogeneous inclusions exactly as would occur with fresh quartz released from bedrock. Because of their sphericity, they represented a set of particles with equal geometric stress concentrating factors, easily amenable to theoretical analysis but different from what would occur in nature. Pressure was applied at 17.5 Mpa as in the previous tests, and after a short time, the temperature was raised to p-melting. Mechanical damage on this load was severe with four spheres totally shattered into small fragments of fine sand and silt size, others greatly reduced in diameter, and still others escaping with only a few craters produced. Apparently the nine spheres suffering the greater damage released fine particles simulating glacial grinding, the latter process originally postulated by Smalley (1966).

These experiments show that coarse silt inclusions in ice apparently unaffected escape compression. Sizes ranging from fine to medium sand are affected by compression depending on temperature. Clearly, the p-melting temperature is critical to produce the greatest degree of fragmentation as shown in Tests 2 and 3. Large particles of equal



SEM Analysis of Glacial Sediments, Figure 6 (**a**) Recovered charge of fragmented sands originally sieved to medium and fine sand size (125–250 μm diameter). Approximately 25–30 grains of the sample were fragmented into smaller sizes; (**b**) Representative quartz fragments from Test 2 of approximately 125 μm diameter, with deeply imbedded conchoidal and subparallel linear fractures and sharp edges with numerous adhering particles; (**c**) Fragments of silica spheres, originally of 250–1,000 μm size recovered (Test 3) after compression in ice at simulated thickness of 1.98 km; (**d**) Recovered fragmented charge from Test 4. Original size of the silica spheres was 3.5 cm. Simulated ice thickness was 1.98 km. Experimental laboratory work compressing alpha quartz and silica spheres at simulated glacial crushing pressures was done in the laboratory of Prof. H. Schloessin, University of Western Ontario, London.

sphericity are subject to considerable comminution when temperature is raised to the p-melting point. The experimental data show that ice of varying thickness is capable of glacial crushing as originally postulated by Krinsley and Doornkamp (1973), but much depends on grain to grain contact, glacial overprinting on preweathered grains, and cold versus warm ice.

Conclusions

The triangular faceted "glacial grain," depicted in Krinsley and Doornkamp (1973), as a triangular faceted, refashioned quartz, with a multitude of fracture and abrasion features is one of the *common* particles found in the sand fraction of tills. As shown here it is by no means the only well-fractured and abraded particle in till, although depending on the ice thickness and distance of transport it could amount to 40% or 50% of grains observed. There are other grains including equant grains with minor damage, flake-shaped grains often with an abundance of abrasion and little fracture, partly streamlined abraded particles with variable damage, and preweathered grains. The preweathered grains often reach 30% of the total population of grains in till observed under the SEM, which means that perhaps as many as 1 in 3 of the grains analyzed might carry important information about preglacial weathering. Indeed, in some instances, the degree of preweathering might yield important information about paleoleaching and the strength of interglacial climates (see Mahaney, 1990a). Indeed, on Mount Kenya, plagioclase and quartz from the last interglacial carried coatings of fibrous and nodular gibbsite in considerable

quantity as determined by XRD and SEM/EDS, the product of aggressive leaching and removal of Si leading to meta-halloysite degradation (Mahaney, 1995).

Microtextures considered of unequivocal glacial origin include directional curved and straight grooves or troughs. Groove is a useful term for lightly imbedded striations, with troughs reserved for deeply embedded features, to the order of 5 μm or more. These are as much the exclusive product of the glacial environment as macrostriations that have been used for nearly two centuries as chief indicators of glaciation. In the microworld it may be that minerals harder than quartz (topaz, zircon, etc.), while of low mass in most tills, could, when in contact with quartz, leave directional troughs and grooves. Perhaps this leads to the production of pencil-shaped zircons commonly found in some tills (Mahaney and Milner, 1998).

Deeply inscribed fractures are common on glacial grains, but not exclusive to the glacial environment. Over a large population of grains, however, conchoidal and subparallel linear fractures would be expected to dominate as one of the most frequently occurring forms. Only thick valley glaciers and glaciers of continental proportions would be expected to produce deeply imbedded features of this type. Sharp edges, where grains have been worn away by abrasion, are also a hallmark of the glacial environment. They are not unequivocally glacial, but taken as a proportion of the whole in a large population of samples they can be expected to have a frequent occurrence.

Relief on glacial grains is often considered high but with extreme abrasion, common with thick ice, grain surfaces may be worn to produce minimum relief. Grains deposited by cirque ice and outlet glaciers often exhibit moderate to high relief, which may in fact mislead investigators into thinking considerable grain modification and reformation has been achieved.

Chattermarks (Folk, 1975; Peternecht and Tietz, 2010), often touted as the common glacial microtexture, are in reality extremely rare, despite infrequent observations that seem to attract attention. Trails of chattermarks forming rune-like grooves, while infrequently common on glacial grains, are now known to be the product of mechanically induced fractures that become visible after chemical etching, a process originally envisioned by Bull (1981). Experimental work carried out by Peternecht and Tietz (2010) confirms that collision of minerals leads to disruption of the internal crystal lattice, the fracture sites dissolving faster than the surrounding mineral fabric. Once the mechanically induced fractures are subjected to chemical weathering, the fracture sites become visible. Chattermarks are therefore considered to be part of a two-stage process; first, mechanical collision during transport followed by chemical weathering at a later stage.

Steplike features resulting from well placed and deeply embedded fractures are unequivocally glacial in origin (Mahaney, 2002). These mechanically induced microfeatures may result from larger grains blasting fragments off smaller grains as a result of their increased mass/energy relationships. Much depends on random events within the ice mass and the probability of grain-to-grain contact, impact angle, force (cone of energy), bulk mass, and hardness of the material.

The fact that so many preweathered grains make the glacial trip without damage means that not all glacial grains come into contact with one another. While preweathered grains provide important information on interglacial climates, their coatings can range from carbonate and silica to iron and manganese; even clay coats have been documented (Mahaney et al., 1996) from the Antarctic. As with other geologic agents, to prove a glacial origin requires a large number of samples from different size fractions (very coarse–coarse; medium; and fine–very fine sand), all documented with replicates.

SEPTA OF ENGLACIAL DEBRIS

Subhajit Sinha
DBS College, Dehradun, Uttarakhand, India

Debris input to glaciers occurs most commonly at ice margins and is thus concentrated along the base of cirques and in medial debris septa that ultimately become medial moraines. Proximal debris addition from rockfalls and increasing debris concentration from below by ice sublimation results in supraglacial debris mantles in the distal direction with great spatial variability in thickness and grain size. As ablation proceeds, debris accumulations represented by englacial septa emerge and form longitudinal or transverse debris ridges separated by areas of cleaner or bare ice.

SERAC

Markus Konz
ETH Zürich Institut für Umweltingenieurwissenschaften, Hydrologie und Wasserwirtschaft, Zürich, Switzerland

The word “serac” originated from the Swiss French sérac, which is a type of a crumbly white cheese. Seracs are needle-like towers, individual blocks, or columns of ice on the surface of a glacier. Their height varies between few meters to tens of meters. They can be found within icefalls or on the lower edge of hanging glaciers (e.g., Post

and Lachapelle, 2000). Seracs are commonly formed by intersecting crevasses where the glacier is periodically broken as it passes over a steep slope. They can cause disastrous hazards and are dangerous to mountaineers due to rapid toppling often with little advance warning time.

Definition

Siberia: a region of northern Asia of Russia, stretching from the Ural Mountains to the Pacific Ocean.
Continental air mass: vast body of air that forms over the interior of a continent, excluding mountainous areas.
Anticyclone: weather phenomenon in which there is a descending movement of the air and a high pressure area over the part of the planet's surface affected by it.
Continental arctic air: air that are extremely cold and dry due to their continental source region between 60° and 90° north latitude.
Tundra: a biome in which tree growth is hindered by low temperatures and short growing seasons.
Taiga: a biome characterized by coniferous forests.

Introduction

Siberia has the largest area of permafrost in the world. Furthermore, the freshwater in the large Arctic rivers of Eurasia that flow from Siberia to the Arctic Ocean plays an important role in the control of the global thermohaline circulation by modifying salinity and sea-ice formation in the Arctic Ocean. In addition, snow and ice greatly affect the lives of the people inhabiting Siberia. This article discusses the characteristics of snow and ice in Siberia.

Geography and climate

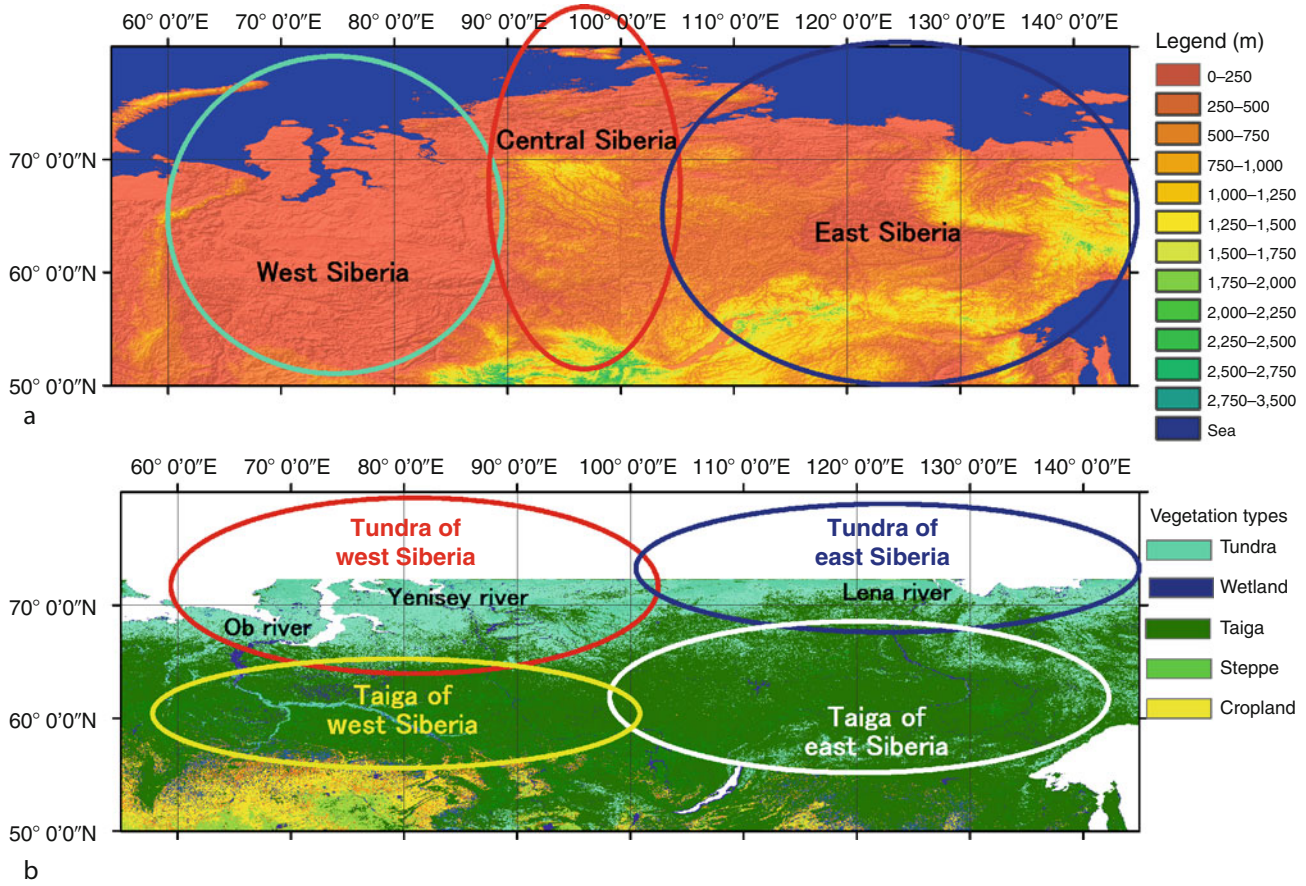
Siberia occupies the Asian part of Russia and consists of three major subregions shown in Figure 1a. In the west, abutting the Ural Mountains, is the huge West Siberian Plain, drained by the Ob and Yenisey rivers. It varies little in relief and includes wide tracts of swampland. East of the Yenisey River is central Siberia, a vast area that consists mainly of plains and the central Siberian Plateau. Farther east, the basin of the Lena River separates central Siberia from the complex series of mountain ranges, upland massifs, and intervening basins that make up East Siberia.

According to *Climates of the U.S.S.R.* by Borisov (1965), there are four major climate zones in Siberia. The climate zones of West and East Siberia are each subdivided into two climate zones according to the dominant vegetation, tundra or taiga. Here, West Siberia as used here includes the central Siberian Plateau. West Siberia is characterized by many days dominated by continental arctic air and East Siberia by prevailing continental temperate climate and continental arctic air masses, which converge to form mainly extensive anticyclones, especially in winter. The taiga corresponds with regions of subarctic and cold continental climate with long, severe winters (up to 6 months with mean temperatures below freezing) and short summers as characteristic, as has a wide range of temperatures between the lows of winter and highs of summer. On the other hand, tundra corresponds with the regions of polar climate with extremely short growing season (6–10 weeks) and long, cold, dark winters. Tundra occupies the region between tree line and polar ice cap. Tundra–taiga boundary is corresponding to the arctic front (Bryson, 1966).

Figure 1b denotes the four major climate regions. The West Siberian tundra region is characterized by contrast in the intensity of solar radiation during the year and by a long, severe winter with frequent passage of low-pressure systems accompanied by violent gales and heavy snowstorms. In contrast, a high-pressure system typically develops over the East Siberian tundra region in winter, leading to stable winter weather and a negligible snow cover. Because of its great continentality, the region is characterized by contrasting conditions between summer and winter. The West Siberian taiga region is characterized by the active movement of air masses from the Atlantic and Arctic oceans with the continental air mass and anticyclones formed in Siberia. The East Siberian taiga region is characterized by marked continentality such as the prevalence of clear-cut anticyclonic weather conditions, very frosty and cold cloudless winter weather and hot summers with high solar radiation, and the sudden onset of seasons.

Frozen ground

Permafrost is the dominant component of the Siberian soil; about 80% of area in the subsurface in Siberia is composed of permafrost. Kondratjeva et al. (1993) showed that permafrost in Siberia mostly developed in the Late Pleistocene during the Sartanian glaciation (Late Wisconsinan/Weichselian, 18,000–27,000 years ago). The average air temperature at that time was 8–10°C lower than at present, and under these very cold conditions, permafrost spreads over Siberia, eventually extending its southern boundary to 48–49° N during the Sartanian glaciation. Subsequently, in the Holocene, the spatial extent of the permafrost was greatly reduced in West Siberia, where the southern permafrost border has been displaced northward to 60° N. Although in East Siberia the permafrost has retained almost the same spatial coverage as during the last glacial period, it has likely become reduced in thickness. Duchkov (2006) showed that permafrost reaches its greatest thickness (more than 1 km) in Yakutia, central Siberia, where it forms the lowest temperature block of



Siberia, Figure 1 Map of Siberia. (**a**) Topography map for geography indicated West, central, and East Siberia and (**b**) vegetation map for climate for tundra and taiga of West and East Siberia.

lithosphere in northern Eurasia. Terrestrial heat flow acts as one of the heat sources for permafrost to determine the lower limit of the permafrost depth. Terrestrial heat flow in the area of Yakutia does not exceed 30 mW m^{-2}, in contrast to other Siberian regions, where terrestrial heat flow is 50–70 mW m^{-2} and the permafrost is no more than 400–600-m thick.

The top layer of soil above the permafrost layer thaws seasonally and is called the active layer. The active layer affected direct runoff and peak flow in a small permafrost watershed, as shown by Yamazaki et al. (2006). Water within the active layer has a role of memory in previous years, because water within the active layer has a residence time of more than a half year and it affects snowmelt runoff due to the change of the capability of infiltration into frozen ground (Suzuki et al., 2006a) and transpiration due to recovering shortage of water for transpiration from the thawing ground water during the summer (Sugimoto et al., 2003). Rest of the parts of Siberia without permafrost are covered by seasonal frost, where the ground freezes in winter and thaws in summer. Zimov et al. (2006) showed that the permafrost stores a large amount of carbon, and if it were to thaw, a great deal of carbon would be released. One of the pathways for terrestrial carbon cycle in permafrost region is carbon transport in the rivers. Suzuki et al. (2006b) showed that a large quantity of dissolved organic matter is transported from the upper catchments of the Lena river to the Arctic Ocean.

Snow

During winter, snow covers all of Siberia. The snowpack structure in Siberia is characterized by a thick layer of depth hoar at the bottom, which forms as a result of the large temperature gradient between the relatively warm soil and cold air. Kitaev et al. (2005) analyzed the distribution of snow over Russia from 1936 to 2000. In East Siberia, the mean snow depth, snow cover days from 1936 to 2000, and snow water equivalent from 1966 to 1996 were 34 cm, 220 days, and 90 mm, respectively, and in West Siberia, they were 34 cm, 192 days, and 133 mm, respectively. In both West and East Siberia, snow depth and snow cover days generally increased from 1936 to 2000.

The presence of snow cover influences the depth of the active layer and of seasonal frost in Siberia. In addition,

snowmelt runoff contributes greatly to the discharge of Siberian Rivers, rather than rain. Tree growth as indicated by tree ring width is related to winter precipitation as snow, because recent tree growth is not only related to air temperature but also to the timing of snow disappearance (Vaganov et al., 1999). A few snow researches have been carried out in the southern mountain region of East Siberia, where Suzuki et al. (2006c) showed that sublimation accounts for nearly 10% of snow ablation beneath larch forest. Furthermore, Suzuki et al. (2006c) found that snow albedo is related to snow density. In the tundra region of East Siberia, Hirashima et al. (2004) developed a land surface model that incorporated blowing snow and estimated that about 40% of winter precipitation sublimated during blowing snow events. Tundra regions of Siberia are characterized by a shallow snowpack and a heterogeneous snow cover because of the small topographic relief, because strong wind induced blowing snow events occasionally, but taiga regions tend to have a uniform snow cover since forest canopy reduced wind speed and large snow-folding capacity.

Glaciers and river and lake ice

Ice in Siberia occurs in glaciers and as river and lake ice. The large volume of ice constitutes an important water resource and influences the inhabitants of Siberia. According to Kotlyakov et al. (1996) and UNEP (United Nations Environment Programme) (2007), from 1950 to 1970, Siberia's glaciers were widely dispersed on mountain ranges, from the Ural Mountains to Kamchatka, covering a total area of about 3,600 km^2 (USSR Glacier Inventory). Since 1970, Siberian glaciers have generally retreated, mainly from lower elevations and southern latitudes, and the amount of retreat has a wide variety in the places.

River and lake ice are of more importance to the people living in Siberia than glaciers because they are an important freshwater resource. The timing of the break-up or freeze-up of lake ice depends primarily on air temperature. Walter et al. (2006) reported that during thaws, a lake in northern East Siberia emits a large amount of methane.

The break-up of river ice in spring occasionally causes large floods in Siberia, especially in permafrost-dominated regions. By incorporating river ice into a river run-off model, Ma et al. (2005) showed that river ice volume greatly affects estimations of snowmelt run-off in the Lena River. Vuglinsky (2002) noted that the knowledge of river ice is important for understanding run-off processes, and the duration of river ice each year also greatly affects the use of large rivers for transporting cargo from or to the sea. Smith (2000) showed that the river ice in central and East Siberia is melt onset 1–3 weeks earlier since 1930s but found no trend in West Siberian river.

Thick icing is commonly observed in the permafrost regions of the northern hemisphere, including Siberia. Icing is often seen on the river in Siberia. In southern East Siberia, aufeis (icing) can be 5–10-m thick. Icing contributes about 10% of annual river discharge (Sokolov and Vuglinsky, 1997). Icing may be an important indicator of groundwater movement in permafrost regions of Siberia.

Summary

Because of the extremely cold winter climate of Siberia, the region is characterized by a thick and extensive winter snow cover and many frozen water bodies in winter. However, people in Siberia are more aware of global warming and its effects on snow and ice in Siberia are posing a threat to infrastructures due to thawing snow and ice. Warming air temperature by itself can cause the shorter periods or less volume of snow and ice in Siberia, but it cannot explain all of the observed changes such as the small changes of timing of river ice freeze-up or permafrost thawing. Vegetation characteristics also influence how warmer air temperatures affect snow and ice in Siberia. Most of Siberia is covered by taiga forest. In East Siberia, the taiga forests consist mainly of larch, which is a deciduous conifer, whereas West Siberia is characterized by wetlands and evergreen coniferous forest. Suzuki et al. (2007) showed that a moss layer protects the soil from heating by the atmosphere and helps to maintain a constant ground temperature and moisture content. Thus, the vegetation type affects snow and ice in Siberia and complicates our understanding of snow and ice cover changes in Siberia. In the future, this subject should be studied by a multidisciplinary approach.

SLUSH AND SLEET OF SNOW

A. K. Singh
DIAT (Deemed University), Girinagar, Pune, Maharashtra, India

Snow that partially melts upon reaching the ground, to the point that it accumulates in puddles of partially frozen water, is slush, whereas sleet is snow falling mixed with rain, that is, rain containing snow. Slush is slurry, mixture of liquid and solid forms of water. A slushy layer of snow also results when rain or meltwater percolates downward from the snow surface but cannot penetrate an icy layer or the ground surface beneath. Because of its low binding strength, slush that forms in hilly terrain, can sometimes pose a hazard by releasing wet snow avalanches. These avalanches can occur even on very gentle slopes where, though they are unable to gather much speed, the large mass of slush can make avalanches destructive. In the natural environment, slush forms as ice and snowmelts. This often mixes with dirt and other materials, resulting in a gray or muddy brown color. Solid ice or snow often blocks the drainage of liquid water from slushy areas and slush goes through multiple freeze/thaw cycles before disappearing completely.

In dry snow crystal growth rate is limited by the rate at which water vapor diffuses across the pores from smaller particles to larger ones. However, in slush, the pores between the ice crystals are occupied by liquid water rather than air and hence the crystal growth rate is driven by thermal diffusion between particles through the water filled pores.

As raindrops pass through layers of air at varying temperatures, while passing through a layer with temperature below the freezing point, they turn into sleet, that is, precipitation of small, partially melted grains of ice. Snowflakes that have melted by passing through a warm layer will turn into sleet if they happen to pass through a freezing layer. Sleet often falls together with snow and rain. It occurs only during the winter, while hail, a different form of icy precipitation, may fall at any time of the year. Sleet is less prevalent than freezing rain and is more difficult to forecast as it develops under specialized atmospheric conditions.

SNOW

A. K. Singh
DIAT (Deemed University), Girinagar, Pune, Maharashtra, India

Snow is a form of precipitation, measured using snow gauge, in the form of ice crystals, usually flakes of star-like crystals that can be in a variety of shapes and sizes. Snow stakes and simple scales can be used to determine the depth of the snow pack. Snow is less dense than liquid water by a factor of $\approx$10 (fresh and dry snow). By the time flakes reach the ground they undergo transformations resulting from growth, disintegration, or agglomeration. Highly branched or dendrite crystals occupy more space between the arms of ice that form the snowflake and this snow will therefore have a lower density, referred to as dry snow and is highly reflective (0.9 and higher albedo). Conditions that create columnar or plate-like crystals will have much less air space within the crystal and will therefore be denser. When all the snow does not melt in the summer it evolves into firn, where individual granules become more spherical in nature, evolving into glacier ice.

Snow is a thermodynamically active material, exhibiting strange behavior near the melting temperature and constantly undergoing metamorphism. Structurally, snow is a granular material characterized by a continuous ice network, formed through cohesion between ice grains, to form

a porous structure. Snow behavior, properties, and processes often fall far outside of those normally encountered in granular materials. Unique properties of snow include its high compressibility.

Once the snow is on the ground, it will settle under its own weight. Recrystallization under stress caused by the weight of the overlying snow becomes predominant, and grains change in size and shape in order to minimize the stress on them with large or favorably oriented grains growing at the expense of others. Increases in density above this initial compression occur primarily due to melting and refreezing, caused by temperatures above freezing or by direct solar radiation. By late spring, snow densities typically reach a value half of water density. This densification of the snow proceeds more slowly after reaching this density and many of the processes become less and less effective.

In many parts of the world, snow is the primary source of water during summer and autumn. Water equivalent is of great interest to water managers wishing to predict spring runoff and the water supply of cities downstream. Sudden melting of snow can cause flooding. Snow is also a source of recreational activity and at the same time turns into a deadly avalanche. Climate is also influenced by snow cover due to its reflection character as compared to other surface materials, and also the absorption of solar radiations.

SNOW BED/SNOW BED VEGETATION

Nadine Konz
Institute of Environmental Geosciences, University of Basel, Basel, Switzerland

Snow beds are defined through the duration of snow cover and snow height leading to an individual geomorphology and a specific microclimatology (Huelber et al., 2006). These conditions lead to an ecological niche for different plants; the snow bed vegetation.

The term snow bed is currently adopted to designate plant communities whose occurrence is determined by the geomorphological situations favoring a long duration of the snow cover (Tomaselli, 1991). One of the most extreme sets of conditions under which plants may grow is those of snow beds. Generally, the snow does not cover the ground to the same depth everywhere: small depressions are filled with snow; ridges are blown free from snow. Places with more snow than a medium depth form the snow beds. Duration of snow cover, character of bedrock, and quantity of available moisture are the three dominating factors that influence the mountain vegetation. The snow cover is generally the one of greatest physiognomic importance (Faegri, 1957). The plant communities of the snow bed belong to the class of *Salicetea herbacea*. These plants are snow covered between seventh and tenth month a year. Snow bed vegetation can be divided into vegetation on siliceous bedrock and limestone. Some examples of snow bed vegetation on siliceous bedrock are *Salicaceae* (e.g., *Salix herbacea*), *Poaceae* (e.g., *Poa alpina*), *Polytrichaceae* (e.g., *Polytrichum sexangulare*), and *Peltigeraceae* (e.g., *Solorina crocea*). Some examples of snow bed vegetation on limestone are *Poaceae* (e.g., *Sesleria albicans*), *Plantaginaceae*, (e.g., *Veronica alpina*), and *Ranunculaceae* (e.g., *Ranunculus alpestris*) (Merz, 2000).

SNOW COURSE

A. K. Singh
DIAT (Deemed University), Girinagar, Pune, Maharashtra, India

Snow course consists of a series of manually marked sampling points or locations where depth and snow water equivalent measurements are made by trained observers. It is an established line, usually from several hundred feet to as much as *a mile long*, traversing representative terrain in a mountainous region of appreciable snow accumulation. Snow course length and the frequency of sampling points are defined depending on site specific conditions such as slope, aspect, land cover, and uniformity of snow cover. Snow course data are, however, subject to a systematic bias because the measurements, obtained by inserting a tube through the snowpack to the soil to cut and hold a snow core, tend to underestimate snow water equivalent due to sampling difficulties associated with ground ice and depth hoar. The size of the sampling cutter can also influence accuracy. Besides, other aspects regarding snow course data that must also be taken into account are consistency of equipment, procedures, and measurement locations over time, and the degree to which a real snow cover condition can be represented by a series of point measurements.

Snowmelt is a major source of water supply to areas in temperate zones near mountains that catch and hold winter snow, especially those with a prolonged dry summer. In such places, water equivalent is of great interest to water managers wishing to predict spring runoff and the water supply of cities downstream.

SNOW COVER AND SNOWMELT IN FOREST REGIONS

Tobias Jonas[1], Richard Essery[2]
[1]Snow Hydrology Research Group, WSL Institute for Snow and Avalanche Research SLF, Davos, Switzerland
[2]School of GeoSciences, University of Edinburgh, Edinburgh, UK

Definition

Snow cover. Snow that accumulates on the ground due to snow precipitation and snow redistribution processes. Typically used for seasonal snow, excluding firn and ice.
Snowmelt. Snow ablation process and/or meltwater originating from the snow cover.

Introduction

The evolution and ablation of the seasonal snow cover in a forest is very different compared to the snow in open terrain. Snow precipitation is partly intercepted by the canopy, from where the snow may subsequently evaporate directly, melt and drip down, or fall off. The canopy also absorbs shortwave radiation and changes the longwave radiation budget. The presence of trees decelerates wind fields near the snow cover surface and thus constrains the turbulent exchange of heat and moisture. Finally, litter fall from trees (e.g., conifer needles or lichens) can have a significant impact on the snow surface albedo, increasing the absorption of shortwave radiation. Due to these differences, the maximum snow water equivalent and the subsequent amount of melt water can easily differ by some 10% from the respective amounts at neighboring open sites, while melt-out dates may be shifted by several weeks. As boreal and subalpine forests cover large areas of the northern hemisphere land surface, snow-forest processes have an important influence on weather and hydrology, even at hemispheric scales. See also the entry on *Snow and Vegetation Interaction*, which covers related topics from an alternative perspective.

Measuring relevant data

A forest canopy typically features a complex and heterogeneous structure. The canopy density may display spatial variability on different scales, e.g., shortwave radiation and snowfall rates below the canopy can significantly differ on the meter scale. The same applies to the distribution of stems and other parts of the vegetation which emit longwave radiation. Given the spatial complexity of important snow cover energy budget forcing terms, it is not surprising that snow cover thickness inside forests often shows great levels of spatial variation. It is hence difficult to measure "representative" data. In this respect, single point measurements below the canopy are typically useless, and snow depth, snow water equivalent (SWE), or snow accumulation rates are normally measured on transects, grids, snow courses, etc. that represent the area of interest (and the spatial scales to be resolved).

Several setups have been used to measure radiation inside forests. Most commonly, arrays of fix sensors have been used to capture the spatial variability of radiation below the canopy (e.g., Link et al., 2004; Pomeroy et al., 2008). Alternatively, radiation sensors have been moved manually or automatically along ground transects, cables, or rails (Sturm et al., 2005; Stähli et al., 2009). Also, infrared thermography has been used to map the emission of longwave radiation (Pomeroy et al., 2009).

Quantitative measurement of snow interception is challenging. While qualitative interception levels can be gathered from periodic observations (e.g., by webcams), the mass of snow intercepted per unit area is a difficult parameter to obtain. Techniques that have been applied include (a) weighing trees or tree-like structures mounted on or suspended from scales (Hedstrom and Pomeroy, 1998; Storck et al., 2002), (b) optically tracking the vertical position of branches, which bend down under the weight of intercepted snow (Brundl et al., 1999), (c) measuring canopy snow using radar absorption (Gustafsson et al., 2010), or (d) absorbing gamma radiation (Calder, 1990).

As important boundary conditions for snow-forest processes, information about the canopy structure/density is required, usually specified through parameters such as sky-view fraction (SVF; the projected fraction of the sky hemisphere visible from a point below the canopy) and leaf area index (LAI; the total projected leaf area per unit area of ground). Manual or optical methods of measuring canopy parameters (e.g., destructive sampling or hemispherical photography) can be time consuming and subject to large uncertainties (Chen et al., 1997). Airborne laser scanning (LiDAR) offers the possibility of canopy structure mapping at landscape scales (Riaño et al., 2004).

Snow distribution in forests

On the meter scale, forest snow cover is typically heterogeneous. Snow depth patterns often mirror canopy gaps, the distribution of shorter vegetation on the ground and thermal radiation effects in the vicinity of stems. As a useful first-order predictor for such small-scale patterns, the sky-view fraction has been found to correlate well with the maximum SWE below forest canopies of varying density (e.g., Pomeroy et al., 2002; Lundberg et al., 2004; Lopez-Moreno and Latron, 2008). Since denser canopies intercept more snow, locations with higher sky-view fractions generally accumulate more snow on the ground than locations with lower sky-view fractions (within the same stand). Some studies even report forest openings to accumulate more snow than nearby unforested sites (Lopez-Moreno and Latron, 2008).

However, snow distribution patterns within forests are certainly not just driven by interception. In addition to snow accumulation phenomena, spatially variable snow ablation processes also contribute to complex distribution dynamics of snow in forests. Energy budget

considerations are therefore covered in a separate section below in more detail.

Understanding snow distribution dynamics in forests is important, since snow accumulated on the ground directly drives runoff from snowmelt. But also, the fate of snow that is intercepted in the canopy is important to consider for the water balance. A significant part of intercepted snow may be evaporated (e.g., 20–30% in a study by Montesi et al., 2003) and hence does not contribute to runoff. Further information is given in the entry on Interception of Snow.

Energy budget of snow in forests

Insight into the specific and interacting effects of physical forest snow processes can be gained by assessing the energy budget of a forest snow cover (Figure 1).

Terms that counterbalance the rate of change in snowpack heat storage are:

- SWR: Net shortwave radiation
- LWR: Net longwave radiation
- THF: Turbulent heat fluxes (sensible and latent)
- PHF: Heat advected by precipitation
- GHF: Heat exchange with the ground (including advection by meltwater)
- PCH: Energy of snowpack phase changes

At a global scale, forests in regions with seasonal snow have characteristics that are so diverse with respect to canopy structure and ambient conditions that there is no general rule for the relative importance of the terms in the energy balance (but see King et al., 2008). In the following, some of the terms are discussed in more detail.

Shortwave radiation (SWR): Transmission of short wave radiation through a forest canopy is a truly three-dimensional phenomenon. Naturally, canopy structure and density are the main predictors for the transmissivity τ_{SWR}, which is the ratio between the radiation below and above the canopy. The simplest way to describe this relationship adopts Beer's law,

$$\tau_{SWR} = \exp(-\kappa \cdot LAI)$$

where, κ is an empirical extinction parameter related to the orientation and clumping of canopy elements. Such descriptions can be enhanced by additionally accounting, e.g., for (a) solar angle, which affects the path length of direct radiation through the canopy or (b) snow interception, which enhances diffuse radiation below the canopy (Stähli et al., 2009). Moreover, multiple reflection effects can entail increased τ_{SWR} during cloudy weather when diffuse radiation dominates the SWR budget below the canopy; these effects can be accounted for using a two-stream radiative transfer approximation (Niu and Yang, 2004). The net SWR on the other hand is also determined by snow albedo, which is the ratio between reflected and incoming radiation at the snow surface. Albedo generally decreases as a snow surface ages because increasing contaminants in the snow increase absorption of visible radiation and increasing snow grain sizes increase near-infrared absorption. Snow albedos may be lower in forests than in the open due to both decreases in the proportion of visible radiation and increases in litter accumulation under forest canopies (Melloh et al., 2002), although net SWR may still be higher in the open due to the higher incoming shortwave radiation.

Longwave radiation (LWR): A forest snowpack receives longwave radiation from the canopy and from the atmosphere through canopy gaps. Since canopy surface temperatures are often very different from atmospheric temperatures, the sky-view fraction (SVF) is an important parameter for the net LWR budget of the snow cover in semi-closed forests. The simplest way to describe the net LWR is:

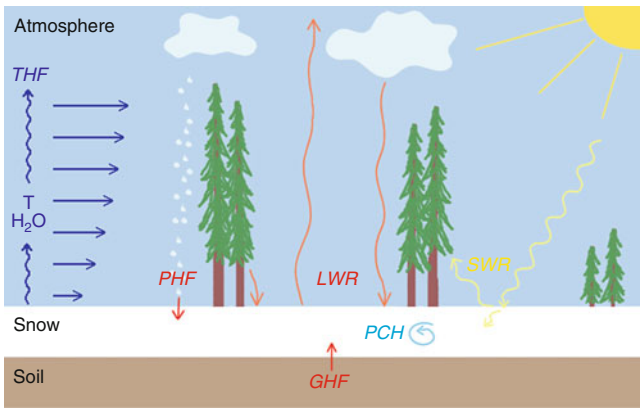
$$LWR_{net} = SVF \cdot LWR_{from\ atmosphere} + (1 - SVF) \times LWR_{from\ canopy} - LWR_{from\ snow\ cover}$$

or using the Stefan–Boltzmann law

$$LWR_{net} = SVF \cdot LWR_{from\ atmosphere} + (1 - SVF) \cdot \sigma T_c^4 - \sigma T_s^4$$

where, T_c and T_s denote the temperatures of canopy and snow surface, σ is the Stefan–Boltzmann constant, and the emissivities of canopy and snow surface are approximated to be 1 (both around 0.97). In practice, T_c is often simplified to equal the air temperatures measured below the canopy, while incoming LWR above canopy can be estimated from air temperature, humidity, and cloud cover using bulk formulae (e.g., Flerchinger et al., 2009). These parameterizations have been evaluated against measurements by Essery et al. (2008) and Pomeroy et al. (2009).

Turbulent heat flux (THF): Latent and sensible heat fluxes can constitute important contributions to the energy balance of a forest snow cover (e.g., Li et al., 2008), which



Snow Cover and Snowmelt in Forest Regions, Figure 1 Schematic of the energy budget of snow in forests.

may appear surprising given that wind speeds are typically low inside forests. Estimating turbulent heat fluxes for a forest snow cover is comparatively difficult and imprecise, since it involves a combination of parameterizing wind speeds, temperature, and humidity gradients. However, snow models that incorporate interactions with vegetation/forest do so with differing levels of complexity (Essery et al., 2009). Only a few attempts have been made so far to measure latent and sensible heat fluxes inside forests over snow using eddy covariance (EC) systems (Molotch et al., 2006; Marks et al., 2008), since applying EC systems in such environments is associated with significant uncertainties. More research is certainly needed to improve the understanding and prediction of turbulent heat exchange inside snow-covered forests.

Snowpack modeling for forest regions

Because of the importance of forest snow processes, many snow models have been developed or modified recently to include vegetation canopies. Thirty-three such models, listed by Rutter et al. (2009), participated in the second Snow Model Intercomparison Project (SnowMIP2) by performing simulations driven by meteorological observations for paired open and forested plots at five sites. The models generally perform complete mass and energy balance calculations for forest canopies and snowpacks, but they were primarily evaluated by comparison with measurements of SWE on the ground. Although the evaluation is complicated by uncertainties in meteorological and snowpack observations, the intercomparison revealed a wide range in the ability of models to simulate snow in open and forested situations. On the larger scales used in climate modeling, Roesch (2006) suggested that the models participating in the IPCC Fourth Assessment Report showed difficulties in determining the extent of snow albedo masking by forests.

Summary

Forest snow is subject to very different ambient conditions compared to snow in open terrain. Accumulation patterns are predominantly altered by interception of snow in the canopy, while melting dynamics are driven by complex processes such as the transfer of shortwave and longwave radiation through the canopy and the turbulent transport of heat and water. Today, many snow models try to reproduce interactions between snow and vegetation, emerging from the need to involve forest snow processes in distributed land-surface models.

SNOW COVER CHANGES IN THE ALPS

Christoph Marty
WSL Institute for Snow and Avalanche Research SLF, Davos, Switzerland

Definition

HS: Snow Depth
RCM: Regional Climate Model
Snow day: A day with a snow depth larger than a given threshold
Winter snow cover duration: Continuous snow depth of at least 1 cm

Introduction

Snow influences life and society in many ways. The amount and duration of snow in the Alps has a high socioeconomic significance in terms of both tourism and hydropower. Many Alpine towns and villages heavily depend on snow, because their economy is dominated up to 90% by winter tourism (Abegg et al., 2007). The vast majority of customers of such ski areas live in the pre-Alpine regions of Switzerland, Austria, Germany, Italy, and France. A longer sequence of almost snowless winters in these heavily populated regions, as was observed between the late 1980s and mid-1990s, caused a discussion about the uniqueness of such a situation and the possible connection to climate change.

Observed changes

The importance of snow for hydrology and tourism in the Alps has led to quite a few studies, which investigated the past variability and trends of the Alpine snow cover. Some of the Alpine countries have a relatively dense network of manual measurement stations available, where daily snow depth and snowfall have been measured with the help of a permanently mounted snow stake, respectively a new snowboard for 50 years or more. This comprehensive dataset and the above-mentioned socioeconomic importance of snow make the Alps a preferred region to investigate changes in snow cover. Remote sensing data of Alpine snow cover have not been used for climatological purposes due to the lack of longer time series and due to the limited data quality, which is caused by the steep topography of the Alps.

In the Swiss Alps, a significant decrease of HS for elevations below 1,300 m asl was observed in the late twentieth century with measurements from more than 100 stations, whereas no significant differences could be detected for high-altitude stations above 2,000 m asl (Scherrer et al., 2004). It was shown that the long-term snow trends in the Swiss Alps are similar for snow depth, the duration of the continuous snow cover and the number of snowfall days (Laternser and Schneebeli, 2003). Earlier investigations concluded that the length of snow season and snow amount have substantially decreased since the mid-1980s, but there have been periods in the records (e.g., 1930s) where snow depth was as low as during the late 1980s (Beniston, 1997). However, a newer study with more data available points out the uniqueness of the series of snow-poor winters over the period of 20 years from 1988 to 2007 (Marty, 2008), in comparison with at least the last 130 years. In particular, it could be shown that the decline is rather caused by an abrupt change than by a continuous decrease. The number of snow days ($HS > 5$ cm) below 800 m asl, for example, dropped by about 50% in the last 20 years compared to the long-term mean before the change.

In the Austrian Alps, an investigation on different snow parameters at 98 long-term stations revealed a more diverse picture (Jurkovic, 2008). The two 20-year periods between 1980 and 2000 and between 1896 and 1916 were compared and tested for changes. Statistical tests detected decreasing trends at the majority of the stations, but

the decline was only significant at the southern Austrian stations. There, a clear decreasing trend was found for the winter snow cover duration and the snow days with HS > 1 cm. A separate analysis of 14 stations with 100 years of data revealed similar results with mostly significantly decreasing snow day trends in southern Austria and no significant trends in the remaining part of the country.

In the Italian Alps, a general decrease in snowfall in the last 20 years of the analyzed time series between 1920 and 2004 could be found using data from 40 stations (Valt et al., 2005).

In the German Alps, a 20–30% reduction of the snow cover duration was found for low-lying areas between 1952 and 1996 (Günther et al., 2006). A smaller reduction was generally observed in higher areas.

In the French Alps, data from only one long-term station at 1,320 m asl was analyzed. There, a clear decreasing trend in the mean snow depth and in the number of days with snow on the ground was detected (Martin and Etchevers, 2005).

Only one study found an increase of snow depth at high altitude based on one station at 2,500 m asl (Beniston et al., 2003), whose data seem to be questionable due to the measurements on a mountain summit and several displacements of the snow stake.

Future changes

Climate models successfully reproduce large-scale parameters such as temperature today. However, investigations on the evolution of the future snowpack under changing climate conditions all battle with the fact that the current climate models have difficulties in representing fine-scaled spatial and temporal variability of snow. Some studies therefore use physical models driven by artificially generated data of future weather to predict the snow depth and duration at local level. Other studies estimate future snow conditions based on a sensitivity analysis of the current variability.

Such a simple approach was chosen by Hantel and Hirtl-Wielke (2007). They assessed the snow-temperature sensitivity in the European Alps based on data of the last 40 years from 268 stations and came to conclusion that the number of snow days (HS > 5 cm) will decrease by 33% per 1°C warming. This corresponds to a reduction of snow cover duration of about 1 month at the height of maximum sensitivity (about 700 m) but falls rapidly above and below that level. The future snow reliability of 666 Alpine ski resorts in six countries was investigated by Abegg et al. (2007). The authors calculated the impact of a 1°C, 2°C, and 4°C temperature increase based on the assumption that the altitudinal limit of natural snow reliability will rise by 150 m per 1°C warming. They concluded that the number of naturally snow-reliable areas would drop by 25% with 1°C, by 40% with 2°C, and by 70% with a 4°C warming.

In the Swiss Alps, the sensitivity of the snow cover to future climate was analyzed for 20 Swiss ski resorts with a more sophisticated approach and came to similar results (Uhlmann et al., 2008). The authors used the HIRHAM RCM model results of the IPCC A2 scenario and an energy balance model to compute future snow reliability. They pointed out that snow will become scarce on the lower ski runs in all resorts and that days with more than the critical 30 cm snow depth will drastically decrease at more than half of the stations. Future changes in two alpine river basins (above 800 m asl) in the Swiss Alps have been investigated with the help of the distributed catchment model WaSiM-ETH (Jasper et al., 2004). A 2.5°C warming and small changes in precipitation were elaborated from 23 regional climate models calculated for the end of the twenty-first century. The authors found a decrease of 70% in the annual mean snow-water equivalent. The duration of continuous snow cover was shortened by about 2 months, while the snow line was raised by about 450 m. A similar study assessed two other alpine river basins (above 1,600 m asl) in the Swiss Alps using the model system Alpine3D and the IPCC A2 and B2 scenarios from 12 RCMs (Bavay et al., 2009). According to these results, the snow volume and the maximum snow-water equivalent at the end of the twenty-first century will be reduced by about 40%. The complete melt of the snow cover will occur about 40 days earlier and the snow line will be shifted by about 900 m, which would be the end of most of the glaciers in these basins.

The future Austrian snow conditions have been analyzed using a simple temperature- and precipitation-dependent snow model by Breiling and Charamza (1999). An assumed 2°C warming and no change in precipitation showed a 50% reduction of snow cover at the mean altitude of residential population in the 85 Austrian districts. The authors also mention that the 2,000 m mark does not seem to be problematic concerning the amount of snow.

For the French Alps, a similar study was undertaken assuming a temperature increase of 1.8°C (Martin and Etchevers, 2005). They used the more elaborated model chain Safran-Crocus, which is usually used for operational avalanche warning and found a 50% reduction of snow depth below 1,500 m asl and 30% snow-covered area in midwinter.

Conclusions

The seasonal snow cover in the Alps is primarily influenced by a high year-to-year variability due to natural large-scale weather patterns. Despite this fact, a general decrease of the snow depth and snow cover duration could be detected since the end of the 1980s for low-lying stations throughout the European Alps. The decline could be linked to anomalous warm winter temperatures in the last 20 years (Scherrer et al., 2004; Marty, 2008), which seem to be unique for at least the last 500 years (Luterbacher et al., 2007).

Regarding future snow cover the two different approaches, the one based on physical models and the other on the current snow-temperature sensitivity, both came to similar results, which, for a 2°C warming, point to a drastic decrease of snow depth and snow-water equivalent of about 40–60% below 1,800 m, a reduction of the snow cover duration of 4–6 weeks and a rise of the snow line by about 300–500 m. According to the RCM projections, the warming in the Alps will be accompanied by a small increase in winter precipitation. Some authors therefore concluded that higher altitudes, where the temperatures are still cold enough for snowfall might experience an increase in snow depth with climate warming. However, the outcomes of two newer studies revealed that the projected increase in winter precipitation over the Alps will not even in the higher resorts compensate for the projected increase in temperature (Uhlmann et al., 2008; Bavay et al., 2009).

Because of the sensitivity of the Alpine snow cover to temperature, the depth, length, and duration of the snow cover is highly influenced by climate change. As warming progresses in future, regions where snowfall is the current norm will increasingly experience rain and the snow on the ground will melt faster. These perspectives leave no doubt that the projected changes will have a large impact on the economic, social, hydrological, and biological systems in the Alpine region.

Ice crystal structure; Snow crystal morphology

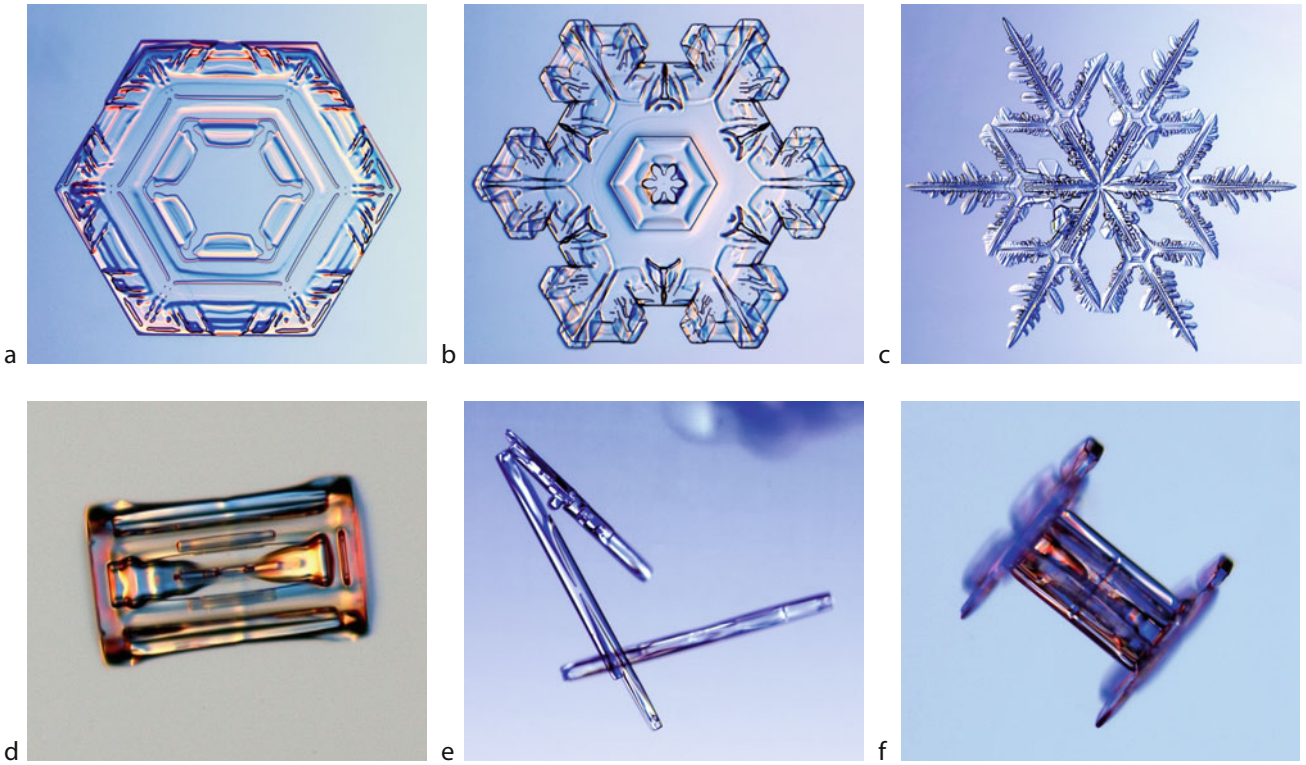
Definition

Snow Crystal Structure refers to the various morphologies of snow crystals that form from condensing water vapor in the atmosphere.

Introduction

Snow crystals, also called snowflakes, are single crystals of ice that grow from water vapor. They form in copious numbers in the atmosphere and are well known for their elaborate, symmetrical patterns. Figure 1 shows several examples of natural snow crystals.

The origin of the varied structures of snow crystals has been the source of considerable curiosity and scientific study for centuries (for a detailed historical account,



Snow Crystal Structure, Figure 1 Examples of several different morphological types of snow crystals found in natural snowfalls in temperate climates. (**a**) A relatively simple platelike crystal, 1.4 mm from tip to tip, with surface markings. Plates with smooth, featureless facets are less common in nature, except at low temperatures ($T < -20°C$) and low humidities. (**b**) A more elaborate platelike crystal, 2.1 mm from tip to tip, with an unusually high degree of complex symmetry. (**c**) A multibranched stellar dendrite crystal, 3.0 mm from tip to tip. These typically form at higher humidities when the temperature is near $T = -15°C$. (**d**) A simple hexagonal columnar crystal, 0.45 mm in length. Some internal hollowing resulted when the initially hollow ends of the column grew over. (**e**) Needlelike crystals, the largest being 1.1 mm in length. Note one needle grew as a slender hollow column before the ends branched. These crystals only grow near $T = -5°C$. (**f**) A capped column crystal, 0.6 mm in length. This crystal began growing as a stout hollow column, and then platelike stellar crystals grew on the two ends of the column. Photos by the author (Libbrecht, 2003).

see Kobayashi and Kuroda (1987) and Nakaya (1954)). With the development of photography in the late nineteenth century, Wilson Bentley (1931) catalogued several thousand snow crystal images in 1931 that he had acquired over many decades. Bentley's images popularized the snow crystal as a winter icon and were largely responsible for the widespread notion that no two snowflakes are alike.

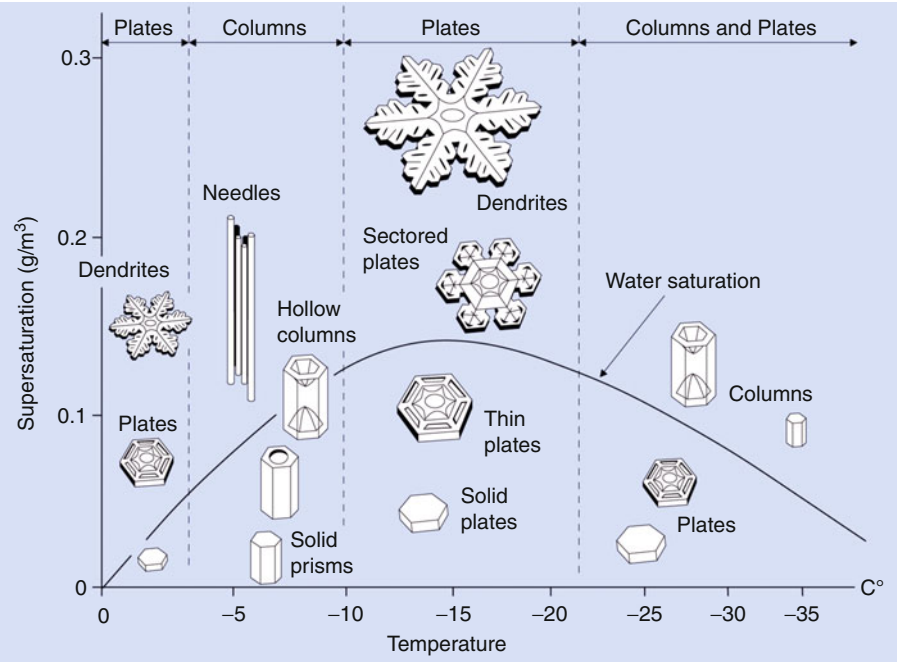
Faceting

When water molecules condense from the vapor phase onto a growing ice surface, the rate of incorporation into the solid lattice is governed by complex molecular dynamics known as *attachment kinetics* (Libbrecht, 2005). Molecules attach especially slowly to molecularly flat surfaces, which have fewer dangling molecular bonds. As a crystal grows, the faster-growing surfaces fill in more readily, so with time one is left with only the slower growing surfaces, which become the crystal facets.

Faceting is the dominant mechanism determining snow crystal structure when the growth is slow or the crystals are small. The resulting structure is that of a hexagonal prism, with two *basal surfaces* and six *prism surfaces*. The process of faceting is how the geometry of the ice crystal lattice is transferred to the structure of a macroscopic snow crystal.

Branching

Snow crystal growth behavior is typically dominated by attachment kinetics in combination with effects of water molecule diffusion through the air. If we begin with a platelike hexagonal prism crystal, then particle diffusion will bring molecules to the six tips of the hexagon at a slightly faster rate than to the neighboring flat surfaces. With a greater supply of material, the tips grow out, which increases the water supply even more. This positive feedback effect is called the *Mullins–Sekerka instability* (see Saito, 1996; Langer, 1980), and it is a ubiquitous feature of diffusion-limited growth. Much of the complex structure seen in snow crystals ultimately derives from this instability.



Snow Crystal Structure, Figure 2 The snow crystal morphology diagram, showing different types of snow crystals that grow in air at atmospheric pressure, as a function of temperature and water vapor supersaturation relative to ice. The water saturation line gives the supersaturation of supercooled water, as might be found within a dense cloud. The morphology switches between platelike and columnar forms as a function of temperature, while higher supersaturations produce more complex structures.

Snow crystal morphology diagram

The observed variety of snow crystal forms prompted the first laboratory investigations of snow crystal growth in 1930s. Nakaya (1954) observed the different growth morphologies as a function of ambient temperature and water vapor supersaturation, and he combined these observations into what is now called a *snow crystal morphology diagram*, shown in Figure 2. This diagram refers to snow crystals growing in air at a pressure near 1 bar, so applies to natural snow crystals.

The increase in structural complexity with increasing supersaturation is explained by the mechanics of diffusion-limited growth and the branching instability, but the changing morphology with temperature remains something of a scientific mystery.

Complexity and symmetry

The sensitivity of snow crystal growth to temperature and supersaturation allows a straightforward explanation for the combination of complexity and symmetry seen in many specimens like those shown in Figure 1. When a snow crystal is first nucleated inside a cloud, faceting dictates that the growth initially takes the form of a simple hexagonal prism. Diffusion limits the growth as the crystal becomes larger, and eventually this causes branches to form. Because ice growth is so sensitive to the local environment, it frequently happens that an abrupt change of some kind will cause all six corners of a simple platelike crystal to sprout arms at the same time.

As the growing crystal travels through the cloud, it experiences different temperatures and humidities along the way, and thus the growth behavior changes as a function of time. All six arms, however, experience the same changing conditions as they grow. The result is a rather complex growth pattern for each arm of the crystal, with all six arms developing roughly the same pattern. Under ideal conditions – for which the growth must be unperturbed by collisions with other ice or water particles – a snow crystal can grow into an elaborate, sixfold symmetrical shape, like those shown in Figure 1. Turbulent motions in the atmosphere cause each crystal path to be different, so each grows into a slightly different complex structure.

There are a number of naming conventions for snow crystals as they are falling (e.g., Kobayashi and Kuroda, 1987) and after metamorphosis of the crystals has taken place on the ground (IACS, 2009).

Definition

Snow deformation. A change in the shape and/or size of snow due to an applied stress.

Introduction

Snow deformation complexity arises because it is composed of ice that exists on the ground near its melting temperature as an intricate three-dimensional porous material formed from new and sintered snow grains that metamorphose over relatively short timescales (Flin et al., 2004; Schneebeli and Sokratov, 2004). Ice exhibits elastic, viscous, viscoelastic, viscoplastic, and brittle deformation that is a function of temperature and loading/deformation rates, and can lead to cohesive failure (Petrenko and Whitworth, 1999). Metamorphism changes the microstructure of snow through the sublimation and diffusion of water molecules from high surface energy surfaces to surfaces with less surface energy or through melting/freezing processes (Bartelt and Buser, 2004; Fierz et al., 2009). Sintering is the process of forming bonds between snow grains by "freezing" the disordered layers on snow grain surfaces that come into contact, or diffusing water molecules to points of contact between snow grains. The size of bonds increase through molecular diffusion of water at rates that increase dramatically as the snow temperature approaches the melting temperature of ice (Blackford, 2007) and with increasing pressure in the bond (Szabo and Schneebeli, 2007). Changes in snow microstructure, and the size of bonds between snow grains, change the mechanical properties of snow that control the deformation response of snow to stress.

Snow microstructure

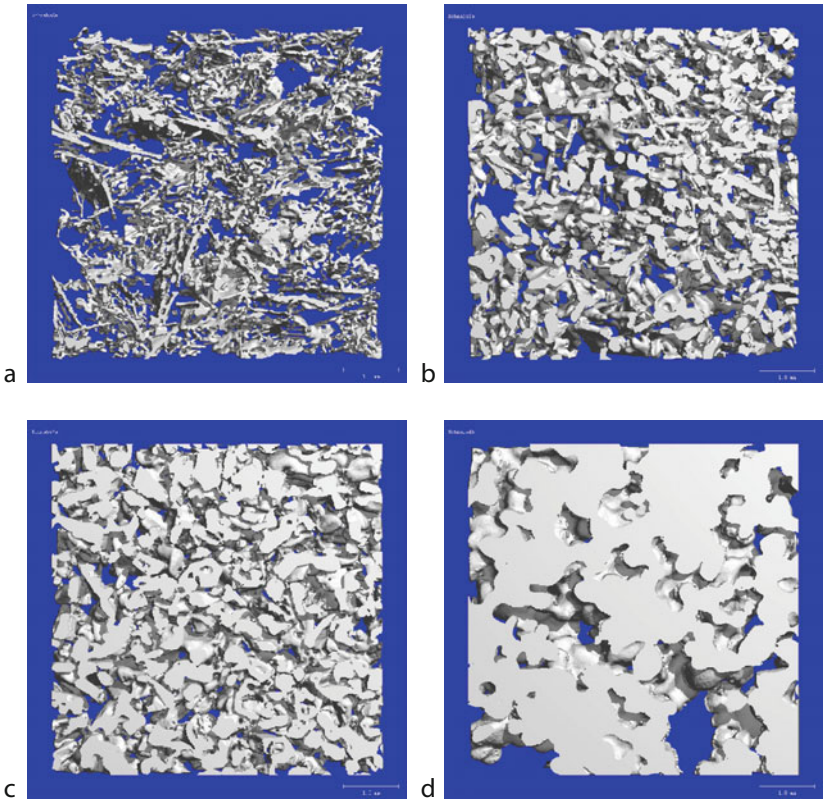
The microstructure of deposited snow is highly variable because snowflakes take many different forms (Nakaya, 1954). New snow is highly porous with fragile and intricate structures similar to foam materials. Snow self-weight densification and metamorphosis can produce microstructures that consist of random variations of grain and bond sizes or stiff, brittle, vertically oriented large grains connected by small bonds (Figure 1) (Armstrong, 1980; Trabant and Benson, 1972). Melting and refreezing of snow produces clusters of extremely large grains, polycrystals, and bonds (Fierz et al., 2009). As the density of snow increases, its microstructure becomes more uniform with decreasing porosity and heterogeneity.

Continuum-scale uniaxial compression, uniaxial tension, and shear

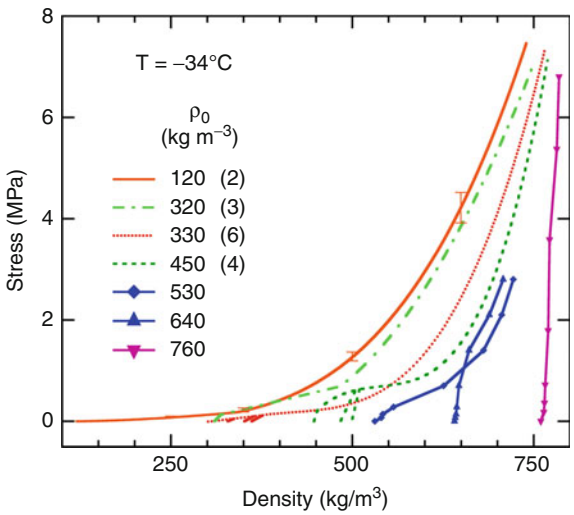
At the continuum scale, snow subjected to stress or deformation in compression, tension, or shear has fundamentally different deformation paths. Under the influence of uniaxial compressive stresses or deformations, low-density snow ($<$300–400 kg/m^3) will initially deform with little resistance (stress or load). The resistance to deformation increases gradually with density until about 450 kg/m^3 whereupon a dramatic increase in resistance occurs with density. The specific path of deformation and overall resistance to compression depends on snow initial density and microstructure, temperature, and the rate of loading/deformation. At relatively high initial densities, greater than about 500 kg/m^3, resistance to compression is a strong function of density and deformation paths coalesce (Figure 2).

Uniaxial tension at constant temperature causes snow to elongate with increasing resistance to deformation that eventually ends in failure. The form of deformation is a strong function of deformation rate. At high rates of deformation ($>10^{-4}$/s), the resistance to deformation increases rapidly until the snow undergoes a brittle failure (Figure 3a). As the rate of deformation decreases (10^{-5}/s), the resistance to deformation initially increases with strain to a relatively constant value and then decreases with strain as microcracks form. Eventually, microcracks will coalesce to form larger cracks that may gradually expand with deformation or cause the snow to rupture (Figure 3b and c). Higher density snow resists deformation more than lower density snow and will deform to a greater extent than low-density snow. At low deformation rates ($<10^{-6}$/s), the resistance to deformation gradually increases with strain (Figure 3d), eventually forming slow opening cracks (Narita, 1980).

Shear deformation occurs when a plane within snow displaces relative to adjacent parallel planes under the influence of shear stresses or displacements. For low-density snow at low loading/deformation rates, resistance to shear increases with shear displacement, often with an associated decrease in snow volume. The magnitude of resistance to shear, at a given shear displacement increases as stresses acting perpendicular to shear planes increase. As the loading/deformation rate increases, for constant temperature, resistance to shear will increase to a maximum, and then decrease to relatively constant values,



Snow Deformation, Figure 1 Snow microstructure at different stages of metamorphism and sintering. New snow with density $\rho = 110$ kg/m^3 (**a**), equilibrium temperature metamorphosed snow, $\rho = 240$ kg/m^3 (**b**), depth hoar, $\rho = 380$ kg/m^3 (**c**), and high-density snow, $\rho = 610$ kg/m^3 (**d**) (Images: M. Schneebeli, WSL Institute for Snow and Avalanche Research SLF).



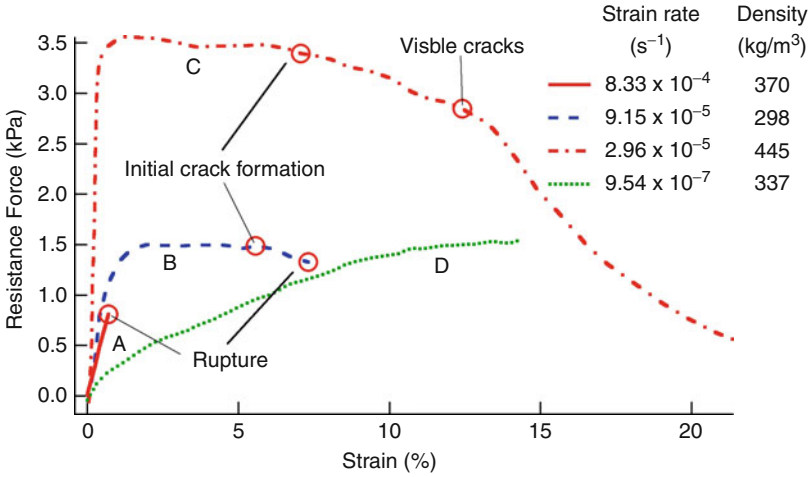
Snow Deformation, Figure 2 Uniaxial compression deformation of snow (Data from Abele and Gow, 1975, 1976). Numbers in parentheses indicate the number of tests.

as shear layers within the snow fail. As temperature increases, resistance to shear decreases. The magnitude of peak shear stresses at failure are functions of the magnitude of the stress perpendicular to the shear planes, temperature, rate of loading/deformation, and density (Figure 4) (McClung, 1977; Montmollin, 1982).

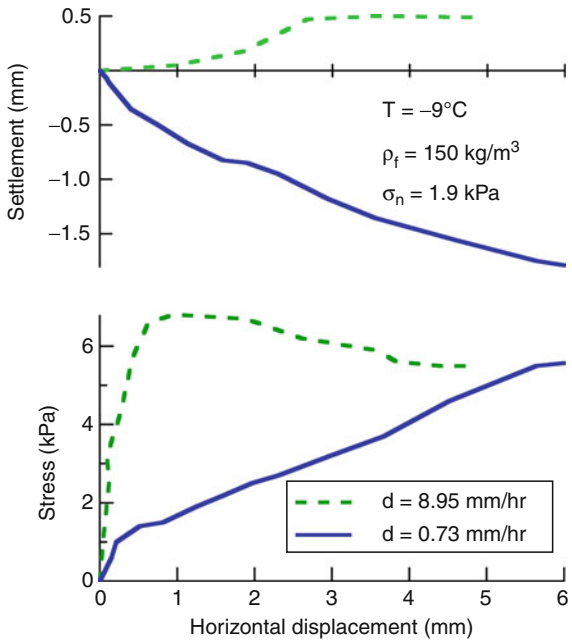
Microstructural and grain-scale processes that control snow deformation

Snow microstructure varies significantly over the range of possible densities from new snow to ice. New snow has no, or very small, bonds connecting grains together (Figure 1a). Metamorphosed snow grains are larger than in new snow (Figure 1b and c). Well-metamorphosed, high-density snow exhibits little microstructural variety, and differences between bond and grain sizes are relatively small (Figure 1d).

The intricate microstructure and small size of bonds compared to grain sizes in low-density snow influences deformation in two important ways. First, loads that cause deformation are not uniformly supported by the microstructural geometry and some geometric pathways support more load than others (Kry, 1975). This means that deformation occurs more rapidly in some parts of the bulk of



Snow Deformation, Figure 3 Resisting force as a function of uniaxial tension strain (Data from Narita, 1980).



Snow Deformation, Figure 4 Shear stress as a function of horizontal (shear) displacement. Negative settlement indicates densification and positive settlement indicates dilation (Data from McClung, 1977).

snow than in others and that as deformation proceeds more of the microstructure geometry may become involved. Alternatively, as some parts of the microstructure fail, other parts of the microstructure will experience increased loading and deformation. Snow microstructure is more uniform in high-density snow so that stress and deformation will also be more uniform. Secondly, stresses applied to bulk snow concentrate at the bonds with the result that most of the deformation occurs in the bonds, not the grains. As bond sizes approach the size of grains, the distinction between grains and bonds disappears and snow deforms as porous ice.

Grain-scale deformation processes act similarly for deformation in compression, tension, and shear. Differences in the expression of the grain-scale processes at continuum scales are due to the differences in the way the loads are applied. At the grain scale, bonds can be subjected to tension, compression, linear or torsional (twisting) shear, bending, or a combination of those (Johnson and Hopkins, 2005). Tension causes bonds to elongate and thin, and eventually to rupture, while compression causes bonds to thicken. Shear allows grains to move past each other, or rotate in place, via creep deformation while remaining bonded, or sliding if the bond ruptures. Bending is a response to combined tension and compression loads that can eventually lead to rupture. Combined conditions of loading or deformation, such as shear and compression, can cause grains to rotate (Faraday, 1859). Sintering affects grain-scale deformation by changing bond thickness and snow microstructure, especially near the melting temperature where sintering rates are high.

Uniaxial compression

During uniaxial compression, assuming that the rate of loading/deformation and temperature are held constant, the bonds between snow grains can thicken or thin, depending on their orientation to stress. At densities below about 300–400 kg/m^3, grains rearrange through viscous creep in the bonds or fracture of the bonds that permit grains to be displaced with respect to each other. This is a shear deformation process at the grain scale even though the continuum-scale deformation is compression (Shapiro et al., 1997). The process of grain rearrangement is generally accommodated within the pore space of the snow such that confinement of the snow has little effect on deformation (Scapozza and Bartelt, 2003). Sintering continues to operate during deformation, producing changes in the

bonds that can be more important in controlling deformation magnitude and rate than the applied stress, at low loading rates or at high temperatures. As grains rearrange, the microstructure tightens and the density of the snow increases resulting in more grain contacts and new sintered bonds that can produce a wide range of values in the mechanical properties of snow. Often, an *apparent* relationship between density and deformation can be established because both the deformation response of snow to stress and the density depend on the snow microstructure and the form of the bonding/grain contacts. Thus, it is the microstructure and bonding, and not the density, which are important for determining snow deformation response to applied stresses.

At initial densities of between 500 and 700 kg/m^3, snow microstructure makes a transition from complex forms to a form that resembles distributed interconnected pores in an ice matrix. The resistance to uniaxial compression of snow increases significantly as the pore space is no longer able to accommodate snow grain rearrangement. The size of bonds between grains grow to become a significant percentage of the grain size causing stress concentrations to decrease to negligible levels that are related to the ratio of the pore space to the overall volume of ice. At these higher densities, deformation becomes a strong function of density.

Uniaxial tension

Uniaxial tension deformation in relatively low-density snow occurs as viscous creep in bonds, or elastic deformation and rupture of bonds, to allow grains to rearrange in an alignment parallel to the axis of tension. Grains that are initially randomly distributed will undergo shear within their bonds and grain rearrangement to achieve alignment with the tensile stress field. As grains become aligned with the tension axis, bonds will elongate and thin. Bonds will begin to rupture in tension producing progressive failure of the snow at low rates of loading or catastrophic failure of the snow at high loading rates (Narita, 1980). As bonds rupture, stress is transferred to the remaining bonds. As snow density increases, the influence of microstructure decreases, and deformation becomes more ice-like.

Shear

During shear, grains attempt to move past each other along shear planes and may be able to do so without change in volume when grains do not interfere with each other and there are no loads perpendicular to the planes of shearing. When loads act perpendicular to planes of shear, grains will move past each other and fill available pore space, reducing snow volume. If grains interfere with each other during deformation, the grains must fail or the snow volume increase (dilate) to allow grains to rearrange into an easy glide configuration. Increasing the perpendicular loading on a shear plane makes it more difficult for interfering grains to move around each other, thus requiring larger shear stresses to dilate the snow or cause grain failure. For higher-density snow, or at higher loading/deformation rates, interference of grains with each other will cause the deformation resistance to increase to a maximum. At this point, deformation resistance decreases to a relatively constant value determined by the sliding resistance between grains and/or the rates of bond or grain rupture, sintering, and re-sintering (Figure 4).

Conclusions

Snow deformation at the continuum scale is complex because of the cumulative influences of snow microstructures that change under the influence of sintering and multiple grain-scale deformation processes. Sintering and grain-scale deformation are both temperature and loading/deformation rate dependent. Continuum-scale reflections of grain-scale mechanisms in uniaxial compression include decreasing volume with an associated increasing deformation resistance. Uniaxial tension produces an initial increase in deformation resistance as grains align themselves with the axis of tension. Once grains are aligned, bonds will fail as deformation continues, causing the resistance to deformation to decrease and cracks to form in the snow. Resistance to shear deformation increases until grains fail or rearrange themselves to move past neighboring grains. If grains can move into available pore space without interfering with each other, then snow density will increase along with resistance to shear. If grain movement is restricted then resistance will increase to a maximum followed by a decline to a relatively constant value as grains fail or arrange themselves in an easy glide orientation. The importance of microstructure and grain-scale processes decreases with increasing snow density such that, at densities greater than about 500 kg/m^3, deformation mechanisms transition to those associated with porous ice.

SNOW DENSITY

Steven Fassnacht
Snow Hydrology, Watershed Science Program,
Colorado State University, Fort Collins, CO, USA

Definition

Snow density is the ratio of snow water equivalent (SWE) to snow depth. When SWE is given in mm of water and snow depth in m, the units of density are kg m^{-3}.

The density of snow can vary by more than an order of magnitude. The density of freshly fallen snow has been observed to range from 20 kg m^{-3} to 250 kg m^{-3} (e.g., Reek et al., 1992; Fassnacht and Soulis, 2002) and is a function of formation conditions in the clouds and the atmospheric conditions through which the snow crystals fall. Upon reaching the ground, snow crystals begin to metamorphose. Prior to melt, the snow can attain a density of 300 kg m^{-3} (e.g., Fassnacht and Soulis, 2002) to 500 kg m^{-3}, depending on the length of time on the ground, meteorological conditions, and the depth of overlying snow.

SNOW DEPTH

Gavin Gong
Department of Earth and Environmental Engineering,
Henry Krumb School of Mines, Columbia University,
New York, NY, USA

Definition

The amount of snow on the Earth's surface at a specific point in space and time, measured as the actual vertical distance from the ground surface to the snowpack surface.

Introduction

Snow depth is arguably the most basic and fundamental descriptive feature of snow that resides on the Earth's surface. It is an intuitive measure of the magnitude of a solid precipitation event, for example, "last night's storm dumped 10 in. of snow on the ground". However the familiarity of snow depth belies its spatiotemporal variability, its physiological importance to the cryosphere, hydrosphere, lithosphere, and atmosphere, and also its societal importance as a water resource, especially in a changing climate (Doesken and Judson, 1997).

Snow depth refers to the actual thickness of a snowpack that overlays the surface, and has some important distinctions from other common snow cover descriptors. The binary presence/absence or the spatial extent of snow cover is the most extensively documented feature since it is the easiest to observe. Although snow extent and snow depth are inherently related, their fluctuations do not necessarily coincide in magnitude, timing, or even phase. This distinction is innate at local scales, where snow depth can vary between two different locations within a snow-covered domain, and can vary at a given location throughout the course of its snow season. At broader regional or continental scales, this distinction is often overlooked; for example, a year with a more extensive October snow cover over North America may be incorrectly assumed to have an anomalously deep snowpack throughout the snow-covered region.

Snow water equivalent refers to the depth of water that would result from a melted snowpack. Although this parameter also represents the amount of snow on the ground, it is not interchangeable with snow depth. The difference lies in the highly variable density of snow (typically 50–400 kg m^{-3}) in contrast to the relatively fixed density of liquid water (~1,000 kg m^{-3}). The density of freshly fallen snow depends on the meteorological conditions producing the snowfall event, and the density of a snowpack varies with depth and from seasonal down to hourly timescales even in the absence of melting. Thus, especially during the winter season, snow depth can vary considerably relative to snow water equivalent.

Observed spatial and temporal patterns of variability

Snow depth is represented as a continuous, nonnegative variable defined over an *x, y, t* coordinate system, where *x* and *y* define a location on the land surface (including glaciers and sea ice), and *t* is an instantaneous point in time. Local spatial variability can arise from factors such as heterogeneous precipitation rates, hillslope orientation, vegetation interception, and wind interaction with surface features. On regional scales (e.g., a watershed), the local variations are often averaged out to consider a homogenous snow depth for hydrologic and water resource applications. An important regional phenomenon is lake-effect snow, where atmospheric warming over lakes induces lifting, condensation, and snowfall over downstream land areas, resulting in regions with high snow depth. At the mesoscale, snow depth generally increases with latitude, but orography and proximity to oceans are key geographic determinants. Snow depths tend to be greater over mountain ranges where consistently lower temperatures facilitate solid precipitation and sustain surface snowpacks. The high heat capacity of water has a warming effect on coastal regions, so that Northern Hemisphere snow depth actually decreases with latitude near the Arctic coasts due to reduced snowfall. Hence, maximum snow depths tend to occur in the high-elevation interior of the North American and Eurasian continents (Foster and Davy, 1988).

Temporal variability can occur over multiple timescales. Snow depth can decrease on hourly-daily timescales via ablation processes such as melting, sublimation, and metamorphic transition from crystalline to granular structure which increases snowpack density. Ablation also occurs on weekly-monthly timescales, but is less apparent since periodic snowfall events increase snow depths. The interaction of snowfall and ablation generally lead to a broad delineation of the snow season, into an accumulation period with increasing snow depth, followed by a melt period with decreasing snow depths. On interannual to decadal timescales, snow depth exhibits structured periodicities as well as unstructured random variability, especially at large spatial scales. For example, twentieth century snow depth measurements gridded over North America indicate a decreasing trend from about 1970 to 2000, especially in late winter and early spring, preceded by an increasing trend from about 1900 to 1970 (Ge and Gong, 2008; Dyer and Mote, 2006). Early twenty-first century records do not clearly continue the late twentieth century decreasing trend; hence, the existence of any long-term anthropogenic trend in the snow depth record is ambiguous.

Measurement methods

Snow depth can be easily measured with a ruled stick or snow board inserted through the snowpack, typically to 1 in. or 1 cm precision. The drawbacks of this method are the limitation to point measurements, and the manual effort required and associated inconsistencies (Doesken and Judson, 1997). Nevertheless, it is commonly used for a wide range of scientific and nonscientific activities due to its simplicity and low cost. Snow depth station measurement networks exist throughout North America and Eurasia, and some stations have records dating back for over a century. Recent efforts have been made to interpolate the station measurements into gridded snow depth time series, particularly over North America (Brown, 2000; Dyer and Mote, 2006), which offer a new opportunity to fully characterize the large-scale spatiotemporal variability of snow depth. However, the gridded values can be constrained by irregular station distribution, which can lead to local biases, relatively coarse gridcell resolution that can dampen the true spatial variability, and insufficient accounting of elevation differences. Therefore, individual gridcell values far removed from station observations should be used with caution.

An alternative method for measuring snow depth utilizes remote sensing of electromagnetic waves. At local scales, an ultrasonic sensor is typically mounted on a permanent stand, and measures the time required for an ultrasonic (~50 kHz) pulse to travel through the air down to and back up from the surface. A shorter travel time is indicative of a shorter travel distance due to deeper snow. A temperature probe is also required since the speed of sound is sensitive to air temperature. At the mesoscale, passive microwave sensors mounted onto orbiting satellites are used to measure the degree of scattering caused by snow grains, which can be related to snow depth or snow water equivalent over broad regions (Cavalieri et al., 2004). The principal advantage of satellite remote sensing over station measurements is consistent spatial coverage, but the precision of satellite-based snow depth estimates is still evolving.

Data assimilation has also been used to infer snow depth values at locations far removed from station measurements. Deterministic snowpack models are used to simulate gridcell snow depth based on more readily available meteorological inputs, and model outputs are constrained to match station measurements where

available. Assimilation techniques for snow depth are still developing, but one available product provides daily snow depth for 1 km gridcells over the continental United States dating back to 2003 (NOHRSC, 2004).

Physical processes and modeling

The physical processes that govern snow depth are driven by energy fluxes as well as moisture fluxes (Dingman, 2002). Snow depth, of course, increases directly in response to snowfall events, but this increase can be short-lived if temperatures do not consistently remain below ~0°C. If the snowpack experiences a sustained net energy loss, snowpack temperatures will decrease, ablation will be minimal, and successive snowfall events will accumulate leading to sustained snow depth increases. If the snowpack experiences a net energy gain, snowpack temperatures will increase toward a maximum of ~0°C. During this warming phase, snow depth changes in the absence of snowfall events are minimal since ablation results from sublimation but not evaporation or melting. Even upon reaching ~0°C, snow depth changes are modest at first since initial melting is retained by surface retention onto snow particles within the snowpack; during this ripening period, ablation results from sublimation and evaporation. Only after surface retention has reached capacity does a melt period commence, in which melted snow infiltrates into the underlying soil, and snow depth decreases conspicuously.

Although the energy fluxes are the primary drivers of snow depth, other physical processes can also have an important influence. Wind-driven transport (i.e., blowing snow) during and between snowfall events can spatially redistribute snow depths, affecting sublimation rates and increasing avalanche risks due to locally high accumulations (Pomeroy et al., 2008). Dust deposition onto a snowpack affects snow depths by decreasing the albedo and hence increasing snowmelt rates at the snow surface. Metamorphic processes within a snowpack, such as gravitational settling, refreezing of snowmelt and water vapor transport, result in the densification of a snowpack over time, which can decrease snow depths even in the absence of snowmelt losses.

Mathematical models have been developed to simulate the evolution of a snowpack and its associated physical processes, by solving the governing equations of mass and energy balance for a one-dimensional system comprised of multiple snow and underlying soil layers. Radiative, turbulent, and diffusive energy exchanges are computed between each layer, from specified optical and thermal properties for snow and the underlying soil, and meteorological inputs at the snow–air interface. These fluxes determine the temperature and density of each layer, which in turn control the snowpack accumulation and ablation processes, and the resulting snowpack depth. Examples of such models include SNTHERM, CROCUS, and SNOWPACK, and they are used for a variety of applications from water supply planning to avalanche warning (Rasmus et al., 2007).

Snow depth is also a prominent land surface feature simulated in large-scale climate models, as part of a land surface parameterization scheme. Because of the gridcell structure of most climate models that is very coarse relative to the physical snow accumulation and ablation processes, these snow parameterizations are necessarily simplified. Typically, only a single snow layer is modeled, primary processes such as albedo are computed simply from vegetation type, snow depth, and snow temperature, and other important metamorphic processes such as refreezing are ignored. Recent improvements have increased vertical resolution, improved vertical physics, and incorporated sub-grid-scale heterogeneity to represent snow depth variability within a gridcell. Overall, climate models capture the broad features of the observed land surface snow regime, although ablation processes at low snow depths are a significant source of both scatter between individual models and overall modeling weakness (Slater et al., 2001).

Socioeconomic importance

Land surface snow depth is of tremendous social and economic importance, affecting many sectors such as water supply, agriculture, fishery, forestry, manufacturing, and tourism (Doesken and Judson, 1997; Frederick and Gleick, 1999). The potential influence of insufficient winter snowpack on water supply and drought risk during the subsequent spring and summer seasons is a major concern in the densely populated mid-latitude regions of the world. The lack of water stored in the form of snow also limits agricultural irrigation, creates shortages of water for industrial users, and damages wildlife habitats. Less snow accumulation in winter or early snow melt in spring are also a major reason for more frequent and prolonged forest fires that put ecosystems and humans in peril. Another impact of snow depth is its influence on the tourism sector, in particular skiing and other winter activities that serve as a major contributor to regional economies in many places around the world. Snow depth variations even on a weekly basis can have a direct financial impact on the local ski and snow sports industry and related businesses, while seasonal to interannual variations can affect employment patterns and construction decisions.

Conversely, excessive snow depths can jeopardize livelihoods and disrupt local economies. The consequences of severe snow storms are usually devastating, resulting in power outages, agricultural damage, and property loss (Doesken and Judson, 1997). Deep snowpacks pose an obvious avalanche risk in mountainous areas, and can also be a primary reason for floods when combined with excessive rainfall during the snow melting season, which may require massive evacuations and damage buildings, bridges, dams, and other infrastructure. Rapid melt of deep snowpacks can also trigger landslides and debris flows which could impair downstream water quality, cause

serious soil erosion, and limit agricultural productivity (Frederick and Gleick, 1999).

The SNOTEL system operated by the United States Natural Resources Conservation Service (http://www.wcc.nrcs.usda.gov/snow/about.html) illustrates the socio-economic value of snow depth. This service regularly collects, transmits, and processes snowpack and related climatic data at roughly 2,000 manual and/or automated sites in the western United States and Alaska, as well as streamflow forecasts for about 740 locations. This information is critical to regional water managers and decision makers in these regions, where, winter snowpack represent the largest component of water storage (Mote et al., 2005). It is used to inform crop optimization plans for irrigation-dependent agricultural land, drought management plans for water supply reservoirs, and flood diversion plans for municipalities. It is also used by local businesses to inform staffing, equipment, and other operational decisions.

Climatic relationships

Land surface snow depth is being increasingly recognized for exhibiting physically based relationships with the overlying climate system, distinct from the more widely studied snow extent relationships (Ge et al., 2009). Although the presence of a snow cover is known to suppress local air temperature, deeper snow has been shown to enhance the temperature suppression. Climate modeling studies suggest that snow depth may have a greater impact on the Indian monsoon than snow extent, via alterations to the hydrological cycle and surface energy budget. Extending to larger scales, snow depth anomalies over Siberia have also been found to influence the dominant mode of extratropical North Hemisphere climate variability.

Conversely, large-scale climate teleconnection patterns have been shown to influence snow depth, particularly over North America. Many of these studies are motivated largely by socioeconomic issues such as water supply in the western United States, and therefore use snow water equivalent rather than snow depth as the snow cover metric. These studies have identified various regional-scale statistical relationships with a disparate set of climatic drivers, for example, the Pacific–North American Pattern (PNA), El-Nino Southern Oscillation (ENSO), Pacific Decadal Oscillation (PDO), and the North Atlantic Oscillation (NAO). More recently, a gridded snow depth dataset covering all of North America has been used to identify more coherent continental-scale relationships with climate phenomena that originate in the extratropical North Pacific. Overall, snow depth is emerging from the shadow of the more readily measured snow extent as having meaningful climatic causes and consequences.

SNOW DRIFT

Richard Bintanja
Royal Netherlands Meteorological Institute (KNMI),
De Bilt, The Netherlands

The process of transporting snow particles due to strong winds is called snowdrift.

In regions with permanent snow cover such as Antarctica, and in regions with seasonal snow cover, blizzards, snowstorms, and snowdrift are common phenomena. Loose surface snow particles are usually present whenever temperatures are below 0°C. When surface winds exceed about 7 m s^{-1}, these particles are picked up by the wind and become airborne. At moderate winds, individual snow particles bounce along the surface – a process called saltation – thereby ejecting more particles at each bounce. This is also referred to as drifting snow, and takes place in the lowest 0.1 m or so of the atmosphere. When wind speeds increase further, the particles become fully detached from the surface. This state of snowdrift is usually referred to as suspension, or blowing snow, and can reach heights of tens to even hundreds of meters. During snowdrifting conditions, individual particles collide, break, and generally become more round while airborne. Starting as snowflakes, they quickly turn into much smaller, rounded particles, which can be more densely stacked when they are deposited again. This process is usually referred to as wind packing.

Persisting winds may transport snow particles tens to hundreds of kilometers before settling down again. The erosion, horizontal transport, and subsequent deposition of snow lead to a significant redistribution of the surface snow, often resulting in surface features like snow dunes. Over the vaste flat snowplains of Antarctica, snow dunes thus formed can reach heights of about 1 m. However, when orography or buildings induce irregular wind patterns, snowdrift can potentially lead to accumulation of tens of meters of snow. Another adverse and potential dangerous effect of snowdrift is the reduced visibility caused by the airborne snow particles; during strong blizzards, the visibility may be reduced to almost zero.

Snowdrift not only involves the transport of snow from one location to the other, it also causes the snowdrifting particles to sublime. Traveling downwind, turbulent updrafts within the snowstorm will keep the particles afloat. Hence, the airborne particles are continuously ventilated, inducing a turbulent moisture flux, or sublimation, which steadily eats away mass from the particle. Snowdrift sublimation is a fairly efficient process, since the airborne particles are ventilated on all sides (in contrast to particles at the surface). This constitutes a two-step mechanism by which the snow surface loses mass: first snow particles are being swept up by the winds, after which they are slowly sublimated away while traveling downstream. Calculations have shown that snowdrift sublimation is generally a significant term in removing mass from the snow surface; averaged over Antarctica, about 15% of all precipitated snow is thus sublimed to water vapor again.

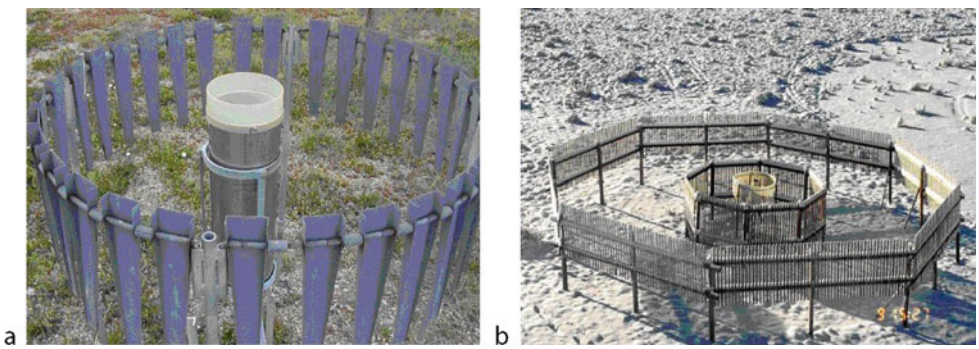
SNOW GAUGE

A. K. Singh
DIAT (Deemed University), Girinagar, Pune, Maharashtra, India

A snow gauge is an instrument used by meteorologists and hydrologists to measure the amount of snow precipitation over a set period of time. Snow stakes and simple rulers can be used to determine the depth of the snowpack, though they will not evaluate either its density or liquid equivalent. Snow gauges measure snowfall water equivalent directly. The snow gauge consists of two parts, a copper catchment container and a funnel-shaped gauge. The snow collection container is generally shielded to reduce wind turbulence around the orifice, as shown in Figure 1, and is mounted on a pipe outdoors and is approximately 1.5 m high, far enough above the snow surface to minimize the accumulation of blowing snow in the gauge, while the container is 51.5 cm in length. When snow has fallen the container is removed and replaced with a spare.



Snow Gauge, Figure 1 Snow gauge. Single alter shield (**a**); double fenced intercomparison reference shield (**b**). (Taken from ams.confex.com/ams/pdfpapers/119076.pdf.)

Snow Gauge, Figure 2 Tipping bucket rain gauges, that is, electric rain/snow gauges (www.omega.com).

The snow is then melted and poured into a measuring glass. While the depth of snow is normally measured in centimeters, the measurement of melted snow (water equivalent) is in millimeters. An estimate of the snow depth can be made by multiplying the water equivalent by ten.

The snow gauge suffers from the problem as that of the rain gauge when conditions are windy as the amount of snow may be under or over reported. Another problem may occur when there is both snowfall and rainfall leading to inaccurate measurement. In all of these cases the observer judgment is of critical importance to ascertain the accuracy of measurement.

Remote reading gauges used by weather stations that work similar to rain gauges have a large catch area that collects a critical weight of snow after which it tips and empties the snow catch. This activates a switch and sends a signal (Figure 2). If the catch container has a heater in it the snow weight is measured accurately. There is a possibility to tip the switch based on volume instead of weight leading to appropriate fill sensing.

SNOW GRAINS

Thomas H. Painter
Jet Propulsion Laboratory/Caltech, Pasadena, CA, USA

Definition and introduction

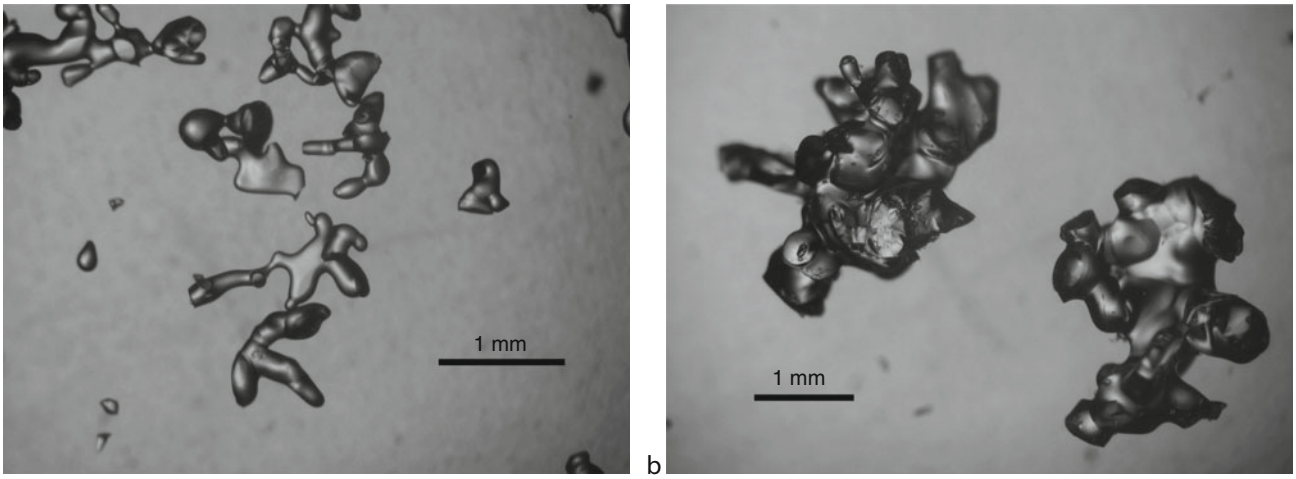
Changes in snow grains and their bonds contribute to changes in snow's albedo, microwave scattering, thermal conductivity, mechanical properties, and gas adsorption. The concept of the snow grain would seem to be easily defined and yet the complexity of the snow matrix and forms resulting from initial conditions and metamorphism renders an exact definition impossible (Mätzler, 1997). This lack of a simple definition results largely because the degree of sintering between the (always) monocrystalline particles varies enormously and concave or highly asymmetric forms are not uncommon. The concept of the snow grain to a remote sensor is substantially different from that to an avalanche forecaster, and their respective defined sizes for the same snow can vary by two orders of magnitude. Here, the concept of snow grains is described through the characterization of shape and size. (Note: sintering is described in the entry on snow bonding.)

We tend to conceptualize snow as a collection of grains because snow precipitates discretely to the Earth's surface and scrapes discretely from a snow pit face (Figure 1). However, the concept of the snow grain is most sound when the degree of metamorphism is modest, and the principal axes of the crystals are similar. The advent of micro-tomography has shown that snow has a much more complex structure than previously thought, and traditional grain-bond models are of little scientific use. Still, grain size and shape is the only possible morphometric measure that can be observed in the field.

Grain shape

In the new International Classification for Seasonal Snow on the Ground (Fierz et al., 2009), the snow grain is defined by its shape and its size. The shape is based mainly on morphological criteria, but also to some degree by its assumed state of metamorphism as described below. This definition relies methodologically on the traditional way of estimating grain size by scraping snow particles from the wall of a snow profile and studying these particles on a gridded black board using a magnifying hand lens or loupe.

The ICSSG (International Classification of Seasonal Snow on the Ground) suggests classification of snow grains according to the following classes: precipitation particles, machine-made snow, decomposing and fragmented precipitation particles, rounded grains, faceted grains, depth hoar, surface hoar, melt forms, and ice formations. As such, the first seven classes are specific to dry snow whereas the last two are specific to a period of



Snow Grains, Figure 1 (**a**) Decomposing precipitation particles from near-surface layer, Mammoth Lakes, California, February, 2001 (Photo: T. H. Painter, from Painter and Dozier (2004), Figure 6). wet snow. The classes are further divided into subclasses for which the description of the physical process is relied upon to assist in assignment of subclass. These classes and subclasses are used in most applications with little confusion but it is understood that the observations involve human interpretation and as such are inexact.

When modeling radiative transfer and thermal conductivity, these classes are often approximated with analytical forms that resemble atmospheric forms (Macke and Mishchenko, 1996; Mishchenko et al., 1999; Painter and Dozier, 2004) but more detailed treatments are emerging (Kokhanovsky and Zege, 2004). Techniques for automatically retrieving grain shape from X-ray microtomography and digital imagery with the metrics of dendricity (to distinguish "new" from "old" snow) and sphericity (to distinguish faceted from rounded grains) have been demonstrated with modest success (Flin et al., 2005; Bartlett et al., 2008).

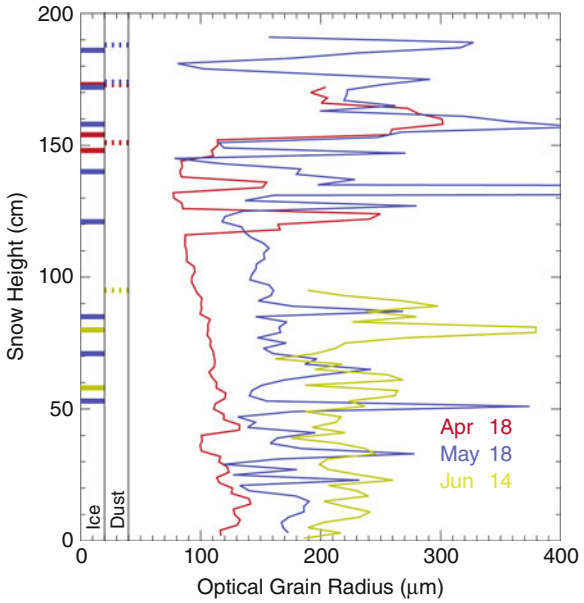
Grain size

The complexity of grain shapes and bonds in snow renders the description of grain size difficult. In the ICSSG, the size is defined by the range of the longest extent of a collection of grains. The maximum dimension of a fresh stellar snowflake can be as large as 10 mm whereas the minimum dimension can be as small as 0.05 mm, having an aspect ratio of 200. By contrast, a rounded polycrystal particle that has experienced persistent melt-freeze cycles can be quasi-spherical with a radius of 1 mm (Figure 1b). Without quantitative description of the grain shapes, comparison of single grain sizes for these two particles would be meaningless for any application.

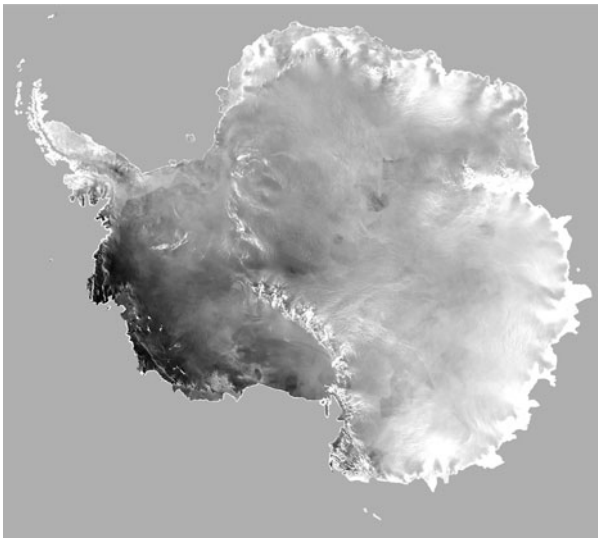
Grain size therefore is often described as the equivalent grain size within the context of application or process. For example, grain size with respect to visible and near-infrared radiative transfer (reflectance, transmission) is described by an optically equivalent grain size, given by the radius of the ice sphere that can represent the optical properties of the observed nonspherical snow. Likewise, equivalent grain size is described for microwave radiative transfer and current efforts are investigating how these equivalent grain sizes are related across the electromagnetic spectrum.

While the concept of "equivalent grain size" is useful from a practical, computational standpoint, a more physically explicit and comparable description of snow grain "size" comes from the specific surface area (SSA). SSA is defined as surface area per unit ice volume ($mm^2/mm^3 = mm^{-1}$) or surface area per unit mass (m^2/kg). The SSA is an essential microstructural parameter for the characterization of sintered materials such as snow, determining radiative properties, adsorption and release of trace gases, and permeability. The radius of the equivalent sphere for a specific surface area is 3/SSA (units of m).

The most fundamental modern method to measure snow SSA is through the determination of adsorption isotherm of gases such as nitrogen or methane (Adamson and Dormant, 1966; Legagneux et al., 2002; Kerbrat et al., 2008). Micro-X-ray tomography and stereology of vertical sections are equally precise (Kerbrat et al., 2008), and have the advantage that they can resolve spatial heterogeneities and very thin layers. Near-infrared photography (Matzl and Schneebeli, 2006) and contact spectroscopy (Painter et al., 2007) likewise give precise results but for the entire snow column at vertical resolutions of <1 mm to ~ 2 cm and far more rapidly than possible with the previous techniques (Figure 2). By resolving heterogeneities and thin layers with these



Snow Grains, Figure 2 Optical equivalent grain radius from contact spectroscopy in the San Juan Mountains, Colorado (From Painter et al. (2007), Figure 4).



Snow Grains, Figure 3 Optical grain size map of Antarctica from the Mosaic of Antarctica from the NASA Moderate Resolution Imaging Spectroradiometer (MODIS) (Haran et al., 2005; Scambos et al., 2007). techniques, we can better understand the influence on optical and microwave radiative transfer and mechanical properties of the snow column (Painter et al., 2007). These techniques do not presently treat grain shapes but in the future, directional retrievals will facilitate simultaneous retrievals of metrics of grain shape and grain size (Painter et al., 2003).

Remote sensing of snow grains

The spectral reflectance of snow is sensitive to changes in the optical grain size and grain shapes. Because of this sensitivity, multispectral and hyperspectral optical remote sensing from airborne and spaceborne platforms has the capacity to invert the measured reflectance for near-surface, optical grain size (Figure 3). The spatial distribution of optical grain size (which can be inverted for SSA) can be mapped using absolute reflectance at discrete bands in the near infrared (Fily et al., 1997), the integral of ice absorption features from imaging spectrometer data (Nolin and Dozier, 2000), and the general shape of the reflectance spectrum (Scambos et al., 2007; Painter et al., 2009).

Summary

Our understanding of the snow grain has come to more quantitative terms since the seventeenth-century observations by Descartes, Grew, Hooke, and Kepler. Even since the previous International Snow Classification of Seasonal Snow on the Ground in 1990, technological and modeling advances have contributed the X-ray tomograph, portable optical spectroscopy, and performance computing. These most recent technologies have allowed us to explore the three-dimensional structure of snow, specific surface area, and the influences of changes in the concepts of grains on energy and mass transfer. At the time of writing, laboratory, field, and remote sensing experiments are exploring the consistency between wavelength specific equivalent grain sizes and our ability to accurately infer SSA, new reflectance technologies, and relationship between passive and active microwave retrievals of snow water equivalent and our best understanding of the grain.

SNOW HYDROLOGY

Sarah Boon, Katie Burles
Department of Geography, University of Lethbridge, Lethbridge, AB, Canada

Definition

Snow hydrology is the study of snow contributions to the hydrologic cycle, particularly snowmelt, meltwater movement within the snowpack, and meltwater contributions to surface runoff.

Snow hydrology processes

The snow accumulation period is characterized by accumulating snow water equivalent (SWE), as observed in many parts of the northern hemisphere and high-elevation locations in the southern hemisphere. During the accumulation period, net energy inputs to the snowpack are negligible: average air temperatures decrease while SWE increases.

The snowmelt period is initiated when air temperatures begin to rise, net energy becomes positive, and SWE begins to decrease. The melt period can be separated into three phases:

1. *Warming*: snowpack temperature increases until the snowpack is isothermal at 0°C.
2. *Ripening*: melt occurs but meltwater remains within the snowpack. At the end of this phase, the snowpack is "ripe": all available pore spaces are saturated with meltwater, and no additional water can be stored (see *Snow Ripening*).
3. *Output*: continuing energy inputs create additional melt. Since the snowpack is saturated, additional melt leaves the pack and contributes to surface hydrology (soil moisture, surface runoff).

The average snowpack may not necessarily follow this exact sequence; in many cases, meltwater is produced at the snow surface prior to the pack becoming isothermal. This meltwater then percolates down through the pack and freezes, releasing latent heat which can act to warm the pack. Alternatively, the snow surface may become isothermal then refreeze until air temperatures increase and melting continues. Snowmelt can be empirically assessed using remote sensing approaches that quantify the areal extent of snowpack and the phase of melt (warming, ripening, output); however, it is difficult to quantify the volume and timing of snowmelt using these approaches (Rango, 1980; Déry et al., 2005; Derksen and MacKay, 2006; Wolken et al., 2009).

Factors influencing snowmelt

The rate and timing of snowmelt is determined mainly by the amount of available energy (Pomeroy and Goodison, 1997), which varies with topography (elevation, aspect), climate and meteorological conditions (maritime,

continental; rain-on-snow events, chinooks), and vegetation cover (open, sub-canopy, shrub, glacier surface). South-facing slopes have higher melt rates than north-facing slopes given increased radiation inputs, while lower elevations melt earlier than high elevations due to higher air temperatures. In maritime climates, rain-on-snow events enhance snowmelt, while in continental climates with frequent föhn (chinook) events, winter melt can occur. Vegetation cover plays a significant role in altering the energy reaching the snow surface, thus melt processes are often divided into open versus forested environments. In open environments (prairie, clear-cut, glacier surface), melt is driven by a combination of both radiative and turbulent fluxes. In forested environments, however, turbulent fluxes are significantly reduced, and radiative fluxes are much more complex. Shrub environments, however, lie between open and forested environments, with reduced longwave radiation inputs relative to a forest, but only slightly reduced turbulent fluxes, and very similar shortwave radiation inputs to open environments.

Snowmelt production: temperature index methods

Snowmelt has historically been calculated using temperature index (degree-day) approaches, which approximate snowmelt as a function of average air temperature (Anderson, 1973):

$$\text{SWE} = M(T_a - T_m) \text{ when } T_a \geq T_m \quad (1)$$

$$\text{SWE} = 0 \text{ when } T_a < T_m \quad (2)$$

where SWE is the snow water equivalent; M is the melt coefficient (also termed melt factor or degree-day factor); and T_a and T_m are the temperature of the atmosphere and snowpack, respectively. This approach assumes that, during melt, $T_m \approx 0°C$, that energy inputs to the pack from longwave and turbulent sources are linear functions of air temperature, and that solar radiation is well correlated with air temperature (Braithwaite, 1984). The melt coefficient can be difficult to determine and is dependent on latitude, elevation, aspect, forest cover, and day of year, all of which must be empirically measured or assumed for various watersheds (Gray and Prowse, 1993). The strength of these models lies in their minimal input data requirements, as air temperature is the most readily available meteorological variable, and their minimal computational requirements. However, these models are highly calibrated (Walter et al., 2005) and are limited to larger spatial scales and longer time periods (i.e., exceeding hourly and daily intervals) (Gray and Prowse, 1993). They are most commonly applied in large-scale watershed models with limited input data; for example, the HBV (Bergström, 1995), SRM (Martinec and Rango, 1986), UBC (Quick and Pipes, 1977), and SWAT (Fontaine et al., 2002) models. Despite their simplistic representation of the snowmelt process, temperature index–based model outputs have been validated in many environments (Beven, 2001).

To improve the physical basis of degree-day models, researchers have defined modified degree-day methods that incorporate additional variables such as snow surface albedo (e.g., Hock, 1999; Pellicciotti et al., 2008). While these models require additional input data and are more computationally intensive than the standard temperature index method, they remain more accessible than energy balance approaches, which can require significant amounts of data and data processing time.

Snowmelt production: energy balance methods

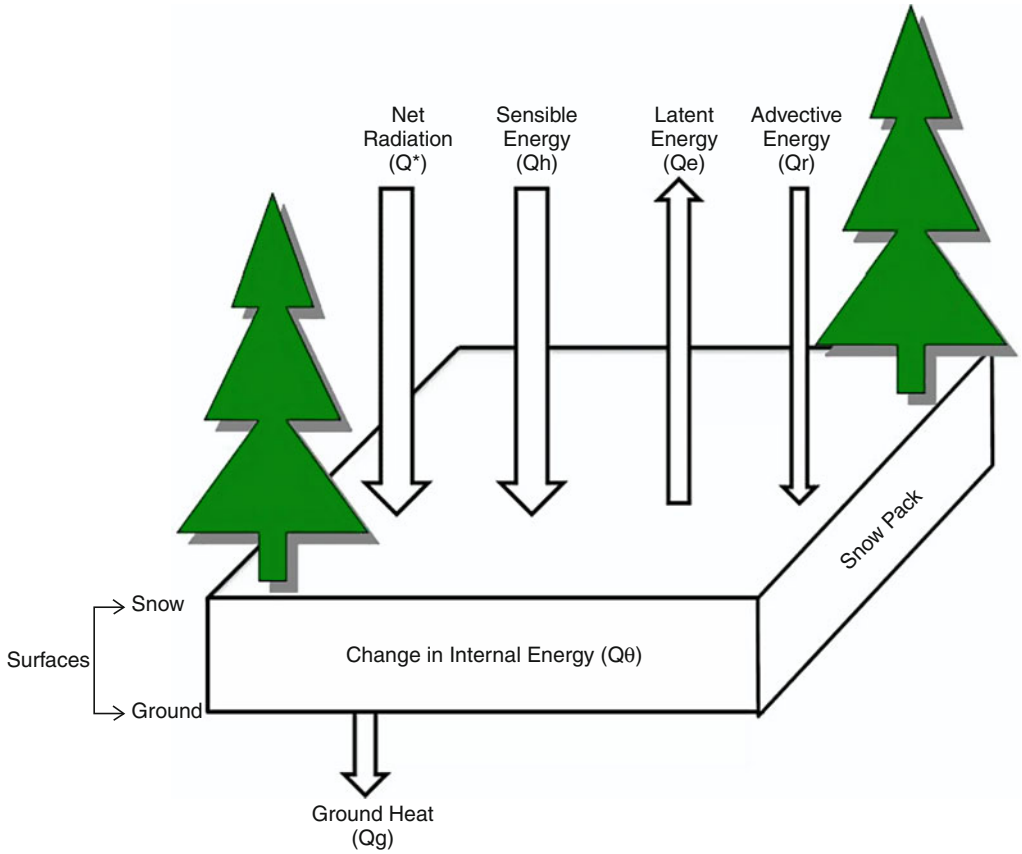
Energy balance models are more complex than temperature index approaches, as they are based on the fundamental physical principles of conservation of energy and mass. Designed for short-term forecasts (e.g., hourly and daily intervals) and highly data intensive (Gray and Prowse, 1993), energy balance models are the most thorough and accurate methods for calculating snowmelt. Figure 1 shows a basic schematic of the vertical energy fluxes during snowmelt in a forested environment. Here we describe the snow surface energy balance in a forested environment, as it is most complex given the ability of the forest canopy (e.g., density, height to live crown, crown depth and diameter, tree condition) to absorb and reflect incoming shortwave radiation, emit longwave radiation, and alter snow surface albedo (Link and Marks, 1999). Forest canopy also increases surface roughness, thereby decreasing wind speeds (Gray and Prowse, 1993).

The energy balance during snowmelt is calculated as:

$$Q_m = Q^* + Q_h + Q_e + Q_g + Q_r - Q_\Theta \quad (3)$$

where: Q_m = energy available for melt; Q^* = net radiation Q_h = convective transport of sensible heat between the air and snowpack; Q_e = latent heat released through condensation of water vapor onto the snowpack or lost through evaporation; Q_g = conduction of heat to the snowpack from the ground; Q_r = advection of heat to the snowpack through rain; Q_θ = rate of change of internal energy per unit surface area per unit time (all in MJ m^{-2} day^{-1}).

Net radiation (Q^*) is the sum of net shortwave (K^*) and net longwave (L^*) radiation fluxes and is the dominant energy flux contributing to snowmelt in forested environments (Link and Marks, 1999; Woo and Giesbrecht, 2000; Koivusalo and Kokkonen, 2002; Spittlehouse and Winkler, 2002). K^* is the total amount of incoming shortwave radiation (K↓) minus outgoing shortwave radiation (K↑). K↓ is representative of the total amount of solar radiation that has reached the ground or snow surface. This includes the portion that is not reflected by clouds or absorbed and scattered by the atmosphere (direct beam [S]), and the portion that is scattered by the atmosphere or above-surface objects such as trees (diffuse solar radiation [D]). K↑ is a function of the surface albedo (α), or reflectivity, which is calculated as the ratio of incoming solar radiation reflected by a surface to the total amount incident on that surface. Albedo declines as snow ages and melts (Table 1), and is also affected by organic debris



Snow Hydrology, Figure 1 Schematic of vertical energy fluxes in a forested environment (Modified from Gray and Prowse, 1993).

Snow Hydrology, Table 1 Albedo of various surfaces (From Gray and Prowse, 1993)

Surface	Typical range in albedo
New snow	0.80–0.90
Old snow	0.60–0.80
Melting snow-porous-fine grained	0.40–0.60
Forests-conifers, snow	0.25–0.35
Forests-green	0.10–0.20
Water	0.05–0.15
Snow ice	0.30–0.55
Black ice: intact → candled → granulated	0.10→0.40→0.55

accumulating on the snow surface (Link and Marks, 1999; Melloh et al., 2001; Winkler et al., 2010). Albedo can also be significantly affected later in the melt season, when the snowpack becomes patchy and the underlying ground surface is exposed (Liston, 1995). K↓ is not limited to the snow surface, but can penetrate up to 10 cm into the snowpack (Brock et al., 2000) , and reach the ground surface in shallow packs (DeWalle and Rango, 2008) with subsequent implications for the energy balance.

K^* in forested stands can be calculated as:

$$K^* = K \downarrow \tau_c(1 - \alpha) \quad (4)$$

where canopy transmissivity (τ_c) is the amount of K↓ transmitted through the forest canopy (Boon, 2009) and is largely dependent on tree type, stand characteristics, stand age, and stand productivity (Geiger et al., 2003). In coniferous forests, up to 90% of incident shortwave radiation may be absorbed by the canopy (Gray and Prowse, 1993).

L^* is the sum of all longwave radiation emitted by the atmosphere (L↓) minus the amount emitted by the Earth's surface (L↑). In the absence of clouds, L↓ is a function of atmospheric temperature and emissivity (ε), the latter of which is dependent on the vertical distribution of atmospheric temperature, water vapor, and carbon dioxide (Oke, 1988). Periods of low cloud cover increase L↓ from the atmosphere (Gray and Prowse, 1993). L↓ is important for snowmelt in dense forests, where a significant proportion of incident shortwave radiation is absorbed by the canopy and reemitted to the snow surface. As snow can more effectively absorb longwave versus shortwave radiation, this causes higher snowmelt rates near tree trunks (Reifsnyder and Lull, 1965) and results in high

spatial variability in melt rates (Bohren and Thorud, 1973). As with L↓, L↑ is dependent on the temperature and ε of the ground surface (Table 2). In forested environments, L^* at the snow surface is the sum of L↓ from the atmosphere, canopy, and tree stems; and L↑ from the snow surface:

$$L^* = \tau_L L\downarrow + (1-\tau_L)\varepsilon_c \sigma {T_c}^4 + (H_t/H)\varepsilon_t \sigma {T_t}^4 - \varepsilon_{ss}\sigma {T_{ss}}^4 \quad (5)$$

L↓ from the atmosphere and canopy is dependent on the sky view factor (τ_L) which is the proportion of hemisphere visible beneath the forest canopy. L↓ from the canopy is a function of the Stefan–Boltzmann law ($\varepsilon\sigma T^4$); where σ is the Stefan-Boltzmann constant = 5.67×10^{-8} W m^{-2} K^{-4} and the fraction of the hemisphere covered by canopy. L↓ from the tree stems is a function of the ratio of the hypothetical hemisphere surface area affected by longwave radiation from the tree trunk (H_t) and the hypothetical hemispherical area emitting longwave radiation to a point on the snow surface located at a distance from the tree trunk (H), multiplied by the energy emitted by the tree stems (Woo and Giesbrecht, 2000). Finally, L↑ from the snow surface is determined by the temperature and emissivity of the snow surface (Table 2).

The turbulent heat fluxes – sensible (Q_h) and latent (Q_e) heat – represent the exchange of energy between the snow surface and overlying air due to temperature and vapor pressure gradients, respectively (Andreas, 2002). These transfers occur not only at the snow surface, but also within the top few centimeters of the snowpack as wind is "pumped" into the pore spaces of the pack itself (Colbeck, 1997). Under dense forest canopies, where wind speeds are generally low, turbulent heat transfers are small (Woo and Giesbrecht, 2000). However, Q_h and Q_e can dominate the snowpack energy balance under strong warm winds, resulting in high short-term melt rates (Moore, 1983; Hayashi et al., 2005).

These fluxes are calculated as:

$$Q_h = \rho C_a D_k (T_a - T_s s) \quad (6)$$

$$Q_e = \rho \lambda_v D_e \left(\frac{0.622}{P}\right)(e_a - e_{ss}) \quad (7)$$

Snow Hydrology, Table 2 Emissivity of various surfaces (From Oke, 1988)

Surface	Typical emissivity range
Snow old → fresh	0.82–0.99
Forests deciduous bare → leaved	0.97–0.98
Forest coniferous	0.97–0.99
Water	0.92–0.97
Ice	0.92–0.97

where: ρ = density of air (kg m^{-3}); C_a = heat capacity of air (J kg^{-1} K^{-1}); D_h = bulk transfer coefficient for sensible heat (m s^{-1}); T_a, T_{ss} = temperature of the atmosphere and snow surface (°C), respectively; P = atmospheric pressure (kPa); λ_v = latent heat of vaporization (2.48×10^6 J kg^{-1}); D_e = bulk transfer coefficient for latent heat (m s^{-1}); and e_a, e_{ss} = atmospheric and snow surface vapor pressure (kPa), respectively.

The bulk transfer coefficients for latent and sensible heat vary with atmospheric condition. Under neutral atmospheric conditions, $D_h = D_e$ (Price, 1977):

$$D_h = D_e = \frac{k^2 u_a}{\left[\ln\left(\frac{z_a}{z_o}\right)\right]^2} \quad (8)$$

where k is Von Karman's constant (0.40), u_a is the wind speed (m s^{-1}), z_a is the height of the wind measurement (m), and z_o is the roughness length of the snow surface (m). Values of z_o range from 0.0002 to 0.02 m, with the greatest roughness lengths over older snow (Moore, 1983). When atmospheric conditions become highly stratified, the bulk aerodynamic method (Richardson number) is used:

$$R_i = \frac{g(T_a - T_{ss})z_a}{{u_a}^2 T_k} \quad (9)$$

where g is the gravitational acceleration (m s^{-2}) and T_k is the mean temperature of the air layer. Conditions are stable when $R_i > 0$, and unstable when $R_i < 0$. Air temperatures during snowmelt are usually >0°C, resulting in log-linear profiles for wind, temperature, and vapor pressure above the snow surface and stable atmospheric conditions, with $D_m = D_h = D_e$ (Price, 1977; Moore, 1983), calculated as:

$$D_m = D_m/(1 + 10R_i) \quad (10)$$

where D_m is the bulk exchange coefficient for momentum.

Ground heat (Q_g) flux occurs at the base of the snowpack and is estimated using soil temperature and moisture data (Gray and Prowse, 1993). Soil temperature generally increases with depth as a result of energy stored during the summer months and geothermal heat, thus establishing a temperature gradient that results in heat conduction upward to the ground surface and the base of the snowpack:

$$Q_g = k_G\left(\frac{T}{z}\right) \quad (11)$$

where k_G is the thermal conductivity of the soil, which varies spatiotemporally as a function of soil texture, soil density, and moisture content (Oke, 1988); T is the soil temperature (°C); and z is the depth of measurement below the ground surface (m). In comparison with Q^*, Q_h and Q_e, Q_g is relatively small on a daily time step (0–6 W m^{-2}); thus it is either assumed to be negligible, or to be a constant value in the energy balance equation

(USACE, 1956; Melloh, 1999). While the effects of Q_g on snowmelt can be ignored over short time periods (Gray and Prowse, 1993), the cumulative ground heat flux should be considered over entire winter seasons (Pomeroy and Goodison, 1997).

Advective energy (Q_r) is supplied to the snowpack by rainfall during the snowmelt period; the magnitude of the energy contribution depends on the regional climate and the frequency and magnitude of rain-on-snow events (e.g., Storck et al., 2002). Q_r is measured as the ratio between rainfall energy content while airborne (prior to contact with the snow surface) and energy content on reaching thermal equilibrium within the pack (Gray and Prowse, 1993). Two main scenarios are considered: (1) rainfall on an isothermal pack where the rain does not freeze; or (2) rainfall on a frozen pack (<0°C) at which point the rainfall freezes, releasing the heat of fusion (Male and Gray, 1981). These processes are calculated as:

$$Q_r = \rho_w C_w P(T_r - T_{ss}) \tag{12}$$

$$Q_r = \rho_w C_w P(T_r - T_{ss}) + \rho_w \lambda_F P \tag{13}$$

where ρ_w = density of liquid water (~1,000 kg m^{-3}); C_w = specific heat of liquid water (~0.0042 MJ kg^{-1}°C^{-1}); P = rainfall rate (L s^{-1}); T_r = temperature of rain (°C); T_{ss} = temperature of the volume of snow (°C); and λ_F = latent heat of fusion (~0.334 MJ kg^{-1}).

Finally, Q_θ is the rate of change of internal energy in the snowpack (Gray and Prowse, 1993). Within deep snowpacks, Q_θ can be relatively small in comparison to other energy fluxes, and is often considered negligible as snowpack temperature during ablation is ~0°C. However, midday snowmelt followed by overnight freezing can result in large changes in internal energy in both shallow snowpacks and the upper layers of deep packs. Q_θ is calculated as:

$$Q_\theta = (\rho_i C_i + \rho_w C_w + \rho_v C_v)\Delta T_i Z_i \tag{14}$$

where: ρ_i = density of snow and ice (~922 kg m^{-3}); C_i = specific heat of snow and ice (~0.0021 MJ kg^{-1}°C^{-1}); ρ_v = density of water vapor (kg m^{-3}); C_v = specific heat of water vapor (MJ kg^{-1}°C^{-1}); ΔT_i = the change in snow temperature (°C); and Z_i = snow depth (m).

Internal changes in snowpack temperature can also be measured using thermistor strings, or modelled using one-dimensional snow temperature and energy balance models such as SNTHERM (Jordan, 1991; Melloh, 1999).

Once the total energy available for melt (Q_m) is calculated, the total amount of meltwater or snow water equivalent (SWE) (in m) can be calculated as (Pomeroy and Goodison, 1997):

$$\mathrm{SWE} = Q_m/(\rho_w \lambda_F B_i) \tag{15}$$

where the thermal quality of snow (B_i) is the fraction of ice in a unit mass of snow (approximately 0.95–0.97) (Male and Gray, 1981).

Water movement through the snowpack

Once melt is initiated, meltwater can flow through the snowpack as both Darcian flow through an unsaturated porous medium (Colbeck, 1976) and as flow "fingers" that concentrate in particular regions of the pack (Colbeck, 1979; Albert et al., 1999). Water movement is a function of the temperature, structure, and water content of the snowpack (USACE, 1956; Waldner et al., 2004); for example, the presence of ice lenses or weaker snowpack layers can cause preferential flow paths within the pack. Observed time lags between melt onset and runoff production are a function of cold content, the liquid-water-holding capacity of the pack, and meltwater transmission through the snowpack as a function of permeability and gravity (Fountain, 1996; DeWalle and Rango, 2008) (see Cross-references).

Runoff generation from the snowpack

Meltwater outflow is generated from the snowpack once it can no longer hold meltwater within its internal pore spaces. This meltwater is then routed to surface runoff via overland flow, subsurface stormflow, and groundwater flow, the timing of which is critical for basin-scale runoff. Thus, snow hydrology is strongly linked with soil moisture and runoff generation, groundwater recharge, spring freshet, and climate change (see Cross-references).

New directions in snow hydrology

Current snow hydrology research is examining key topics around the relative importance of topography and vegetation cover in driving the snowmelt energy balance. Research suggests that south-facing slopes are more sensitive to changes in forest canopy cover than north-facing slopes, given the role of the canopy in attenuating incoming shortwave radiation and driving fluxes of incident radiation at the snow surface. Research is also detailing the role of forest litter and atmospheric dust on snow surface albedo, the snowmelt energy balance, and subsequent melt and runoff. Shifting weather patterns have increased long-range dust transport from arid/semi-arid regions to mountain snowpacks (Painter et al., 2007), while increasing rates of forest disturbance have enhanced forest litter production and incorporation into the snowpack (Winkler et al., 2010). While both dust and forest litter have significant impacts on snow surface albedo, they behave differently in terms of their effect on spectral albedo – thus new research is examining the spectral reflectance properties of both contaminant types in an effort to quantify their impact on snowmelt and runoff. Additional research is examining the relationship between snow hydrology and soil moisture (Seyfried et al., 2009; Williams et al., 2009), which is critical for determining patterns of runoff generation at the watershed scale (James and Roulet, 2009). Finally, research continues to assess the effects of shifts in air temperature and precipitation amount and type

as a result of climate change, and associated forest cover change, on snow hydrology (Bales et al., 2006; Lundquist et al., 2008; Jost et al., 2009). See Cross-references.

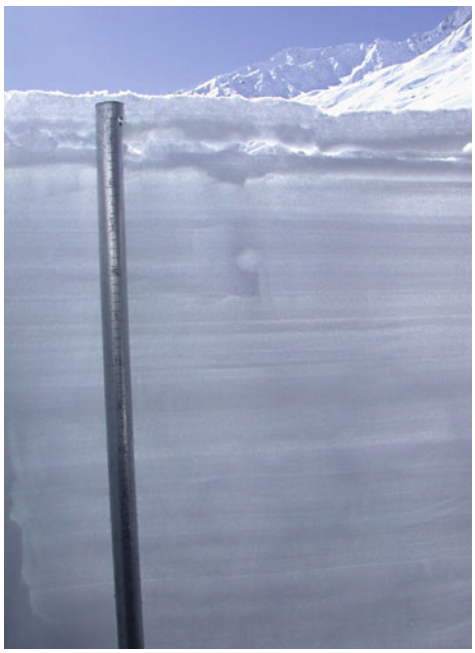
SNOW LAYER

A. K. Singh
DIAT (Deemed University), Girinagar, Pune, Maharashtra, India

Snow cover forms layer by layer (Figure 1), from one storm to another through interaction with atmosphere along with densification, accumulating in high-altitude geographic regions. In order to follow the evolution of a given snow layer, it is necessary to construct a time profile, based on a series of pits excavated through the snow cover at periodic intervals where density, crystal size and type, temperature, and other properties of the individual layers can be analyzed.

Assessing the formation and stability of snow layer is important in the study and prediction of avalanches. Many of the mechanical and thermal properties of snow that are significant to avalanche formation are related to a large extent on snow density. Temperature, crystal type, superimposed load, and temperature gradient all play a role in determining snow density. There is a strength variation in the snowpack due to its multilayered character. The mechanical properties of snow layers determine if it is stable enough to prevent an avalanche. Such stability information requires analysis of snow on avalanche slopes on a regular basis. The snow layers in which depth hoar formation (TG metamorphism) takes place show a distinctly different densification pattern. The density increases very slowly (reflecting the common observation that depth hoar layers undergo little settlement), and



Snow Layer, Figure 1 Snow layers in snow cover.

requires over 100 days to reach a value of 300 kg/m^3. The density values are also of importance in evaluation of forecasting snowmelt runoff as snow covers are important water resources that feed streams and rivers. Snowpacks are also studied in relation to climatic change and global warming.

SNOW LOAD

A. K. Singh
DIAT (Deemed University), Girinagar, Pune, Maharashtra, India

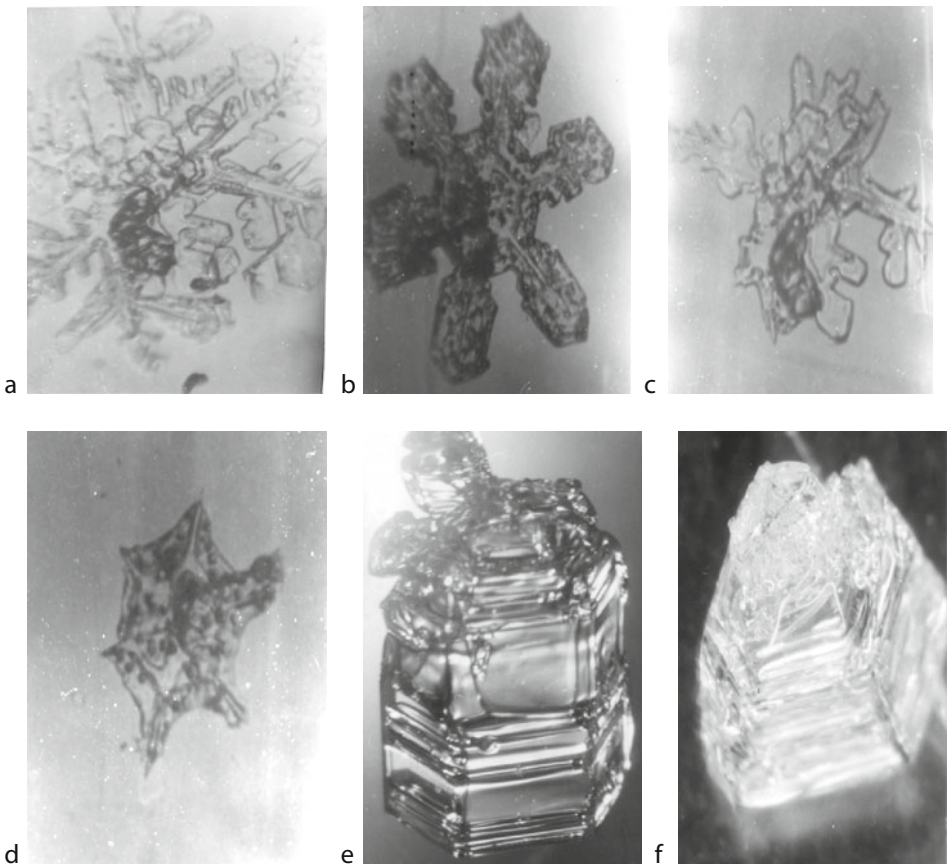
Snow load is the force acting on a structure. Load causes stress, deformation, and displacement in structures. Assessment of its effects is carried out by the methods of structural analysis. Excess load or overloading may cause structural failure. In addition to the load magnitude, its frequency of occurrence, distribution, and nature (static or dynamic) are important factors in design.

The load resulting from the accumulation of snow on a roof in a severe winter must be taken into account in designing buildings in snow-bound hilly regions. The unit weight factor is used in the design of a flat or pitched roof for the probable amount of snow lying upon it. Roof failures in snow-bound regions are often associated with early spring rains, and, therefore, it is advisable to add to the snow load, the load of rainwater also, that might be retained in the snow.

SNOW METAMORPHISM

A. K. Singh
DIAT (Deemed University), Girinagar, Pune, Maharashtra, India

Since snow, in nature, exists close to its melting point, it transforms with time depending on the physical parameters of the snow environment. This process is called metamorphism. Under metamorphism we study change in crystal structure with change in temperature and pressure conditions. Fresh snow crystal is a branched structure (Figure 1a and b), which immediately after touching the ground starts decaying (Figure 1c and d). Researchers have described three types of thermal metamorphism, namely, Equi-temperature (ET) or equilibrium forms,



Snow Metamorphism, Figure 1 Snow grains, (**a, b**) new snow (**c, d**) rounding of snow (**e, f**) depth hoar (TG) snow.

Temperature-gradient (TG) metamorphism or kinetic growth forms (Figure 1e and f), and Melt-freeze (MF) metamorphism. Depending upon the temperature and temperature gradient inside snow cover, felt-like crystal may either convert to round or ET or TG grains. In almost all the situations there is fast destruction of branches of fresh snow crystal to felt-like structure. TG metamorphism is the source of weak layer formation in the snow cover and is of importance in avalanche studies and is an active research field in snow and ice community. Metamorphic modification of structure, texture, and density of snow is accompanied by changes in the mechanical properties of snow.

For ET growth, curvature effects are dominant in changing the crystal morphology, and vapor pressure over convex region is higher than that over concave region. Due to this, vapor transfer takes place from convex to concave surface thereby rounding off fresh snow crystal or felt-like crystal. During ET metamorphism the density changes from approximately 80 to 250 kg m^{-3}. Equilibrium form dominates snow pack at low temperature gradients and temperatures above −6°C.The process of equilibrium form goes through various stages, that is, rounding, growth of neck or bond, and further rounding and becoming almost equi-dimensional. This process has great significance in avalanche formation. The rounding of the snow grains and the neck formation tend to increase snow strength in tension, compression, as well as in shear.

For TG growth, if air temperature is very low or snow pack is very shallow, there exists a strong temperature gradient. Vapor migrates from higher temperature to lower temperature regions upwardly. On countering an obstruction or grain the vapor is directly deposited over the grain surface, thereby forming faceted or inverted cup-like crystal structures (Figure 1e and f) that are instrumental to avalanche formation. These depth hoar grains, being angular in character, generally do not bond well and exhibit extremely poor strength in shear. The depth hoar layers have high compressive viscosity and therefore snow density remains constant during formation.

The melt-freeze (MF) process occurs due to cyclic variation in snow surface temperature, resulting in formation of large poly-granular grains after repeated cycles of melting and refreezing and is known as MF metamorphism. In spring, the entire snowpack becomes isothermal near 0°C, however, the temperature varies considerably between day and night, resulting in melting and refreezing.

SNOW MICROSTRUCTURE

Christine Pielmeier
WSL Institute for Snow and Avalanche Research SLF, Warning and Prevention, Davos Dorf, Switzerland

Synonyms

Snow texture

Definition

The most recent definition of snow microstructure is given in the International Classification of Seasonal Snow on the Ground (Fierz et al., 2009, p. 3): "Snow on the ground is a highly porous, sintered material made up of a continuous ice structure and a continuously connected pore space, forming together the snow microstructure." Hence, snow microstructure is the size, shape, and number of structural elements and their arrangement in a sample of snow. A previous definition by Arons and Colbeck (1995) distinguished between snow microstructure and snow texture. They defined snow texture in terms of microstructure and mesostructure. Snow texture combines on the microscale the size and shape of individual ice particles with the three-dimensional arrangement and interconnectedness of the grains and pore spaces in a mesoscale specimen of snow.

Genesis

The microstructure of snow in the atmosphere (new snow) is initially determined by the meteorological (crystal type, snow fall intensity, temperature, wind, radiation) disposition during the snow fall period. After the snow reaches the ground it forms the snowpack. Properties of the ground or of the existing snowpack influence the deposition process. Postdepository metamorphism as well as mechanical and meteorological impacts produce large and persistent changes in the snow microstructure as long as the snowpack exists on the ground. Snow microstructure disappears either by melting of the snowpack or by the transformation of firn to glacial ice.

Relevance of snow microstructure

The snow microstructure is complex, since size, shape, and number of structural elements and their arrangement vary widely spatially and also temporarily in natural snowpacks. Thermodynamic, electromagnetic, and mechanical processes in snow depend highly on the microstructure of snow. Hence, the current state of the snow microstructure itself has a feedback effect on all processes within the snowpack and consequently on the future microstructure.

Measurement and simulation

Traditionally, snow microstructure is approximated by measuring the properties of isolated grains, knowing that it is an incomplete model of the three-dimensional ice-air-matrix (Fierz et al., 2009). Porous materials such as snow can be described by their porosity, specific surface area, and curvature. Recent progress has been made to simulate the thermal, mechanical, and electromagnetic properties of snow (Schneebeli, 2004; Flin and Brzoska, 2008; Kaempfer and Plapp, 2009; Satyawali et al., 2009), and to correlate to specific surface area and porosity (Johnson and Schneebeli, 1999; Matzl and Schneebeli, 2006; Dadic et al., 2008; Toure et al., 2008).

Conclusion

Recent studies show the importance of considering the snow microstructure in order to explain the snow

properties correctly. To improve our knowledge of thermodynamic, electromagnetic, and mechanical processes in snow, the snow microstructure has to be quantified and considered in the analysis and in simulations.

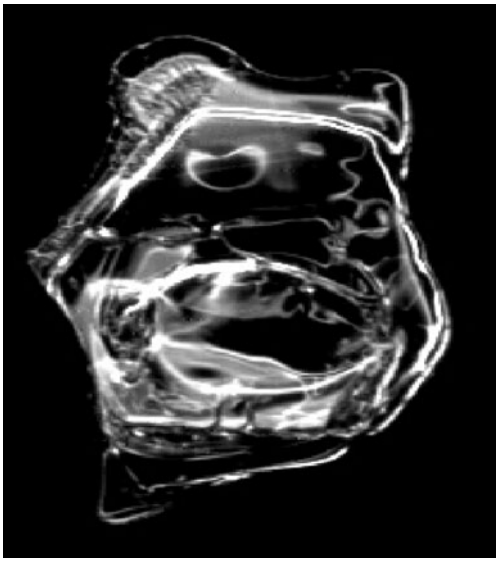
SNOW PELLET

A. K. Singh
DIAT (Deemed University), Girinagar, Pune, Maharashtra, India

Snow pellets are symbolized by white ice particles that fall as precipitation, grow by supercooled water, and break apart easily when landing on surface. Falling snow may partially melt and refreeze into a rain drop before it reaches the ground, as shown in Figure 1. These snow pellets are also referred to as sleet. Snow pellets can also occur when snowflakes melt about half way then refreeze as they fall. Soft hail also grows in a way similar to the growth of snow pellets. Snow pellets have whiter appearance than sleet. Snow pellets are typically a few to several millimeters in size and have small air pockets embedded within their structure and have visual remnants of ice crystals unlike sleet.

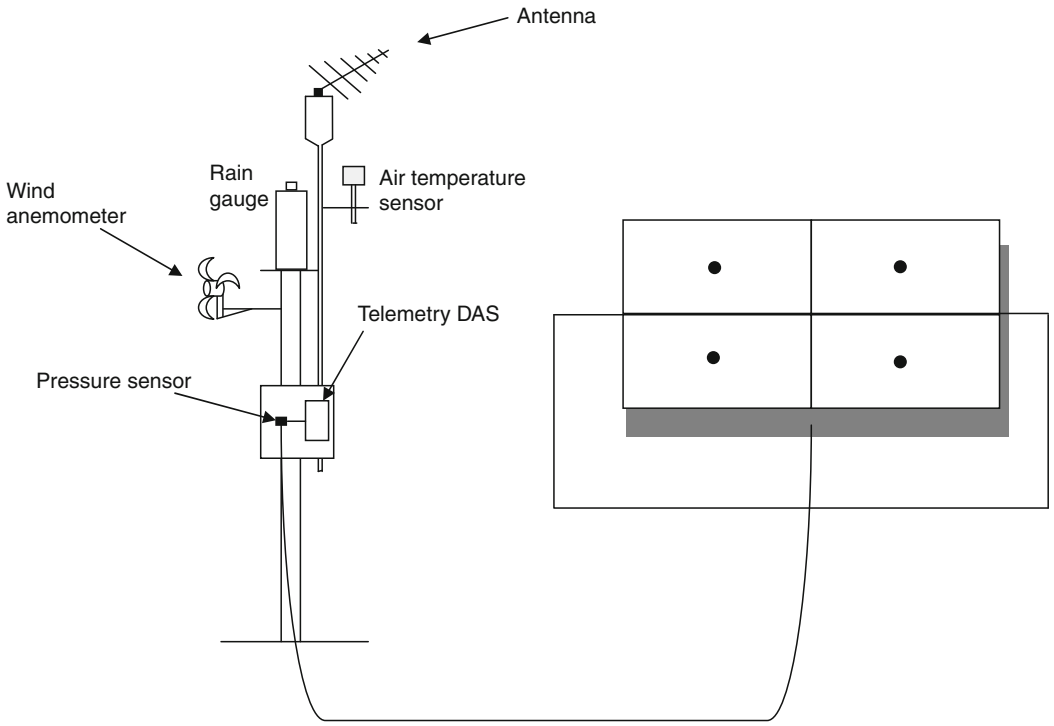


Snow Pellet, Figure 1 An image of partially broken and melt/refreeze snow grain.

SNOW PILLOW

A. K. Singh
DIAT (Deemed University), Girinagar, Pune, Maharashtra, India

The snow pillow provides a point value of the average water equivalent of snow which has accumulated on it. It is based on the detection of the hydrostatic pressure caused by snow. It is a large air mattress filled with an antifreeze fluid (mixture of methyl alcohol and water or a methanol–glycol–water solution, in the ratio of 1:1, having a specific gravity of 1). The fluid pressure responds to changes in the weight of snow on it, and is measured with a manometer or pressure transducer or load cell, as shown in Figure 1. Telemetry data acquisition systems (DAS) can be installed to provide continuous



Snow Pillow, Figure 1 Schematic of snow pillow with telemetry data acquisition system.

measurements of water equivalent. Complete system consists of a DAS, a shaft encoder that tracks the movement of the float in the standpipe from the pillow, 12-volt battery for powering and mounted solar panel for recharging the batteries. A float connected to a shaft encoder records the distance the antifreeze is pushed up the standpipe. The DAS contains a transmitter to send the recorded data to the central station. Snow pillows are made up of different materials and come in various shapes and sizes. The stainless steel snow pillows have the problem of repair.

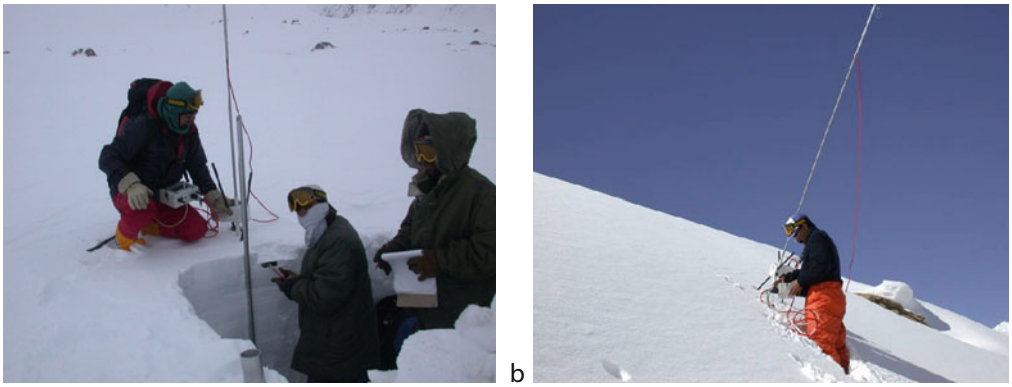
A small pillow used in a deep snow gives a pressure reading indicating a higher snow water equivalent than the actual. As the response of smaller pillows to the added weight of a heavy snowfall on a deep pack is longer than the larger pillows, it can produce an erroneous depth-time distribution for a storm. Intermittent freeze-thaw periods or rain on snow events may lead to the formation of ice layers within the pack, causing bridging, leading to lower values of the recorded water equivalent. In shallow snowpack the diurnal temperature changes may give spurious indications of snowfall or snowmelt due to expansion or contraction of the fluid in the pillow. Pillow sites should be near existing meteorological stations, or snow pillow should be equipped with certain meteorological instruments like precipitation gauge, thermograph, and anemometer.

Snow pillows are powerful tools for the study of precipitation measurements, particularly in mountain areas. It has been reported that pillows provide rough estimates of daily snowmelt losses from the snowpack. Pillow records can also be used to study meltwater formation as a function of climatic parameters. For the purpose of flood forecasting or inflow to reservoirs, it is of utmost importance to choose representative sites after surveying. Combined with measurements of snowmelt runoff, pillow records may also be useful for evaporation from snow cover.

SNOW PIT

A. K. Singh
DIAT (Deemed University), Girinagar, Pune, Maharashtra, India

The snow pit provides information about the stability of snow. It is a trench exposing a flat, vertical snow face from the snow surface to the ground, usually referred to as snow stratigraphy, as shown in Figure 1. Digging a snow pit reveals more about the snowpack structure than is visible from the surface and requires a little more practice and experience. Smoothen the uphill wall until it is vertical



Snow Pit, Figure 1 Image (**a**) snow pit observation in progress, image (**b**) usage of Snow Micro Pen (SMP).

and the different layers of snow can be seen by pressing the snow layer so weak layers can be identified. After preparing the snow pit, temperatures on the data sheet are recorded and markings of each snow layer are done. For each layer, record the crystal size and type, hardness and density. Typical stratigraphy results are shown in Figure 2. The detection of snow layers and their mechanical behavior is most important in the assessment of snow pack stability. It allows study of the characteristics of the different layers of the snowpack that have developed as the snow has changed due to compaction and weather changes. Snow pits are used in mountainous areas to determine if one layer might slip on another causing an avalanche. The most effective snow pits should be dug near potential avalanche starting zones. As snow accumulates and changes over time, it develops layers marked by physical differences that are used to determine the history of the snowpack and are broadly classified as new snow, firn, or depth hoar. The new snow layer consists of new sharp crystals lying loosely on the top of the snow bank that are slowly being compacted by additional falling snow. The firn layer lies just below the new snow layer and consists of crystals that have lost their sharp edges due to evaporation, freezing, and compaction. They are rounded into more sphere-like shapes, during the process of becoming particles of ice. This snow is dense and the grains are more closely bonded together, which increases the mechanical strength of the firn layer. At the bottom of the snowpack lies the depth hoar layer consisting of snow crystals that have transformed (metamorphosed) into lumps of ice through evaporation, condensation, and compaction. This layer is weakly bonded than the firn or new snow layers. The depth hoar layer is loose and grainy and it is often nicknamed as sugar snow.

Many snow pits are not possible over a day by classical methods due to their time-consuming procedure. Recently an automated method has been developed, called SnowMicroPen (SMP) to identify the snow layers and their strength over a large area in a short interval of time. SMP motor and sensor is shown in Figure 3.

SNOW RIPENING

A. K. Singh
DIAT (Deemed University), Girinagar, Pune, Maharashtra, India

Snow repining is the transition from a dry, subfreezing snow cover to isothermal snow, which can freely conduct water, that is, snow coming to full development, becoming mature for melt. It is a process during which the snow pack attains a state where it yields meltwater, including warming of the snowpack to 0°C. If the snow is ripe and air temperature is above freezing point, snowmelt occurs, otherwise positive energy first brings down snow to 0°C, that is, satisfying cold content of a few centimeters of top snow.

equipment such as bladelike runner or set of wheels attached to the shoe. Skating can be used for leisure activity, traveling, and in different forms of the sports activity as mentioned above in synonyms.

Origin: skating is regarded as the oldest winter sports back in times as long as 4,000 years in southern Finland as studied by Formenti and Minetti (2008). Skating as winter sports was quite famous in the Netherlands and other European countries in present. It is believed that skating in North America is brought by the British personnel during the eighteenth century (Flower, 1976). Earlier, the skates were made up of sharpened, flattened bone strapped to the bottom of the foot. With the advancement of the technology, the skates took form of steel blades, which invented by the Dutch in thirteenth century (Ice skating, 2009). The working principal of ice using skates is quite interesting. The metal blade at the bottom of the skates can glide with little friction over the surface of the ice. But variable leaning and digging of one of its edges into the ice will give skater a better ability to increase the friction and control of the movement.

The present-day skating had taken many forms such as roller skating, skateboard skating, and street skating. These forms use the wheels (often known as "spins") with skateboard instead the typical metal blade shoe. These forms of skating enhanced the outdoor sports activities, which were limited to the presence of snow and ice. Although, skating is a famous sport (winter or street), some hazard associated with this should be avoided as they may lead to serious injuries to head and legs. The practice and training of skate should be performed under suitable guidance and professional supervision.

SNOW SKIING

Ashok Kumar Verma
Department of Geography and Environmental Studies, Cold Regions Research Center, Wilfrid Laurier University, Waterloo, ON, Canada

The word Ski is derived from the Old Norse word "skio," which means split piece of wood or flat log (Flower and Killy, 1977; The History of Skiing, 2009; Skiing and Creation of Norwegian Identity, 1996).

The historical evidence of the ski is found in the Norway and Scandinavian literature that describe the ancient use of skiing for the livelihood (hunting), for military purpose, and as an efficient means of transportation. The oldest and accurate evidence documented in the region of Sweden and Norway dated back to 2,500–4,500 BC by archaeologists. The earliest reference of the skiing as winter sports is found in Procopius (560–559 AD), which mentions the race of Skridfinner – sliding finnes (Flower and Killy, 1977).

Present-day skiing is famous winter sports in all the cold climate countries such as North America, Europe, and some Asian countries and, recognized by the international Olympic organization and International Ski Federation. The worldwide popularity of ski as winter sports can be explained by the fact that the establishment of winter Olympic games for such sports. Over the time, skiing has evolved and divided into several categories and taken different forms of winter sports with respect to location and need namely, Alpine skiing, Backcountry skiing, Randonnee and Telemark skiing. In spite of its popularity as winter sports, the learning of ski by amateurs should be performed under proper guidance and supervision (Skiing, 2009). The ignorance of suitable learning environment and personnel can lead to fatal accidents causing major injuries and in some cases could even lead to death.

SNOW STORM

A. K. Singh
DIAT (Deemed University), Girinagar, Pune, Maharashtra, India

Steady snows of significant intensity accompanied by a certain amount of wind are often referred to as snowstorms. A massive snowstorm with strong winds (about 35 mph or more) is known as a blizzard. Snowstorms are usually considered to be less dangerous than ice storms. Mountain snowstorms can produce cornices and avalanches. Standing dead trees can be brought down by the weight of the snow, especially if it is wet or very dense. Even a few inches of dry snow can form drifts, many feet high under windy conditions. An additional danger, following a snowy winter, is spring flooding if the snow melts suddenly due to a dramatic rise in air temperature. Deaths can occur from hypothermia, infections brought on by frostbite, car accidents due to slippery roads, fires or carbon monoxide poisoning due to alternative heating methods after a storm causes a power outage, or heart attacks caused by overexertion while shovelling heavy wet snow.

SNOW AND VEGETATION INTERACTION

Christopher A. Hiemstra[1], Glen E. Liston[2]

Definition

Snow and vegetation interaction describes how the assemblage of plants in an area influences snow accumulation and ablation and the subsequent effects of the snow on plants.

Introduction

Snow and vegetation interact in two principal ways. First, snow accumulation and ablation processes and patterns are influenced by vegetation's physical structure and spatial arrangement. Second, snow deposition and melt patterns affect vegetation's distribution and growth. These interactions take place at fine scales (1 mm to 100 m) and are common to all environments where snow and vegetation coexist. The most striking examples of snow and vegetation interaction are found where high winds, abundant snow, and isolated groups of trees interplay to create snow distributions that vary from 0.5 m to 5 m deep within horizontal distances of 100 m or less.

Vegetation effects on snow

Vegetation influences snow accumulation through canopy interception and by altering wind patterns within and around vegetation. All plants intercept snow to varying degrees as long as leaves, branches, or stems are exposed and there is a surface upon which snow can be deposited (see *Interception of Snow*). The exposed canopy's structure is important in determining the amount of interception and retention that occurs. For example, evergreen trees and shrubs retain leaves in winter; these leaves are densely arranged on their stems and provide abundant horizontal surface area. As a result, these leaves and branches are efficient at intercepting and retaining snow, even in windy locations. In contrast, deciduous trees and shrubs with vertically oriented stems present little surface area for snow interception. Moreover, that branch's surface can be smooth (e.g., aspen and birch) and light winds easily scour snow from the branches.

The rigidity of the plant also plays a role in interception. Branches with a snow burden may droop and jettison snow, or the stems may drop to the snow surface and become buried in the snowpack. Further, a plant's ability to intercept snow may change over time. In grasslands, leaves that were upright and readily intercepted snow in the fall become prostrate by mid-winter due to leaf and stem comminution through high winds, decomposition, and previous snow accumulation.

In areas where snow transport by wind is common, vegetation plays crucial roles in snow transport and resultant snow accumulation patterns. In windy environments, vegetation has a "snow holding depth," defined to be the maximum snow depth captured within and to the lee of the vegetation structure that is not available for wind redistribution (Liston and Elder, 2006). This depth varies as a function of vegetation height, canopy structure, and the spatial arrangement of individual plants. As one would expect, taller vegetation has a higher snow holding depth; in similar conditions, forested areas can retain more snow compared with grassland or alpine and arctic tundra. Structurally, plants with a dense canopy possess a larger snow holding depth compared with spreading plants of identical height. Areas dominated by many plants hold more snow than sparsely vegetated areas. As a general rule, vegetation can capture snow depths within ~60–90% of the plant's height, but this can vary substantially depending on vegetation height, structure, and spatial arrangement. If snow is shallower than the

vegetation's snow holding depth, the snow is generally not available for wind transport and snow redistribution in the environment will be limited. If snow depth exceeds this height and wind is sufficient, snow above the holding depth is available for transport and snow erosion will occur. In the case of taller forests, snow holding depth is almost always higher than actual snow depth.

In snowy and windy landscapes, snow depths frequently vary with dominant vegetation types as snow holding depths change through space. Agricultural areas in winter often feature recently tilled soils holding little-to-no snow while adjacent fields containing stubble from the previous growing season have a snowpack approximating the stubble height. Likewise, natural systems have varying snow holding depths corresponding with shifting vegetation types that exacerbate and emphasize snow–vegetation interactions. Vegetation's ability to produce deep snows is especially evident in upper treeline areas. On Libby Flats at 3,200 m elevation in the North American Rocky Mountains of southeast Wyoming, abundant winter snow precipitation (~71 cm SWE) and high winds (mean = 10 m/s) transport snow to the lee sides of tree patches and lines of trees (ribbon forests; Billings, 1969) that are 4–12 m tall and are maintained by snow deposition patterns (see below). At the end of each winter, 2–7 m of snow accumulate on the lee side of tree islands and ribbon forests and these drifts last well into summer (Figure 1). Trees are embedded in a matrix of subalpine meadow that has a smaller holding depth and acts as a source area for the lee sides of trees (Hiemstra et al., 2006). Drifts produced on the lee of trees in this area have a large effect on vegetation patterns, ecosystem processes, and growing season length (see below).

Vegetation can be used for snow management. On the high plains (shortgrass steppe with <20 cm holding depth) of North America, living snow fences consisting of several rows of trees and shrubs are planted upwind of roads susceptible to drifting snow. These windbreaks can be effective as long as the transplanted trees and shrubs remain vigorous. Additionally, crop stubble will often be left standing in the fields to retain winter snows needed to recharge soil moisture for the next crop.

While vegetation shapes snow accumulation patterns and overall distribution, it also affects snowpack metamorphism and ablation. A canopy influences soil temperatures before the snow arrives and alters subsequent thermal fluxes at the snow-soil interface and snowpack temperature gradients between the soil and upper snow surface. This gradient influences snow metamorphism occurring within the snowpack throughout the winter. Plant leaves, stems, and boles embedded in the snow conduct energy away from or into the snowpack depending on existing temperature gradients between the atmosphere and the ground. In environments where vegetation protrudes above the snowpack, shortwave radiation warms the exposed vegetation and longwave radiation emitted from the vegetation melts snow surrounding the vegetation (see *Snow Cover and Snowmelt in Forest Regions*). Snowpack properties and melting rates change with distance from exposed vegetation as heat islands associated with the vegetation are advected downwind over the remaining snow cover (Liston, 1995). In the Arctic, the snow-free season has arrived 1–9 days decade^{-1} earlier than in the recent past (Chapin et al., 2005) and increased shrub dominance (Sturm et al., 2005) will lengthen the snow-free season and alter energy budgets. In simulations

Snow and Vegetation Interaction, Figure 1 Large snowdrifts formed on the lee side of tree islands remain well into summer on Libby Flats (photo taken July 3, 1998). The prevailing winter wind direction is from left to right. Vegetation not covered by snow is growing, while vegetation covered by the snow awaits its growing season.

of a vegetation shift from shorter arctic tundra to taller arctic shrubland, snow melts 11 days earlier due to enhanced shrub cover and corresponding changes in the surface energy budget (Strack et al., 2007).

Vegetation is not always associated with accelerated snowmelt. A thicker canopy, such as that associated with forested environments, intercepts shortwave radiation above the snowpack and delays snowmelt. Vegetation can enhance the amount of snow in an area by capturing blowing snow and reducing sublimation.

Inasmuch as vegetation affects soil temperatures, snow accumulation patterns, ablation, and sublimation, vegetation can play an important role in resource management and water yield. Since vegetation plays such key roles in governing snow processes and distributions, it is critical to design observations and water resource forecast schemes around predominant vegetation types within watersheds. Further, vegetation can change slowly through succession or land cover change that gradually alters snow–vegetation interactions. Vegetation can also be disturbed (e.g., fire and widespread beetle outbreaks), consequently altering the snow cycle and energy and water budgets.

Snow effects on vegetation

Snow distribution has important implications for vegetation. Prevailing wind direction, snowfall, and resultant snow distribution patterns are often similar year after year (Walker et al., 2001), so that relatively steady-state environmental conditions are produced. These repeating conditions create characteristic spatial variation in ecosystem properties such as growing season length, soil and permafrost temperatures (Zhang, 2005), decomposition (Gilmanov et al., 2004), susceptibility to fungal predation (Cunningham et al., 2006), species composition (Billings, 2000), and primary production (Bowman and Fisk, 2001). Observations show strong correlations among snow season length and timing, temperatures, and vegetation growth (Jonas et al., 2008). Experiments with winter snow-free periods (Bokhorst et al., 2008) and earlier snowmelt dates (Wipf et al., 2009) show the importance of snow in terms of timing and insulation for vegetation. Vegetation exposed to harsh winter temperatures due to mid-winter snowmelt is susceptible to damage, and with advanced snow-free dates and accelerated growth, some plants may be damaged by extreme early-season temperatures before they are hardy.

Alpine vegetation distributions are often depicted in terms of a mesotopographic gradient (Johnson and Billings, 1962), where interplay among snow cover, wind exposure, and topographic position explain vegetation distribution patterns. For example, fellfields dominated by cushion plants are located on windy, snow-free ridge tops, while snowbed vegetation is predominant under long-lived lee-side snowbanks where growing season length is brief. Forest patterns, such as ribbon forests (Billings, 1969), have been explained by an abundance of leeward snow limiting tree survival to create alternating lines of forests and open glades. In areas where snow distributions repeat year after year, those patterns can be mirrored by vegetation distribution patterns and inferences can be made about snow depths based on existing vegetation and ecosystem patterns, and vice versa.

Snow can also physically affect trees by scouring and avalanches. While many plants are buried and protected by snow, taller shrubs and trees protrude above the snowpack and are exposed to saltating and suspended snow moving at and above the snow surface. Blowing snow crystals are abrasive and can damage leaf cuticles. This damage eventually leads to water loss and desiccation that kills plant leaves and meristems (Hadley and Smith, 1986). It is blowing snow that causes winter mortality of tree leaves and creates flagged trees commonly observed at treeline, where the only live branches above the snowpack are on the lee side of the tree's stem. Heavy snowfall events and avalanches can damage branches, produce scars, and uproot trees and the damage can be examined to study avalanche frequencies and distributions.

Summary

Vegetation plays a large role in snow distribution patterns; it interacts with snow through interception, by retaining blowing snow, and by reducing sublimation losses due to blowing snow. Vegetation can accelerate or delay snowmelt depending on canopy characteristics and the amount of incoming energy. In turn, snow affects ecosystem structure and function, including the distribution of vegetation in landscapes. The effect of snow on ecosystems is especially important in areas where most precipitation arrives as snow and growing seasons are relatively short.

SNOW WATER EQUIVALENT

Michael Durand
Byrd Polar Research Center, Ohio State University, Columbus, OH, USA

Definition

Snow water equivalent (SWE) is the equivalent depth of liquid water that would result from complete melting of a snowpack.

Introduction

In many parts of the world, snowmelt runoff is a critical water resource. It has been estimated that one-sixth of the global population lives in areas where streamflow is dominated by snowmelt runoff (Barrett et al., 2005). For water resource studies, and for applications such as long-term water supply forecasting, the liquid water equivalent stored in a snowpack is the most important quantity of interest, since SWE represents the amount of water that will be available during spring melt.

Snowpack accumulation on land results from atmospheric precipitation as snow. Snowpack is generally composed of air and frozen snow grains, as well as liquid water. At a point in space, snow density varies vertically with depth; the bulk density of the snowpack is defined such that the product of the snow depth and bulk density is equal to the SWE. Due to the presence of air within the matrix of snow grains, bulk density is generally less than that of pure ice, which is 917 kg m^{-3}; thus, SWE is generally less than the snow depth.

Measuring SWE

Manual in situ methods of measuring SWE are of two general types, both of which rely upon measurements of the snow mass, which can be converted to SWE. The first in situ type of SWE measurement is obtained by inserting a hollow pole vertically through the snowpack and into the underlying soil. The mass of the pole and the snow are then measured; as the mass of the pole is known, SWE can then be determined (Dingman, 2002). This method is generally practiced as part of a snow survey. The second type of in situ SWE measurement consists of vertical measurements of snow density at predefined intervals (e.g., 10 cm) through the snowpack. In order to obtain these measurements, a snow pit must be excavated. A snow pit also offers the opportunity to measure snowpack stratigraphy and the snowpack temperature profile in addition to the SWE; excavating a snow pit is generally far more labor intensive than snow surveys.

In contrast to the manual methods of measuring SWE, snow pillows are installed at a remote location, and consist of a pressure sensor that measures the mass of a snowpack that accumulates in a given location. Snow pillows can be configured to transmit snow mass observations to a central location where they can be archived. This approach allows for measurement of SWE in near-real time while obviating the need for potentially dangerous navigation of often complex terrain (e.g., in mountainous areas) by snow surveyors. As an example, the SNOw TELemetry (SNOTEL) network of snow pillows in the Western United States records SWE in several hundred locations (Serreze et al., 1999); data are made publicly available via World Wide Web archival and distribution.

Methods to measure SWE from airborne and spaceborne platforms have been developed over recent decades. For example, terrestrial radiation emitted at microwave frequencies is routinely measured from space by such

platforms as the Advanced Microwave Scanning Radiometer – EOS (AMSR-E) aboard the Terra and Aqua platforms. By observing the attenuation of the radiometric brightness at different microwave frequencies, global estimates of SWE can be inferred, albeit at coarse spatial scales (e.g., Chang et al., 1987). From airborne platforms, measurements of gamma radiation emitted by the earth surface can be used to infer SWE. The SWE retrieval exploits the fact that gamma radiation responds to isotopes in the upper 20 cm of soil; when the soil is covered by snow, the gamma emissions are modulated (Liston et al., 2008). For instance, the National Operational Hydrologic Remote Sensing Center (NOHRSC) in the USA performs regular airborne surveys using gamma radiation measurements (Fritzsche, 1982). Remote sensing of SWE is thus a field that is becoming more mature. Building on this remote sensing heritage, radar measurements at microwave frequencies can be used to infer SWE; the European Space Agency is currently planning the CoreH2O satellite mission to make high spatial resolution global measurements of SWE via microwave radar remote sensing (Rott et al., 2008).

Summary

SWE is an integrated measure of the potential water resources stored in a snowpack. For purposes of water resources planning, it is typically characterized by in situ measurements of snow mass; large-scale estimates are achieved by in situ measurement networks. Remote sensing estimates of SWE are becoming more mature. The upcoming CoreH2O mission has the goal of making high-resolution global measurements of SWE, enabling a significant advance in global cryospheric characterization.

SNOWBOARD

Amit Kumar
Department of Geology, Centre of Advanced Study in Geology, Punjab University, Chandigarh, India

The measurement of snow depth is made on the snowboard whose surface is kept free of snow before the snowfall. The snowboard is at least a 40 cm × 40 cm piece of plywood or lightweight metal and is placed on the surface of snow. The board is painted white or covered with while flannel, which provides a reference level for measurements.

Snowboard is also termed as a single thin, constructed with a laminated wood core with a steel edge, attached to the feet to ridden in snowboarding to descend a snow-covered slope area, and used to glide on snow. Snowboards generally have a length between 140 cm and 165 cm and a width between 24 cm and 27 cm. A different variety of snowboards exists according to riding preferences. Throughout the world, skiing sports develop great business in winter season. At high altitude areas, it offers exciting opportunities to develop snowboarding in mountain ranges. To enjoy snowboarding, which is the best sport that has gained immense popularity all over the world, the snowboard has been used worldwide.

SOLIFLUCTION

Stephen J. Walsh, Daniel J. Weiss
Department of Geography, University of North Carolina, Chapel Hill, NC, USA

Definition

Solifluction, the "slow gravitational downslope movement of water saturated, seasonally thawed materials" (Thomas and Goudie, 2000), is most commonly associated with alpine and/or arctic environments where seasonal and diurnal freeze-thaw cycles are prominent drivers of geomorphic activity (French, 1996). It is often coincident with cryoturbation (e.g., frost heaving and needle ice activity), the processes by which surficial materials, including soils and their residual parent materials, are mechanically mixed, moved, and sorted by repeated freezing and thawing. In contrast, solifluction and cryoturbation produce distinct features

including hummocks, stripes, sheets, lobes, and terraces (Matsuoka, 2001). Typically, these features are linear or quasi-linear, may be regularly spaced, and tend to occur parallel to the slope contour. Kessler and Werner (2003) identify the underlying mechanisms responsible for producing striped periglacial patterned ground on hillslopes, as feedback processes related to ice lens and stone transport within freezing soils.

Features and processes

Among identified solifluction features, lobes and terraces are most commonly observed and are frequently associated with alpine periglacial environments (French, 1996). Solifluction lobes and terraces are reported in areas including the Colorado Front Range, USA (Benedict, 1970), New Zealand (Billings and Mark, 1961), the Yukon Territory, Canada (Hugenholtz and Lewkowicz, 2002), Iceland (Douglas and Harrison 1996), the Olympic Mountains of Washington, USA (Hansen-Bristow and Price, 1985), Norway (Matthews et al., 1998), and the Northern Rocky Mountains of Montana, USA (Butler and Malanson, 1989). Solifluction terraces typically consist of flat areas (i.e., treads) covered by coarse materials that are adjacent to sloped areas (i.e., risers) covered by fine materials (Washburn, 1980). In contrast, solifluction lobes have a characteristic curved, lobate form (Benedict, 1970). Both lobes and terraces occur parallel to slope contours and often cover entire hillslopes. When occurring in areas covered by tundra, the alternating areas of surficial materials may produce turf-banked terraces and/or turf-banked lobes as vegetation establishes on the exposed fine materials. Vegetation does not, however, typically establish on the stone-covered treads, probably in response to mechanical disturbance from needle ice activity and frost heaving (Butler et al., 2004; Douglas and Harrison, 1996). Turf-banked terraces and lobes may also form in areas of relic solifluction features that are no longer experiencing downslope movement.

A key factor distinguishing solifluction from other processes influencing the production of periglacial patterned ground is slope angle, as solifluction requires slopes sufficiently gradual to retain water and yet sufficiently steep to allow downslope gravitational movement of materials. Further contributing to this process is permafrost that limits infiltration of water, thereby facilitating saturated conditions. The relationship between slope angle and patterned ground is explored, for example, by Butler and Malanson (1989), who categorize pattern ground types in alpine areas of Glacier National Park, Montana, USA as polygons, turf-banked terraces, and larger terraces dominated by frost shattering. Of these types, solifluction is considered most important for turf-banked terraces that are observed in areas with slope angles ranging from 5 to 22 degrees. This finding concurs with observations from Iceland by Douglas and Harrison (1996), who identify solifluction as the source of downslope movement for turf-banked terraces found on slopes ranging from approximately 5–19°. Likewise, Hansen-Bristow and Price (1985) report on turf-banked terraces in Olympic National Park, Washington, USA, that are coincident with slopes ranging from 5° to 20°. Several other environmental factors are proposed as contributing to the maintenance and formation of solifluction forms. These include a continental climate regime (Hansen-Bristow and Price, 1985), a threshold depth of snow (Hugenholtz and Lewkowicz, 2002), terrace and lobe orientation in relation to prevailing wind and the spatially variable pattern of snow scouring and drifting (Billings and Mark, 1961; Selkirk, 1998; Hugenholtz and Lewkowicz, 2002), mean annual air temperature depth of ice lens formation, slope inclination (Matsuoka, 2001), and presence of permafrost (Butler and Malanson, 1989).

Examples from Glacier National Park, Montana, USA

Solifluction features are often found in association with vegetated surfaces, and these surfaces may play a role in the formation of soliflucted landforms. Vegetation has been found to increase the soil moisture content, prevent rapid downslope movement, insulate the ground surface against extreme temperature, thereby depressing the freezing point of the soil, retarding surface runoff (Hansen-Bristow and Price, 1985), and altering the effective soil depth and stoniness of the soil (Malanson et al., 2002). The relationship between solifluction features and vegetation is not unidirectional, as these features may produce advantageous conditions for distinct vegetation types. For example, Butler et al. (2004) describe exfoliation of turf-banked terrace risers as a source of micro alluvial fans, occurring on stone-covered treads, that serve as seedling establishment sites above the existing alpine treeline. Solifluction features may also encourage tree line advance by providing topographic shelter for seedling establishment (Resler et al., 2005).

Turf-banked terraces found in Glacier National Park, Montana, USA are well described in the literature and provide an illustrative example of solifluction feature characteristics. Figure 1 shows a broad area of solifluction treads and risers on Lee Ridge, Glacier National Park, Montana, USA; Figure 2 is a more localized view of the tread/riser complex in the same geographic area. Turf-banked terraces found in the Park have treads and risers that typically range from less than 1 m to several meters in width. These sites are usually found on slight elevation gradients, with the individual stripes oriented parallel to the contours of the slope. Rock treads are covered with a thin veneer of coarse clasts (i.e., pebbles and cobbles), ranging from 3 to 8 cm in depth, that are typically coated with small populations of lichens, indicating a relict condition (Butler and Malanson, 1989). In contrast, vegetated risers are dominated by sand, silt, and clay (Butler and Malanson, 1989), and are populated by a dense ground cover of alpine tundra flora that is principally comprised of *Dryas octopetala* in association with *Salix reticulata, Carex ruspetris, Korbresia myosuroides, Oxytropis sericea,* and

Solifluction, Figure 1 A regional view of solifluction steps and risers on Lee Ridge, Glacier National Park, Montana, USA.

Solifluction, Figure 2 A local view of solifluction steps and risers on Lee Ridge, Glacier National Park, Montana, USA.

Selaginella densa (Bamberg and Major, 1968). Bamberg and Major (1968) use a soil movement plot to conclude that *Dryas* terraces are stable even though some amount of movement is recorded. This finding is confirmed by Butler and Malanson (1989), who hypothesize that no movement has taken place in the turf-banked terraces since the harsher climate of the neoglacial period. More recently, spatial patterns of turf-banked terraces, and their association with terrain settings, are explored using spatial digital technologies and geostatistical analysis (Walsh et al., 2003a, b).

Summary

Solifluction is a common feature of alpine environments throughout the world. Characterized by turf-banked, terraces and lobes, freeze-thaw conditions, in concert with moderate slope angles, can produce broad landscapes of patterned ground composed of alternating sequences of steps and risers. Vegetation, soil moisture, soil stoniness and depth, cryoturbation, terrain configuration, and climate conditions are among the factors that contribute to the formation of solifluction and dictate its geographic distribution.

SOLUTE IN GLACIAL MELTWATERS

Martyn Tranter
Bristol Glaciology Centre, School of Geographical Sciences, University of Bristol, Bristol, UK

Introduction

Solutes in glacial meltwaters are generated by reactions that are comparable with other temperate and tropical latitudes, yet the factors controlling the production of solute are different. Factors controlling chemical weathering in other environments, such as the continual presence of water, soil, and vegetation (Drever, 2003), are not applicable to glacial environments, which are largely frozen for significant periods each year. The residence times of liquid water in glaciated catchments are often low (Knight, 1999), there are thin, skeletal soils at best, and vegetation is either absent or limited (French, 1996). However, glaciated catchments usually have high specific runoff, there are high concentrations of freshly comminuted rock flour, and adsorbed organic matter or surface precipitates that may hinder water-rock interactions are largely absent (Tranter, 2003). In short, the rapid flow of water over fine-grained, recently crushed, reactive mineral surfaces maximizes both the potential rates of chemical weathering and chemical erosion.

Composition of solutes

The chemical composition of glacial runoff from ice sheets, ice caps, and glaciers around the world is shown in Table 1 (after Brown, 2002; Tranter, 2003), which also includes the composition of global mean river water for comparative purposes. Sea salt, largely derived from marine aerosol, is a variable component of glacial runoff, and the dominant non-sea salt ions are Ca^{2+}–HCO_3^-–SO_4^{2-} – Mg^{2+}. The concentration of glacial runoff is usually inverse to discharge – hence low discharge waters are concentrated, whereas high discharge waters are dilute. The concentration of low discharge waters approaches ~1 meq/l (of positive charge) from smaller temperate, lower latitude glaciers, and ~3 meq/l for larger glaciers at higher latitudes. Glacial runoff is usually more dilute than global mean river water, and usually contains more K^+ and less Si for a given specific runoff (Anderson et al., 1997). The Ca^{2+}:Si and HCO_3^-:SO_4^{2-} ratio of glacial meltwaters are high and low, respectively, when compared with the principal world river waters, making glacial runoff an end member of global riverine water (Tranter, 2003). This is because glaciers preferentially weather carbonates and sulfides from the bedrock.

Glacial chemical weathering

The principal reactions that comminuted bedrock undergoes in glaciated terrain are summarized below, assuming that the bedrock is primarily composed of silicates and aluminosilicates.

Solute in Glacial Meltwaters, Table 1 The concentration of major ions in glacial runoff from different regions of the world (after Brown, 2002). Concentrations are reported in μeq/l

Region	Σ^+	Ca^{2+}	Mg^{2+}	Na^+	K^+	HCO_3^-	SO_4^{2-}	Cl^-	Source

(2002); 7: Raiswell and Thomas (1984); 8: Steinporsson and Oskarsson (1983); 9: Hasnain et al. (1989); 10: Brown (2002); 11: Collins (1979); 12: Thomas and Raiswell (1984); 13: Anderson et al. (2000); 14: Rasch et al., 2000; 15: Axtmann and Stallard, 1995; 16: Livingstone (1963)

Glacial comminution crushes bedrock and exposes the trace reactive components within crystalline aggregates more rapidly than would be the case in temperate and tropical soils, where new minerals are ultimately accessed via solubilization of the crystalline silicate lattices. Hence, glaciers are effective at solubilization of trace reactive components in the bedrock, which include carbonates, sulfides, and fluid inclusions. Laboratory experiments and direct sampling of waters from the glacier bed (Tranter et al., 1997, 2002) show that the initial reactions to occur when dilute snow and ice melt first access glacial flour are carbonate and silicate hydrolysis (Equations 1 and 2). These reactions raise the pH to high values (>9), lower the PCO_2 (to $\sim 10^{-6}$ atms), and maximize the water's potential to adsorb CO_2. Carbonate hydrolysis produces a solution with a Ca^{2+} concentration of ~200 μeq/l, with HCO_3^- the dominant anion.

$$\underset{\text{calcite}}{Ca_{1-x}(Mg_x)CO_3(s)} + H_2O(l) \leftrightarrow (1-x)Ca^{2+}(aq) + x\ Mg^{2+}(aq) + HCO_3^-(aq) + OH^-(aq) \quad (1)$$

$$\underset{\text{K-feldspar}}{KAlSi_3O_8(s)} + H_2O(l) \leftrightarrow \underset{\text{weathered feldspar surface}}{HAlSi_3O_8} + K^+(aq) + OH^-(aq) \quad (2)$$

The relatively dilute meltwater in contact with fine-grained glacial flour promotes the exchange of divalent ions from solution for monovalent ions on surface exchange sites. Hence, some of the Ca^{2+} and Mg^{2+} released from carbonate and silicate hydrolysis is exchanged for Na^+ and K^+.

$$\text{glacial flour} - Na_{(2-z)}, K_z(s) + (1-x)Ca^{2+}(aq) + x\ Mg^{2+}(aq) \leftrightarrow \text{glacial flour} - Ca_{(1-x)}, Mg_x(s) + (2-z)Na^+(aq) + zK^+(aq) \quad (3)$$

The high pH derived from hydrolysis enhances the dissolution of aluminosilicate lattices, since Al and Si become more soluble at pH > 9. Hydrolysis of carbonates results in a solution that is near saturation with calcite and aragonite. It is only in these types of waters that aluminosilicate dissolution is greater than carbonate dissolution. The influx of gases (including CO_2 and O_2), either from the atmosphere or from basal ice, and CO_2 produced by microbial respiration (see below) both lower the pH and the saturation with respect to carbonates. In addition, sulfide oxidation produces acidity (see below). Hence, almost all subglacial meltwaters are undersaturated with respect to calcium carbonate. The rapid dissolution kinetics of carbonates with respect to silicates means that carbonate dissolution continues to have a large impact on meltwater chemistry, despite carbonates being present often in only trace concentrations in the bedrock. For example, Haut Glacier d'Arolla has a bedrock, which is composed of metamorphic silicate rocks. Carbonates and sulfides are present in trace quantities in bedrock samples (0.00–0.58% and <0.005–0.71%, respectively). There are also occasional carbonate veins present in the schistose granite. Despite the bedrock being dominated by silicates, sulfide oxidation in subglacial environments dissolves carbonate to silicate in a ratio of ~5:1 (Tranter et al., 2002), compared to the global average of ~1.3:1 (Holland, 1978).

The acid hydrolysis of silicates and carbonates (Equations 4 and 5) that arises from the dissociation of CO_2 in solution is known as carbonation. Carbonation occurs in a restricted number of subglacial environments because ingress of atmospheric gases to these water-filled environments is restricted. It largely occurs in the major arterial channels at low flow, particularly near the terminus, and at the bottom of crevasses and moulins that reach the bed. Fine-grained sediment is flushed rapidly from these environments, and there is little time for the formation of secondary weathering products, such as clays, to form.

Hence, silicates dissolve incongruently, as crudely represented by Equation 4.

$$\underset{\text{anorthite}}{CaAl_2Si_2O_8(s)} + 2CO_2(aq) + 2H_2O(l) \leftrightarrow Ca^{2+}(aq) + 2HCO_3^-(aq) + \underset{\text{weathered feldspar surfaces}}{H_2Al_2Si_2O_8(s)} \quad (4)$$

$$\underset{\text{calcite}}{Ca_{1-x}(Mg_x)CO_3(s)} + CO_2(aq) + H_2O(l) \leftrightarrow (1-x)Ca^{2+}(aq) + xMg^{2+}(aq) + 2HCO_3(aq) \quad (5)$$

There is a limited body of evidence, which suggests that microbial oxidation of bedrock kerogen occurs (Wadham et al., 2004), and if this is the case, carbonation as a consequence of microbial respiration may occur in debris-rich environments, such as in the distributed drainage system and the channel marginal zone.

$$C_{org}(s) + O_2(aq) + H_2O(l) || CO_2(aq) + H_2O(l) \leftrightarrow H^+(aq) + HCO_3^-(aq) \quad (6)$$

The dominant reaction in subglacial environments is sulfide oxidation, since, following hydrolysis, this is the major reaction that provides protons to solution, so lowering the pH, decreasing the saturation index of carbonates, so allowing more carbonate dissolution (Equation 7). Sulfide oxidation occurs predominantly in debris-rich environments where comminuted bedrock is first in contact with water. It is microbially mediated, occurring several orders of magnitude faster than in sterile systems (Sharp et al., 1999). It consumes oxygen, driving down the pO_2 of the water.

$$\underset{\text{pyrite}}{4FeS_2(s)} + 16Ca_{1-x}(Mg_x)CO_3(s) + 15O_2(aq) + 14H_2O(l) \leftrightarrow 16(1-x)Ca^{2+}(aq) + 16xMg^{2+}(aq) + 16HCO_3^-(aq) + 8SO_4^{2-}(aq) + \underset{\text{ferric oxyhydroxides}}{4Fe(OH)_3(s)} \quad (7)$$

Earlier studies suggested that the limit on sulfide oxidation was the oxygen content of supraglacial melt, since subglacial supplies of oxygen are limited to that released from bubbles in the ice during regelation, the process of basal ice melting and refreezing as it flows around bedrock obstacles. However, studies of water samples from boreholes drilled to the glacier bed show that the SO_4^{2-} concentrations may be two or three times that allowed by the oxygen content of supraglacial meltwaters (Tranter et al., 2002). This suggests that oxidizing agents other than oxygen are present at the glacier bed. It seems very likely that microbially mediated sulfide oxidation drives certain sectors of the bed towards anoxia, and that in these anoxic conditions, Fe(III), rather than O_2, is used as an oxidizing agent (Equation 8). Sources of Fe(III) include the products of the oxidation of pyrite and other Fe(II) silicates in a previous oxic environment, as well as that found in magnetite and hematite.

$$FeS_2(s) + 14Fe^{3+}(aq) + 8H_2O(l) \leftrightarrow 15Fe^{2+}(aq) + 2SO_4^{2-}(aq) + 16H^+(aq) \quad (8)$$

Support for anoxia within subglacial environments comes from the $\delta^{18}O$–SO_4, which is enriched in ^{16}O when sulfide is oxidized in the absence of oxygen (Bottrell and Tranter, 2002).

The realization that there is microbial mediation of certain chemical weathering reactions in subglacial environments (Sharp et al., 1999; Skidmore et al., 2000; Bottrell and Tranter, 2002) has resulted in a paradigm shift, since the types of reactions that may occur in anoxic sectors of the bed include the common redox reactions that occur, for instance, in lake or marine sediments (Drever, 1988). A key difference in glacial systems is that the supply of new or recent organic matter is limited to that inwashed from the glacier surface, such as algae, insects and animal faces, or overridden soils during glacier advance. By contrast, the supply of old organic matter from comminuted rocks is plentiful. Given the thermodynamic instability of organic matter in the presence of O_2 or SO_4^{2-}, it seems likely that microbes will have evolved to colonize subglacial environments and utilize kerogen as an energy source. The first data to support this assertion is stable isotope analysis from Finsterwalderbreen, a small polythermal-based glacier on Svalbard, which has shale as a significant component of its bedrock (Wadham et al., 2004). The $\delta^{18}O$–SO_4 of waters upwelling from subglacial sediments are very enriched in $\delta^{18}O$, and the $\delta^{34}S$ is enriched in ^{34}S, which suggests that cyclical sulfate reduction and oxidation has been occurring. The $\delta^{13}C$ of DIC (dissolved inorganic carbon) is negative, consistent with the assertion that organic matter has been oxidized. Mass balance calculations suggest that a possible source of organic matter is kerogen, but the necromass of dead bacteria cannot be discounted. Whatever is the source of organic matter, sectors of the bed at Finsterwalderbreen are so anoxic that sulfate reduction is occurring (Equation 9).

$$\underset{\text{organic carbon}}{2CH_2O(s)} + SO_4^{2-}(aq) \leftrightarrow 2HCO_3^-(aq) + H_2S(aq) \quad (9)$$

It is possible that methanogenesis occurs under certain ice masses, since methanogens have been isolated from subglacial debris (Skidmore et al., 2000). The low $\delta^{13}C$–CH_4 and high concentration of methane found in gas bubbles within the basal ice of the Greenland Ice Sheet are consistent with there being methanogenesis within the basal organic-rich paleosols.

To date, there are few studies of glacial chemical weathering on bedrock with a significant evaporitic content. Work at John Evans Glacier in the Canadian High Arctic has shown that gypsum is dissolved in some areas of the bed, and that mixing of relatively concentrated Ca^{2+}–SO_4^{2-} waters with more dilute Ca^{2+}–HCO_3^-–SO_4^{2-} waters results in $CaCO_3$ precipitation due to the common ion effect (Skidmore (U. Montana) personal communication, 2010).

A key feature of the above chemical weathering scenarios is that relatively little atmospheric or biogenic CO_2 is involved. Hence, whereas ~23% and ~77% of solutes, excluding recycled sea salt, found in global mean river water is derived from the atmosphere and rock, respectively (Holland, 1978), atmospheric sources account for a maximum of 3–11% of solute in glacial runoff (after Hodson et al., 2000).

SOLUTES IN GLACIER ICE

Renoj Thayyen
Western Himalayan Regional Centre, National Institute of Hydrology, Jammu (J&K), India

Source

Dissolved ions (solute) in the glacier ice are mainly derived from the atmosphere by means of deposition of atmospheric particles on the glacier through precipitation. The deposition of atmospheric particle on the glacier is roughly proportional to their concentration in the atmosphere. Direct deposition of dust particles on the glacier, especially in the accumulation zone is also a major source

of solute in the glacier. At the subglacial zone of the glacier, solute entrainment happens in association with the relegation processes.

Processes

After the deposition in the accumulation zone of the glacier chemical constituents in the snowpack undergo various changes during the freeze thaw cycles. Preferential releases of ionic species from the snowpack occur during the densification processes. Impurities reach the ice grain boundary during recrystallization and reject most of the impurities to meltwater and the new ice formed will be purer. Solute concentration and its characteristics in the glacier ice with respect to the original solute characteristics of the snowpack are determined by the densification environment of the glacier. Glacier ice formation in subzero temperature ensures preservation of snowpack chemical characteristics to a great extent whereas in warmer climate, solute concentration in glacier ice undergoes major changes due to preferential elution processes.

Use

Atmospheric particle or aerosols originate from a variety of natural and manmade sources and chemical compositions of ice core provide good information on atmospheric particulate loading at the time of deposition and act as a good source of information for climate change studies. Radioactive isotopes derived from nuclear or volcanic activity is a very good time marker in the glacier ice.

SPECIFIC MELT RATE

Pratap Singh
Tahal Consulting Engineers Ltd, New Delhi, India

The specific melt rate represents the melt rate over unit area and is represented in the unit of mm/day. Prevailing weather condition in a particular area has a control on the specific melt rate. Specific melt rate of snow/ice can be determined by allowing a small block of snow/ice to melt under natural weather conditions and observing the melt runoff and weather condition. Specific melt rate can be computed using energy balance approach or using temperature index approach. In general, empirical relationships are established between specific melt rate and mean daily temperature. The specific melt rate of glaciers ice is higher than that of snow due to lower albedo of ice. While computing the runoff from a snowfed or glacier fed basin, first specific melt rate is estimated and then runoff is derived by multiplying it with the representative area.

STABLE ISOTOPES

Bhishm Kumar
Hydrological Investigation Division, National Institute of Hydrology, Roorkee, Uttarakhand, India

The atoms of an element that do not decay with time or take infinite time to decay are called stable isotopes of that element (See *Oxygen Isotopes* and *Hydrogen Isotopes*).

Stable Isotopes, Table 1 Stable isotopes with their isotope ratio, abundance and commonly measured phases

Isotope	Ratio	% Natural Abundance	Reference (abundance ratio)	Commonly measured phases
^{2}H	$^{2}H/^{1}H$	0.015	VSMOW (1.5575×10^{-4})	H_2O, CH_2O, CH_4, H_2, OH^- minerals
^{3}He	$^{3}He/^{4}He$	0.000138	Atmospheric He (1.3×10^{-6})	He in water or gas, crustal fluids, basalt
^{6}Li	$^{6}Li/^{7}Li$	7.5	L-SVEC (8.32×10^{-2})	Saline waters, rocks
^{11}B	$^{11}B/^{10}B$	80.1	NBS 951 (4.04362)	Saline waters, clays, borate, rocks
^{13}C	$^{13}C/^{12}C$	1.11	VPDB (1.1237×10^{-2})	CO_2, carbonate, DIC, CH_4, organics
^{15}N	$^{15}N/^{14}N$	0.366	AIR N_2 (3.677×10^{-3})	N^2, NH_4^+, NO_3^-, N-organics
^{18}O	$^{18}O/^{16}O$	0.204	VSMOW (2.0052×10^{-3}) VPDB (2.0672×10^{-3})	H_2O,CH_2O,CO_2, sulfates NO_3^-, carbonates, silicates OH^- minerals
^{34}S	$^{34}S/^{32}S$	4.21	CDT (4.5005×10^{-3})	Sulfates, sulfides, H_2S, S-organics
^{37}Cl	$^{37}Cl/^{35}Cl$	24.23	SMOC (0.324)	Saline waters, rocks, evaporates, solvents
^{81}Br	$^{81}Br/^{79}Br$	49.31	SMOB	Developmental for saline waters
^{87}Sr	$^{87}Sr/^{86}Sr$	$^{87}Sr = 7.0$ $^{86}Sr = 9.86$	Absolute ratio measured	Water, carbonates, sulfates, feldspar

Over 2000 isotopes of 92 naturally occurring elements have been identified out of which several hundred are stable isotopes. But for hydrological investigations, we talk much about hydrogen and oxygen stable isotopes. As we know water molecule is made up of two hydrogen atoms and one oxygen atom therefore, many combinations (18) are possible out of which $^{1}H^{1}H^{16}O$, $^{1}HD^{16}O$, $HD^{18}O$, $^{1}H^{1}H^{17}O$, and $^{1}HD^{17}O$ are important. The stable isotopes with their isotope ratio, abundance, and commonly measured phases are listed in Table 1 (Clark and Fritz, 1997).

STAGE-DISCHARGE RELATIONSHIP

Amit Kumar
Centre of Advanced Study in Geology, Department of Geology, Punjab University, Chandigarh, India

Synonyms

Rating curve

Definition

The relationship between the amount of water flowing in a river or stream and stage at any particular point is usually known as stage–discharge relationship. Stage–discharge relationships for flow in rivers and channels are established by concurrent measurements of stage (y) and discharge (Q) (through velocity measurements, dilution methods, or other techniques) and the results are fitted graphically or statistically to yield the development of rating curves. The dynamic relationship between stage and discharge, which is unique to a particular selected station along the river, can be determined via mathematical relationships.

Introduction

Hydrologists, watershed managers are often interested in estimating stream discharge. Discharge is the flow rate of water passing a point on a stream at an instant in time; therefore, continuous flow measurement of river discharge is a hard and expensive task in hydrology. To overcome this problem, the stage reading at hydrometric gauges are permanently taken and the discharge of any time at which the actual discharge is unavailable will be estimated through a developed relationship between discharge and stage. To study the stage–discharge relation and the capability of long-term data in establishing a permanent stage–discharge relationship, and also to determine the best time to measure the discharge of rivers. More accurate values for discharge can be obtained when a permanent gauging station has been established on a stretch of a river where there is a stable relationship between stage and discharge, and this has been measured and recorded. Once this relationship is established, readings need only be taken of stage, because the discharge may then be read from a stage–discharge curve.

Stage–discharge relationship

Hydrological studies relied on stage–discharge relationships to monitor discharge in shallow streams of all depths. Hydrologists would typically get on a time-intensive program to rate a stream using a current meter to measure instantaneous discharge against several different stage events and a rating curve was developed. The stage–discharge relationship is based upon the relationship between stream water depth (stage) and discharge at a cross section. The relationship will be different for every cross section, and will change at a cross section as the cross section changes through time (aggrades or degrades).

The first step is to identify a permanent cross section. The cross section should be in a stable portion of the stream where the intensity of erosion and deposition is less. The second step is to install a stage staff or depth meter in the channel/well at the cross section. The stage staff must be fixed and permanent. Its stability and the cross section are crucial for developing a meaningful stage–discharge relationship. In the next step, the area of cross section of the river at a gauging site and the velocity of flow through the cross-sectional area are to be measured. The applied method at the cross section to estimate discharge over a wide range of value of discharge (low flow to peak flow) is known as area–velocity method. After enough observations, a stage–discharge relationship (equation) can be developed to correlate stage and discharge. Once the stage–discharge relationship is developed, discharge can be computed directly by only monitoring of the water level at the cross section over time. The extrapolation of computed values must be under the range of discharge used to develop such relationships.

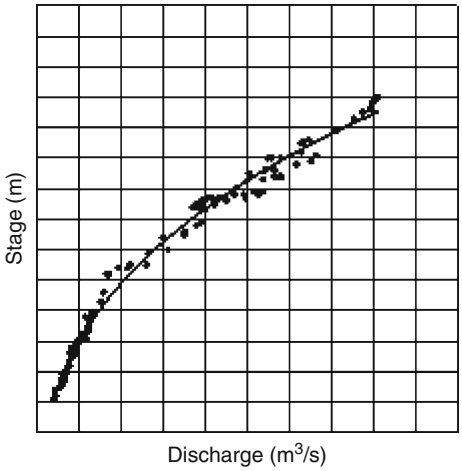
If such relationship for a gauging station is and does not change with time constant, the control is said to be permanent. If it changes with time, it is called shifting control.

When measured value of stage and discharge are plotted on arithmetic paper, the result is an approximate parabolic curve, as shown in Figure 1. The curve can be expressed as

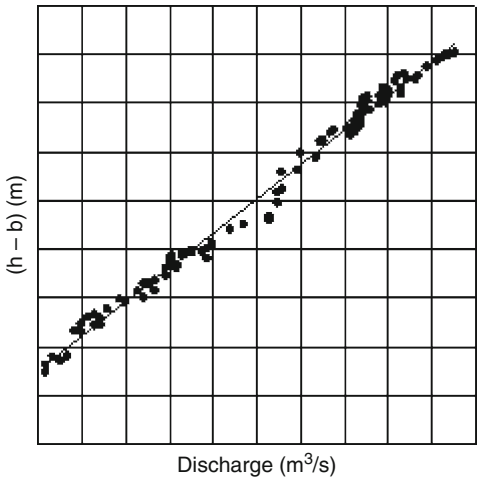
$$Q = a(h - h_0)^b \tag{1}$$

In which h_0 is a constant, representing the gauge reading for zero discharge, and a and b are rating curve constant. This relationship can also be expressed graphically by plotting the observed stage against corresponding discharge values in logarithmic paper, the plot is straight line, as shown in Figure 2. The equation becomes

$$\log Q = \log a + b \log(h - h_0) \tag{2}$$



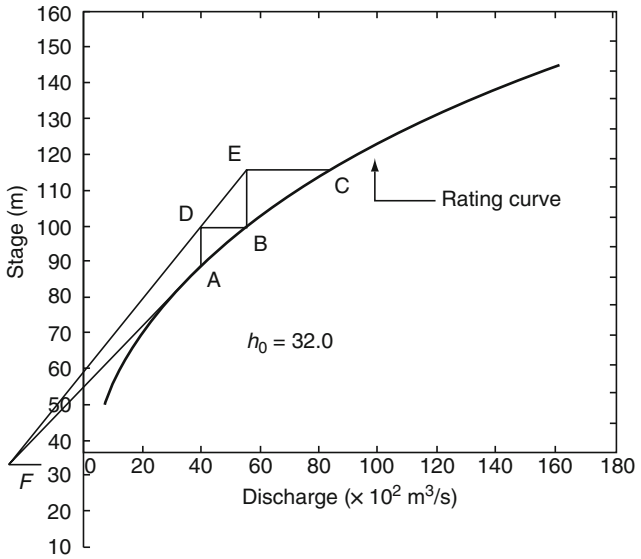
Stage-Discharge Relationship, Figure 1 Stage–discharge relationship curve (*arithmetic plot*).



Stage-Discharge Relationship, Figure 2 Stage–discharge relationship curves (*logarithmic plot*).

The best value of constants a and b can be obtained using the least square method; however, constant h_0 must be found beforehand, and this can be estimated in several ways. A trial-and -error method can be used to yield h_0, which then gives the best-fit curve. Another way is to extrapolate the rating curve corresponding to $Q = 0$ and then plot log Q versus log $(h–h_0)$. If the plot is the straight line, then the value of h_0 obtained by extrapolation is acceptable. Otherwise, another value in the neighborhood of the previous value of h_0 is selected and the procedure is repeated.

A graphical method to determine h_0 has been reported by running (Wisler and Brater, 1959). According to this method, Q and h are plotted on arithmetic scale and a



Stage-Discharge Relationship, Figure 3 Running's method for estimation of constant h_0.

smooth curve is drawn through plotted points. In Figure 3, three points, A, B, and C, are selected in such a way that their geometric progression is as follows.

$$\frac{Q_A}{Q} = \frac{Q_B}{Q} \tag{3}$$

The vertical lines are drawn at A and B, and horizontal lines drawn at B and C. Thus, D and E are obtained as intersection points with verticals. Two straight lines are drawn through E and D, and stage–discharge curve is assumed to be a parabola in this method.

Another method of computing h_0 is analytical. From a smooth curve of Q versus h, three values of discharge, Q_1, Q_2, and Q_3, are selected such that $Q_1/Q_2 = Q_2/Q_1$. The corresponding values of stage are h_1, h_2, and h_3. Then, using equation

$$\frac{(h_1 - h_0)^b}{(h_2 - h_0)^b} = \frac{(h_2 - h_0)^b}{(h_3 - h_0)^b} \tag{4}$$

$$\frac{(h_1 - h_0)}{(h_2 - h_0)} = \frac{(h_2 - h_0)}{(h_3 - h_0)} \tag{5}$$

$$h_0 = \frac{h_1 h_3 - {h_2}^2}{h_1 + h_3 - 2h_2} \tag{6}$$

Alternatively, all three parameters, a, b, and h_0, can be obtained by optimization.

The simple rating curve is generally satisfactory for a majority of streams where rapid fluctuation of stage is not experienced at gauging section. The adequacy of the curve is measured by the scatter of data around fitted

curve. When there is a permanent control, the rating curve is essentially permanent. If the rating curve is made using a range of stages from low to high, it can be used to interpolate the discharge for any stage of flow between the measured stages without measuring that flow. It is important to check the stability of the curve by parabolic discharge measurement, and to extend it with each new observed high stage. Changes in channel shape, due to scouring or sedimentation, can change the effect of control and thereby change the rating curve.

For some gauging stations, there may be two or more control each for a particular range of stage. The rating curve for such a station is discontinuous; the point of discontinuity corresponds to the stage reflecting the change in control. An example is the start of submergence of a weir control when the tail water level below the control rises above the lowest point of the control. Even under such conditions, the simple rating curve may be satisfactory if the control is permanent, free of backwater, and the stream slope is steep.

Summary

There have been a number of developments in recent years that have resulted in new and better estimation of stage and discharge relationships. Many types of equipments for both instantaneous measurements of flow and full-time monitoring of ungauged river were to be used for discharge measurements. Discharge is important for the hydrologic studies, considerable efforts to be made to collect this data as WMO recommended norms, by developing number of hygrometry stations in various geographical locations.

STATIONARY GLACIER

Renoj Thayyen
Western Himalayan Regional Centre, National Institute of Hydrology, Jammu (J&K), India

Synonyms

Standstill glacier

When horizontal velocity component of a glacier equals the horizontal component of ablation, glacier terminus remains stationery (Boulton, 1986). Glacier margins advance, retreat, or remain stationery in response to the variations in glacier mass balance. Frontal margins of the glacier will remain at same position when $U_{hx} = a_b/\tan \alpha$, where U_{hx} is the horizontal velocity component, a_b is the ablation rate, and α is the glacier surface slope. ($a_b/\tan \alpha$) constitute the horizontal component of ablation. While the position of the glacier termini is stationery, glacier ice itself is in motion but removed from the terminus region at a rate equal to the velocity.

STRATIGRAPHY OF SNOWPACKS

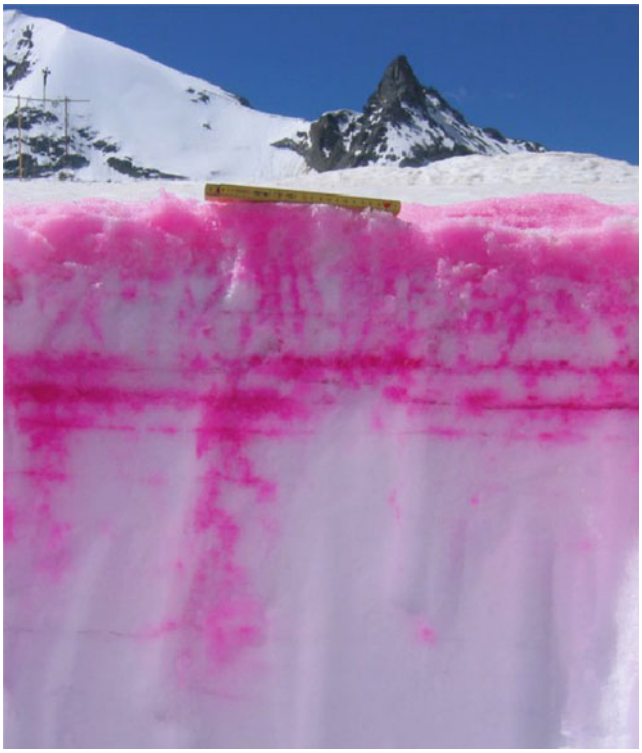
Peter W. Nienow[1], Fay Campbell[2]
[1]School of Geosciences, University of Edinburgh, Edinburgh, UK
[2]Department of Geographical and Earth Sciences, University of Glasgow, Glasgow, UK

Definition

Snowpack stratigraphy. Snowpacks are often characterized by a number of distinctive "stratigraphic" layers in which the properties of the snow vary vertically in terms of density, crystal shape, grain size, and hardness. These individual layers when combined make up the stratigraphy of a snowpack.

Introduction

Any snowpack, whether of a seasonal or multi-year duration, will develop a layered structure (Figure 1) during its formation which will evolve through time. Each layer is formed by the deposition of falling snow, the redistribution of windblown snow, or a combination of these two processes. The initial snowpack is subsequently modified by compaction and thermal metamorphic processes resulting in the gradual densification of the snowpack. Surface melting, percolation, and under certain conditions, refreezing of meltwaters further modifies the snowpack and enhances the rate of densification. Snowpacks are typically heterogeneous with each layer varying in terms of density, crystal shape and grain size with subsequent implications for both porosity and permeability. An understanding of snowpack stratigraphy is important because the complex structure of an individual snowpack affects: (1) its stability, and therefore propensity to fail catastrophically in an avalanche; and (2) the snowpack hydrology (qv *Temperature Profile of Snowpack*) and therefore the rate at which meltwater is released from a given snowpack with implications for the runoff characteristics from snow-covered catchments. Snowpack



Stratigraphy of Snowpacks, Figure 1 Layered snowpack stratigraphy as revealed in a snow-pit, excavated 1½ h after a dye injection on the snowpack surface at Haut Glacier d'Arolla, Switzerland on 27 June 2004. The ruler at the surface is 20 cm long. (Photo: F. Campbell).

stratigraphy has traditionally been investigated in situ through the excavation of snow-pits and detailed vertical sampling of the snow characteristics of the walls therein (Fierz et al., 2009). More recently, numerical models have been developed to simulate the evolution of snowpack stratigraphy and stability (e.g., Brun et al., 1992; Jordan, 1991; Lehning et al., 2002).

Physical properties of the snowpack

The physical properties of the seasonal snowpack are controlled by processes operating on the snow during its formation in the atmosphere, deposition on the ground, and time on the ground. A thorough understanding of the processes of snowcover formation is therefore critical for understanding how the stratigraphy of a snowpack develops and evolves through time. More comprehensive discussions of snowpack development, characteristics, and processes from deposition to melt are provided by Male (1980), Marsh (2005), Lehning et al. (2002) and Pielmeier and Schneebeli (2003); a summary of those aspects most relevant to snowpack stratigraphy is given here.

Snowpack formation and evolution: dry snow processes

Snow Crystals (qv) forming in the atmosphere take on a range of sizes and a diverse variety of forms depending on the temperature and humidity of the atmosphere at the time of their formation and as they fall to the ground (Male, 1980). Crystal size and shape may be altered by wind action both as snowflakes fall to the ground and once deposited, with *Grains* (qv) broken and abraded into more equidimensional particles (Male, 1980).

As the seasonal snowpack is typically deposited by a series of winter storms, a characteristic layered (qv *Snow Layer*) structure develops, with varying layer properties depending initially on the conditions under which the snow was deposited. Between storms, the snowpack surface may be modified by freezing rain, packing by wind action, or surface melting and refreezing, resulting in the formation of thin, high-density layers which subsequently separate snow strata (Male, 1980). These "ice" layers, though rarely of solid ice, are relatively impermeable compared to the lower density and more permeable snow strata, and play an important role in controlling the physical properties of the snowpack, especially with respect to *Snow Hydrology* (qv) (Colbeck, 1975a; Campbell et al., 2006; Figure 1).

Once on the ground, snowflakes undergo a rapid *Snow Metamorphism* (qv) driven by water vapor gradients between convex and concave surfaces, allowing the snowpack to assume a lower energy state by reducing its total surface area relative to mass. In this process, known as equilibrium growth or equi-temperature metamorphism due to the small temperature gradients under which it takes place (Sommerfeld and LaChappelle, 1970), snowflakes and broken particles can be reduced to more spherical snow grains in a matter of days, and smaller grains melt and disappear as larger grains grow. In this way, grains may attain a diameter of up to 1 mm even while still below 0°C, and the rounding of grains can allow an increase in *Snow Density* (qv) to between 580 and 600 kg m^{-3} (Sommerfeld and LaChappelle, 1970), compared to only 50–70 kg m^{-3} for new snow deposited under calm conditions (Paterson, 1994).

If the snowpack is subject to a temperature gradient, the resulting movement of water vapor between grains that are at different temperatures drives kinetic growth metamorphism, producing characteristic faceted grains known as surface and depth hoar. More detailed information about the processes of equilibrium growth and kinetic growth metamorphism can be found in Sommerfeld and LaChappelle (1970) and Male (1980).

As metamorphism proceeds, the breaking up and rounding of dendritic particles is accompanied by the formation of bonds at points of contact between grains. This process, known as sintering, leads to an increase in snow density and strength. The snowpack, previously a matrix of single crystal or polycrystalline ice grains, becomes a complex three-dimensional network of connected particles (Male, 1980).

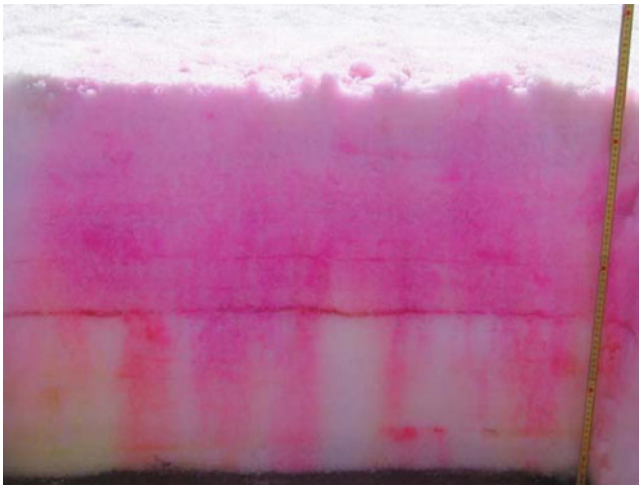
Snowpack formation and evolution: the metamorphism of wet snow

When liquid water is first introduced into the snowpack, it initiates a rapid metamorphism, whereby small ice grains are eliminated while larger grains grow rapidly until they reach diameters of 1–2 mm, with important implications for subsequent snowpack strength and hydrology (qv *Snow Hydrology*; *Stratigraphy of Snowpacks*). A thermodynamic analysis of the relationship between grain size and phase equilibrium temperature (Colbeck, 1975b) shows that this process can be understood as the result of differences in the melting temperature of small and large grains caused by the difference in their radii of curvature. Due to their smaller radius of curvature, melting temperature is higher for large grains than for small, and larger grains therefore exist at a higher temperature than smaller grains. This temperature difference drives heat flow by conduction toward the smaller grains. As a result, smaller grains decrease in size and eventually disappear, while larger grains increase in size, conserving the total mass.

The diverse grain forms found in both dry and wet snow at various stages of development are brought together by Fierz et al. (2009) in the International Classification for Seasonal Snow on the Ground. While primarily based on grain morphology, the scheme includes valuable information about the physical processes that lead to different grain types.

Snowpack structure

Metamorphism (qv *Snow Metamorphism*) of the snowpack through both dry and wet processes alters the initial snowpack stratigraphy and ensures that snowpack structure is continuously evolving following the initial deposition of falling or redistributed windblown snow. Investigations of snowpack stratigraphy, through snowpit studies (Fierz et al., 2009), typically reveal a horizontally layered structure in which crystal size, shape, and density vary with depth. These horizontal layers affect the permeability of the snowpack with implications for the transfer of surface meltwaters or liquid precipitation down through the snowpack (Figures 1 and 2). Where percolating meltwaters refreeze at depth, ice layers and ice lenses form. These layers may be spatially extensive where the boundary between two different stratigraphic units within the snowpack is consistent over long horizontal length scales (Pfeffer and Humphrey, 1998). If however the snowpack is characterized by a complex stratigraphy and snowpack permeability with numerous undulating stratigraphic boundaries, often due to the presence of sastrugi and windcrusts, the ice layers will rarely be spatially continuous even at short length scales of <1 m (Parry et al., 2007). The horizontal nature of the snowpack stratigraphy is disrupted by the downward percolation of water, which has been observed to percolate through both arctic and temperate snowpacks, via preferential flow-fingers or pipes (Figure 2) which occupy only a fraction of total snowpack volume but transmit a large proportion of flow (Marsh and Woo, 1984).



Stratigraphy of Snowpacks, Figure 2 The pattern of percolation as revealed by dye-stained surface meltwater in an excavated snow-pit 2½ h after a dye injection on the snowpack surface at Haut Glacier d'Arolla, Switzerland on 25 July 2004. An ice layer, 30 cm above the glacier surface, retains dye above it allowing continued downward flow through preferential flow-fingers. (Photo: F. Campbell).

The characteristic horizontal layering within a snowpack will affect the strength of the snowpack with implications for snowpack failure and avalanches. For example, the presence of a weakly bonded hoar layer within the snowpack provides a potential failure plane that will shear easily thus promoting the likelihood of an avalanche. As a result, avalanche forecasting is highly dependent on knowledge both of the in situ snowpack stratigraphy and our ability to predict, using models, how snowpack structure (and thus strength) will change through time (Lehning et al., 2002).

Modeling snowpack structure

The physical processes governing snow temperature evolution, grain metamorphism, densification, surface melt, and water transport have been brought together to produce comprehensive snow process models to simulate the energy and mass evolution of a snowpack through time given surface meteorological conditions. Well-established models include CROCUS, developed by the French national meteorological service (Brun et al., 1992), SNTHERM, from the US Army Corps of Engineers Cold Regions Research and Engineering Laboratory (CRREL) (Jordan, 1991), and the Swiss Federal Institute for Snow and Avalanche Research's SNOWPACK (Lehning et al., 2002). In the case of both CROCUS and SNOWPACK, the need for accurate snow stability information for avalanche warning purposes provided the impetus for detailed snowpack modeling, with SNOWPACK in particular including detailed information about snow microstructure

and resulting mechanical stability (Lehning et al., 2002). Advances in numerical modeling and the importance of effective prediction of snowpack stability ensure that investigations of snowpack stratigraphy will continue to be a well-researched area of snow science.

Summary

The processes that are responsible for the development of a snowpack ensure that it is characterized by internal "stratigraphic" layers in which the physical properties such as grain size, crystal type, density, and moisture content vary. Following the initiation of a snowpack as a result of snowfall or redistributed windblown snow, the stratigraphy of the snowpack continuously evolves due to physical compaction and the processes of both dry and wet-snow metamorphism. A detailed physical understanding of the processes that control snowpack stratigraphy is important because its complex structure affects: (1) the stability of the snowpack and its likelihood to fail as an avalanche; and (2) the permeability of the snowpack and the rate at which meltwaters are released from a given snowcover. There are numerous ways to characterize and investigate snowpacks as described in a detailed historical review on "Developments in the Stratigraphy of Snow" by Pielmeier and Schneebeli (2003). In recent decades, developments in both computational power and of the detailed understanding of snowpack processes has resulted in advances, through numerical modeling, in the simulation of the evolution of snowpack stratigraphy and stability (e.g., Brun et al., 1992; Jordan, 1991; Lehning et al., 2002).

STREAMFLOW TRENDS IN MOUNTAINOUS REGIONS

Peter Molnar, Paolo Burlando, Francesca Pellicciotti
Institute of Environmental Engineering, ETH Zurich, Zurich, Switzerland

Definition

Streamflow is a hydrological variable measured at a defined river cross-section; it spatially integrates the runoff generating processes in the contributing watershed, including precipitation and air temperature. *Trends in streamflow* are progressive changes in the time series of streamflow that can be detected with *statistical methods* and their statistical significance can be assessed. Mountainous regions are particularly vulnerable to streamflow change because of their high specific runoff and the sensitivity to the distribution of precipitation and air temperature, and the processes of snow accumulation and melt.

Introduction

In the context of *climate change*, precipitation and temperature changes potentially have severe impacts on runoff in mountainous regions where the snowpack, glaciers, and small ice caps play a crucial role in runoff formation.

IPCC (2007) projects that widespread mass losses from glaciers and reductions in snow cover over recent decades will accelerate into the twenty-first century, reducing water availability, hydropower potential, and changing seasonality of flows in regions supplied by meltwater from major mountain ranges. It is therefore important to use statistical methods to detect gradual changes (trends) in streamflow from instrumental records and to attribute these changes to their possible causes.

In most cases, the *attribution* of discovered trends in streamflow to their causes is difficult. Because streamflow measurements integrate the runoff generating processes in the upstream watershed, they reflect not only the seasonal variability in precipitation and temperature, but also the variability in land surface properties (vegetation, soil, topographic characteristics such as slope and aspect, rock cover, glaciers, etc.). The existence of statistically significant trends in streamflow together with other hydroclimatic variables like precipitation and air temperature are an indication but not proof of causality. Only detailed knowledge about the physical processes of runoff formation in the tested basin can provide conclusive evidence.

In mountainous regions, there are additional issues related to *snow and ice*. Precipitation in winter builds the snowpack and contributes to streamflow in the following spring and summer seasons during snowmelt. The effect of temperature changes on the snowpack is therefore crucial for understanding streamflow trends (e.g., Stewart, 2009). Glacier change itself may result in both increasing or decreasing trends in streamflow during a warming trend, depending on the glacier mass balance (e.g., Huss et al., 2008). In the short-term, warming can lead to increased glacier runoff (e.g., Pellicciotti et al., 2010), while in the long-term, glacier recession can decrease the glacier mass to the point where a reduction in glacier runoff can result (e.g., Stahl and Moore, 2006).

An important element in any hydroclimatic trend detection is the choice of the *time period* over which data are tested. Hydroclimatic data generally exhibit variabilities at both short and long timescales. The time period is related to the purpose of the testing and should be chosen carefully so that discovered trends are not attributed erroneously to external factors when in fact they could be part of the natural long-term periodicity (e.g., Cohn and Lins, 2005; Laternser and Schneebeli, 2003). Furthermore, if trends in several variables are to be compared, it is fundamental that the time period is the same for all tested variables.

Methods

Several statistical tests for detecting changes in statistical properties of time series exist. Here, we focus only on the most common ones used in studies of gradual change (i.e., trends not jumps) in hydroclimatic data from the recent literature, with a special focus on streamflow. The details of the tests can be found in any statistical textbook, Helsel and Hirsch (1992) is recommended. Streamflow trend testing consists of four basic steps (Table 1).

Exploratory data analysis

In data preparation, attention should be paid to the type and resolution of data used. It is important to test streamflow for trends at several temporal resolutions. Daily data can indicate shifts in the distribution of streamflow, for example, the frequency of low and high flows (e.g., Birsan et al., 2005), while monthly and seasonal data can indicate the presence of seasonal shifts in the runoff regime, for example, the timing of spring snowmelt (e.g., Zhang et al., 2001). If daily data are available, it is advisable to study trends in quantiles Q_p, that is, daily flows exceeded with a frequency 1-p, for a range of p including minima and maxima on a seasonal basis. This gives an indication of shifts in the distributions of streamflow. Several time periods T should be tested, analyses could also be conducted on moving windows to identify more precisely in time when maximum change occurs (see Pellicciotti et al., 2010, for an effect of different time windows on trend detection). It is important to choose basins that are undisturbed, so that anthropogenic effects such as flow regulation, which are common in some mountain basins used for hydropower production, are ruled out.

Trend computation methods

The objective of testing is to compute a test statistic that quantifies the trend present in the data. In streamflow trend testing, there is a preference for nonparametric methods because the underlying distributions of the data are not known and are often non-normal. The four most common tests are listed in Table 1. Linear regression (LR) and Sen's robust slope estimator (SEN) estimate the magnitude of the trend slope b, which is useful when the magnitude of change itself is of importance. LR should be used only if the trend is linear. The Mann-Kendall (MK) test computes the test static Z and the Spearman rank correlation (RC) the test statistic t. These two tests have similar power and both are nonparametric methods not sensitive to outliers. The MK test is the most widely used test in the literature and is recommended for hydroclimatic data. It is distribution-free and captures linear and nonlinear monotonic trends. However, it is advisable to use more than one test in any trend detection study.

Testing statistical significance

At each site, the computed test statistic (b, Z, t) needs to be tested for its significance. The null hypothesis H_0 of no trend ($b = 0$, $Z = 0$, $t = 0$) is rejected at a chosen significance level α based on the computed test statistic and its distribution. For LR and SEN, the t-ratio is computed and tested with the Student's t distribution, for MK the test statistic Z is tested with the standard normal distribution, for RC the Student's t distribution may be used. In general if the test statistic, e.g., $|Z| > Z_{crit}(1 - \alpha/2)$ for a two-tailed

test, then H_0 is rejected and it is concluded that the detected trend is statistically significant, that is, it is not likely to be due to random fluctuations, with the probability α of being wrong (Type I error). Sometimes a p-value is reported, that is, the probability that the computed test statistic would occur provided H_0 is true, values of $p < \alpha$ are statistically significant. Commonly used significance levels are $\alpha = 0.05, 0.1$. The power of a test is the test's ability to detect a trend when it really exists. The power is high when the detection error (Type II error) is low. The critical significance levels of the test statistics are affected by serial (auto) correlation in the data. Several methods have been developed to account for this (Table 1), details can be found in the review by Khaliq et al. (2009). The most commonly used method is the Trend-free prewhitening approach (Yue et al., 2002). Serial correlation is not likely to be high in inter-annual hydrological data, however it is advisable to compute the serial correlation coefficient for raw and detrended data to check if it is significantly $\rho > 0$. If serial correlation is an issue, variance correction and resampling methods have been found to perform well. In spatial studies, the field (spatial) significance of trends is tested by resampling (bootstrap) methods in order to identify if the spatial coherence of site-significant trends is nonrandom. For example, this could be the case for streamflow changes driven by large-scale regional climate shifts, the presence of glaciers, etc.

Assessing causality

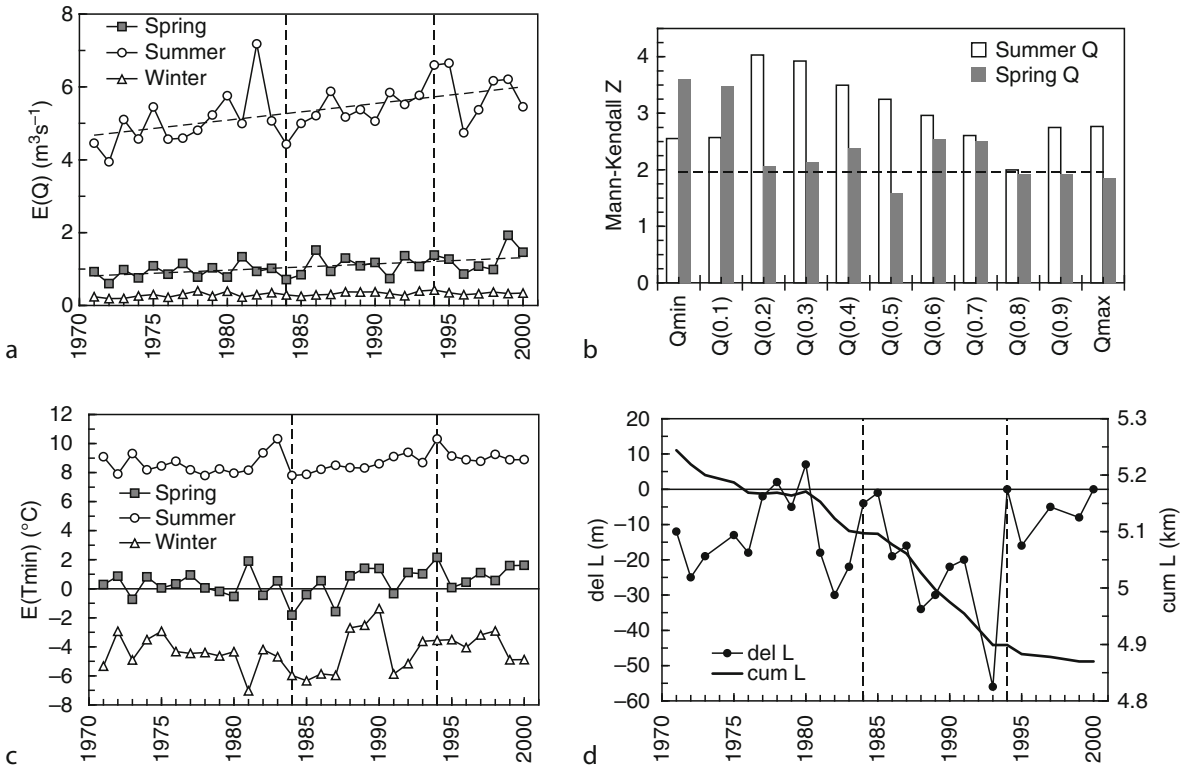
The attribution of discovered trends in streamflow to their causes may be data-driven (indirect), for example, multivariate regression between streamflow and other hydroclimatic variables, or model-driven (direct), for example, by physically based rainfall-runoff modeling. The most common explanatory variables are precipitation (wet day frequency and intensity) and air temperature (minimum, maximum, mean), but if available, other variables like evaporation, snow cover duration and depth, glacier mass and length, etc. may be used. Long-term climate teleconnections may be examined by correlations with climate indexes such as ENSO, PDO, NAO, etc., which capture large-scale climate variability. Basin vulnerability to streamflow trends may also be examined by multivariate regression of trend statistics with static basin properties, such as basin area, average slope, soil type, rock and glacier coverage, vegetation cover, etc. (e.g., Birsan et al., 2005).

Example

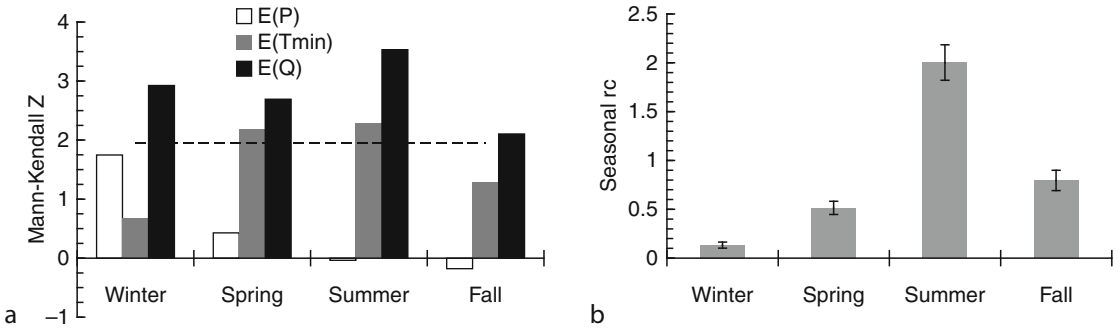
An example of a streamflow trend testing procedure following the steps above is presented for the mountainous Oberried Basin, Simme River, central Switzerland. A 30-year record of daily streamflow (1971–2000) is studied for this 35.7 km^2 basin, which is 34.6% glaciated (Plaine Morte glacier) and has an average altitude of 2,370 m. Daily precipitation data are from the station Boltigen lower in the valley and daily minimum and maximum temperatures are measured at Adelboden in the neighboring valley for the same period.

In step (1) data were quality checked and aggregated to seasonal and annual totals, and seasonal quantiles Q_{min}, $Q_{0.1}$, ..., $Q_{0.9}$, Q_{max} were computed. Mean streamflow appears to be consistently increasing over the study period, especially in the summer (Figure 1a). There is pronounced seasonality typical of glacio-nival regimes, with highest flows in the snow and ice melt period in May-June-July. In step (2) the whole 30-year period was used for trend testing. The LR and MK trend tests were applied to the data and the trend slopes b and test statistic Z were computed. In step (3) statistically significant trends (α = 0.05) were found in Q in all seasons by both LR and MK tests. Quantile analyses showed that summer and spring increases were strongest for low and moderate flows (Figure 1b). But changes were statistically significant in most quantiles. Serial correlation was not present in the detrended data so prewhitening was not conducted. Field significance cannot be tested with one station. Assessing causality in step (4) focused on minimum temperatures T_{min} and precipitation P. Precipitation frequency and mean intensity did not show any meaningful trends in the study period, except for a small increasing trend in winter intensity. Statistically significant trends were however found for minimum temperature increases in spring and summer (Figure 1c). Spring in particular is a sensitive season because minimum temperatures fluctuate around 0°C, so even small increases may increase the likelihood of liquid precipitation and snowmelt. We also focused closer on the 10-year period 1984–1994 (Figure 1) where consistent increases in summer T_{min} were observed jointly with increases in runoff and glacier retreat and no major changes in P. The glacier retreated by almost 400 m between 1971 and 2000.

In summary, the seasonal MK Z for mean P, T_{min}, and Q in Figure 2a shows that temperature increases are likely the dominant reason for increases in streamflow, especially in the spring and summer months when they are



Streamflow Trends in Mountainous Regions, Figure 1 (**a**) Mean daily streamflow for the spring, summer, and winter seasons in Oberried (1971–2000) with linear trend line shown. (**b**) Mann-Kendall test statistics Z for quantiles Q_p of daily flows for the summer and spring seasons (Z_{crit} at α = 0.05 is shown with dashed line). (**c**) Mean minimum daily temperature for the spring, summer, and winter seasons. (**d**) Plaine Morte annual glacier retreat (ΔL) and total glacier length (ΣL) for the studied period (data from Glaciological reports, 1881–2008). Vertical lines show the rapid glacier mass loss period 1984–1994.



Streamflow Trends in Mountainous Regions, Figure 2 (**a**) Seasonal Mann-Kendall *Z* for mean precipitation, minimum temperature, and streamflow (Z_{crit} at $\alpha = 0.05$ is shown with dashed line). (**b**) Seasonal runoff coefficient (*rc*) computed as the ratio *rc* = E(*Q*)/E(*P*) with error bands due to altitude and wind corrections to convert point gauge precipitation to basin-wide estimates.

statistically significant ($\alpha = 0.05$). Small increases in winter precipitation may also contribute to the snowpack in winter and subsequent snowmelt. In Oberried, like in most mountain basins, the runoff coefficient *rc* (ratio between streamflow and precipitation) is strongly seasonal (Figure 2b). In fact in winter there is very little runoff $rc \approx 0$, while in summer $rc \approx 2$, which means that roughly half of the runoff volume comes from snow accumulated in the previous winter and from glacier melt.

Selected streamflow trend studies

Regional effects

There are large regional differences in streamflow trends in mountainous and/or cold environments, which are confounded by the fact that studies use different time periods. Main commonalities are that streamflow trends are often correlated with large-scale climate patterns (indexes such as NAO, PDO, etc.), with general warming, and less clearly with precipitation changes. For example, increasing trends in *Q* have been observed in the Eurasian Arctic rivers (1936–1999) (Peterson et al., 2002). In Canada, decreases in annual *Q* have been observed in the Pacific Climatic region (1960–1997) (Burn and Elnur, 2002) and in northern Canada (1964–2003) (Dery and Wood, 2005), as well as southern Canada (1967–1996) (Zhang et al., 2001). Predominantly increasing trends in *Q* were found in the continental USA (1944–1993) in particular for moderate and low quantiles, but there was regional variability (Lins and Slack, 1999) and often trends in streamflow were not entirely consistent with changes in precipitation and temperature (1948–1988) (Lettenmaier et al., 1994). Therefore, single site studies of streamflow trends should be examined in their regional context before any extrapolation of the results is made.

Glaciers and snow

In glacierized basins, summer streamflow has been found to increase due to glacier melt (e.g., Birsan et al., 2005; Pellicciotti et al., 2010) but also to decrease in areas where the glacier mass is past the critical point (e.g., Stahl and Moore, 2006). A review of other observations of glacier runoff changes can be found in Casassa et al. (2009). Single site case studies, like our Oberried example above or the study of Ye et al. (2005) of a glacier in Tianshan, show that summer runoff increases are primarily correlated with summer temperature rises and secondarily with precipitation increases. Pellicciotti et al. (2010) demonstrated that spring and summer streamflow increased for selected glacierised basins in the Swiss Alps, in relation to an increase in temperature and decrease in the seasonal snowpack. They also showed a shift in the timing of runoff due to earlier melt onset. However, they found that the magnitude and sign of trends vary with different time periods, in particular for those periods that include phases of positive glacier mass balance. Birsan et al. (2005) found a strong relation between upward streamflow trends and glacier coverage especially for summer moderate and low flow quantiles, which represent the snow and ice-melt contribution to flow. Similarly, Hodgkins (2009) found that higher summer flows were present in glaciated basins compared to non-glaciated ones during a shift from a cold to a warm phase of the PDO. In terms of melt, warming may also result in a shift in the seasonality and timing of flow (Pellicciotti et al., 2010). In several Canadian rivers, ice conditions have been found to begin and end earlier in more recent years (Zhang et al., 2001; Burn and Elnur, 2002). These observations suggest that temperature effects on streamflow trends should be a focus point of any trend detection study in mountainous regions, especially those with glaciers.

Summary

Streamflow trend detection is presented in four steps: (1) exploratory data analysis, (2) trend test methods and statistics, (3) testing for statistical significance, and (4) assessing the causality of streamflow trends. Trend detection is always connected with the choice of a time period, which should reflect the purpose of the analysis and be mindful of long-term climate oscillations that could be present. Streamflow trend attribution in mountainous regions to its causes is nontrivial, because it is difficult to separate the combination of precipitation and

temperature effects on runoff generation in high altitude catchments, the seasonal processes of snow accumulation and delayed snow melt, and the effect of the retreat and thinning of glaciers. A survey of studies highlights that streamflow trends are regionally dependent and should be investigated on a seasonal basis together with changes in precipitation and air temperature in order to capture the essence of streamflow change and its possible causes, in particular in glacierized basins.

Glacier structure

Definition

Structural glaciology is the study of depositional and deformational structures in glaciers on all scales.

Structural glaciology

Glaciers demonstrate a wide range of structures that reflect their dynamic behavior. Such structures resemble those in rocks found in mountain belts, and as such, glaciers can serve as large-scale models of rock deformation

(Hambrey and Lawson, 2000). Interest in structural glaciology dates back to the early days of glaciology as a science, when pioneers such as James Forbes and John Tyndall investigated glaciers in the European Alps. However, it took the leap in understanding of the mechanics of glacier flow, triggered by Glen and Nye in the 1950s, and the subsequent introduction of structural geological principles to provide the basis for modern understanding of structures in glaciers.

Today, our knowledge of the structures of valley glaciers is well-founded, but up-scaling these ideas to ice sheets is still in its infancy. Structural glaciology is important not only for understanding glacier dynamics, but also in explaining water-routing through glaciers and glacial depositional landforms.

Glacier structures reflect both ductile and brittle deformation, and sometimes a combination of the two. Interpretation of structures requires consideration of two main concepts. Just as in rocks, ice is subject to multiple phases of deformation, referred to as "polyphase deformation." The early structures form in the upper reaches of the glacier, with later structures forming below and commonly overprinting pre-existing structures, resulting in complex associations of intersecting features. The second concept is that of cumulative (or finite) strain, since structures, once formed, continue to evolve under changing stress regimes. Adding increments of strain gives the cumulative strain, and may reflect both simple shear and pure shear. Such strains are expressed graphically as strain ellipses. They may be determined from direct measurements of velocity or by means of numerical modeling, supported by detailed 3-D mapping in the field (Hambrey and Lawson, 2000).

Before being subject to deformation, glacier ice is generally stratified from the progressive accumulation of snow and its conversion to *firn*. Internal deformation of ice under the action of gravity modifies and overprints this "primary structure." The most important ductile structures are:

- *Foliation*, which is a discontinuously layered structure originating from the simple shear and pure shear of pre-existing inhomogeneities, including stratification (Figure 1).
- *Folds*, which occur on scales from centimeters to kilometers, and reflect progressive compression or shear.
- *Boudinage*, a structure difficult to spot, but having the appearance of a string of sausages (from the French "boudin"); it results from ductility contrasts between different types of ice.
- *Ogives*, which are light and dark bands of clean and dirty ice respectively that commonly form below icefalls.

Brittle structures are dominated by *crevasses* – open V-shaped fractures in the ice, formed where ice is under tensile stress. They can be several tens of meters deep and several meters wide and are the main hazard to travel over glaciers, especially when snow-covered. Related to crevasses are *crevasse traces* which are closed water- or snow-filled crevasses, or tensional veins where the bounding ice walls have not physically separated. In addition, there are a variety of faults illustrating visible displacements, with thrust-faults being of particular importance through their role in recycling debris from the bed. A well illustrated account of glacier structures may be found in Hambrey and Alean (2004) and in their website, www.swisseduc.ch/glaciers/earth_icy_planet/glaciers05-en.html.

Structural Glaciology, Figure 1 Foliation in Gornergletscher, Switzerland, looking down-glacier toward the Matterhorn.

With different parts of a glacier developing their own distinctive suites of structures, depending on whether they are subject to shear, compression, or extension, the resulting structural assemblages may be of considerable complexity. Extensional flow regimes are dominated by crevasses and crevasse traces, the latter especially providing an historical record of dynamic regimes that may no longer exist. Compressive flow regimes, particularly at the base of an icefall typically show longitudinal foliation at the margins and arcuate foliation (derived from crevasse traces) across the middle. Within these structures folds on various scales can be identified. Icefalls may severely modify or even obliterate earlier structures. In the compressive zone near the snout foliation may be folded, whilst low-angle thrusts may develop, all superimposed on the aforementioned assemblages. Surge-type glaciers are a special case, and although they demonstrate all of the above attributes, they are further characterized by looped moraines and pervasive thrusting.

Understanding structures on glaciers aids interpretation of depositional landforms, including moraines dominated by folding and thrusting of ice and sediment, and of longitudinal ridges related to foliation, or transverse ridges related to crevassing. Thus, glacial geomorphological mapping needs to embrace knowledge of structural processes in the glaciers themselves.

Summary

Structural glaciology involves the investigation through mapping and 3-D analysis of the structures observed within glaciers. Analysis follows a structural geological approach on the grounds that glacier ice deforms in a manner resembling processes occurring in metamorphic rocks close to the melting temperature. The original primary structure comprises stratification of snow, firn, and ice in the accumulation area. Secondary structures include both brittle and ductile forms. Of these, brittle structures include crevasses, crevasse traces, faults, and thrusts; whereas ductile structures include foliation, folding, and boudinage. Structural glaciology is of fundamental importance in evaluating debris entrainment and transfer, and the subsequent deposition of sediment as landforms.

SUBGLACIAL BOREHOLE INSTRUMENTATION

Philip R. Porter
Division of Geography and Environmental Sciences, School of Life Sciences, University of Hertfordshire, Hatfield, Hertfordshire, UK

Definition

Subglacial borehole instrumentation: Instruments inserted via boreholes into the glacier substrate, usually used to measure basal motion and physical and hydraulic properties of basal sediments.

Introduction

Where glaciers overlie a sedimentary substrate, both sliding (Glacier Sliding) and deformation of subglacial sediments may contribute to total forward motion (Dynamics of Glaciers and Glacier Motion/Ice Velocity), yet the processes that control the partitioning of basal motion between sliding and deformation are not fully understood. This problem has arisen partially due to a lack of in situ monitoring of mechanical and hydrological conditions (Glacier Hydrology) at the ice-bed interface. However, hot-water drilling allows direct access to the ice-bed interface and direct monitoring of the processes of glacier basal motion (Subglacial Processes) is then made possible via the use of instrumented boreholes.

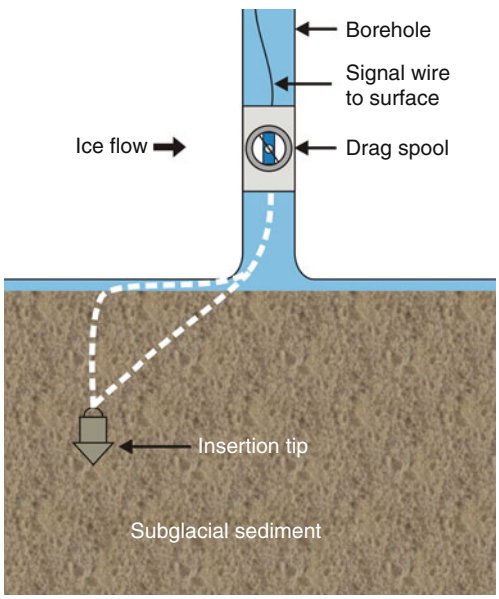
Much of the pioneering work to develop subglacial borehole instrumentation was carried out at Trapridge Glacier, Yukon Territory, Canada. Instruments are installed into the glacier substrate using a borehole percussion hammer, the operation of which is described in detail by Blake et al. (1992). Briefly, this comprises a 2 m long tubular structure around which is mounted a striker or "hammer" that can be repeatedly raised and dropped onto an anvil at the base of the hammer by an operator at the glacier surface. Subglacial instruments are housed within a "sheath" or attached to a "finger" at the base of the hammer below the anvil and the resultant percussive force drives the subglacial instrument progressively deeper into the substrate (see Blake et al., 1992).

This technique has been successfully used to install instruments into the substrate of Trapridge Glacier (e.g., Blake et al., 1992; Blake et al., 1994; Fischer and Clarke, 1997a; Fischer and Clarke, 1997b; Fischer et al., 1999; Kavanaugh and Clarke, 2001), Storglaciaren, Sweden (e.g., Iverson et al., 1994; Hooke et al., 1997; Fischer et al., 1998), Unteraargletscher, Switzerland (Fischer et al., 2001), and Bakaninbreen, Svalbard (e.g., Porter et al., 1997; Porter and Murray, 2001; Murray and Porter, 2001). Inevitably however, there are limitations associated with installing instruments in situ remotely from the surface beneath thick ice, aside from the obvious logistical demands. Firstly, the hot-water drilling process itself is likely to evacuate sediment from the base of the borehole to a depth of several decimeters (Blake et al., 1992) and it will inevitably take some time for sediment to intrude into the resultant void and for hydraulic and sedimentary equilibrium conditions to be reestablished. Secondly, although insertion depth can be monitored at the surface with an estimated accuracy of 0.01 m, exact placement of the sensor with respect to the ice-bed interface will always be unknown and careful interpretation of results is therefore required. Notwithstanding these issues, subglacial borehole instruments have the capacity to yield much useful information concerning basal motion and the factors that control it.

Measuring sliding

In order to effectively assess the relative contributions to glacier motion of sliding and sediment deformation, some independent measure of both these components of flow is required. Drag-spools are simple devices that give a continuous, quantitative measure of basal sliding. These instruments were first deployed beneath Trapridge Glacier (Blake et al., 1994). The drag-spool consists of a miniature multi-turn potentiometer attached to a spool, around which is wound several meters of thin string. This string passes out through a sealed plastic housing and is attached to a brass insertion tip. This tip is anchored in the subglacial sediment using the percussion hammer, while the drag-spool itself remains frozen and fixed into the borehole. As the glacier moves over its bed, the anchor remains fixed within the sediment and string is paid out from the spool. As displacement between drag-spool and anchor increases, progressive rotation of the spool and potentiometer causes a resistance change within the device (Figure 1). This resistance change is logged at the glacier surface and is converted to a glacier sliding rate using calibration data gained prior to installation.

Initial results from Trapridge Glacier indicated that basal sliding accounted for 50–70% of total glacier flow with measured basal sliding rates ranging from 40 to 80 mm d^{-1} and that peak sliding rates corresponded with rises in basal water pressure (as opposed to peak water pressure, Subglacial Drainage System) as recorded by pressure transducers suspended in boreholes (Blake et al., 1994). This latter finding conflicts with observations made elsewhere that peak glacier velocity and peak basal water pressure (Meltwater Pressure) generally coincide (e.g., Iken and Bindschadler, 1986; Kamb et al., 1985; Kamb and Engelhardt, 1987; Hooke et al., 1989). Fischer and Clarke (1997a) suggested that the relationship between sliding rate and rising basal water pressure observed beneath Trapridge Glacier could be explained in terms of "stick-slip" sliding processes operating at the ice-bed interface. As basal water pressure begins to rise, local strain buildup in the ice is released as basal ice decouples from the bed and the resultant increase in basal sliding is registered by drag-spools. However, once this strain is released, further increases in basal water pressure do not result in subsequent increases in the rate of basal sliding.



Subglacial Borehole Instrumentation, Figure 1 Conceptual diagram of a drag-spool installed within a borehole. Note the two possible locations for the drag-spool string (dashed white line) that will be dictated by sediment stiffness. Adapted from Blake et al. (1994) and Murray (1998).

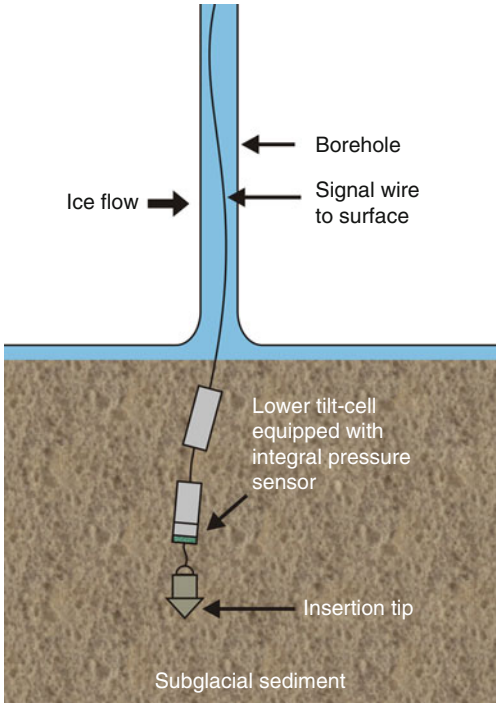
Measuring deformation

Measuring the deformation rate of basal sediments is important both in order to assess the contribution of basal sediment deformation to flow and to obtain baseline stress and strain data to enhance understanding of the rheological properties of basal sediments. Qualitative measurements of total strain have been obtained from Trapridge Glacier using a resin filled tube (a "bed cast") inserted into basal sediments. A heating wire catalyzes the resin after several days of monitoring and the resultant deformation of the now-rigid tube once removed from basal sediments provides an indication of the extent of basal sediment deformation (Blake et al., 1992). A development of the bed cast is a rubber rod to which strain gauges are bonded (Blake et al., 1992). The advantage of the rubber rod over the bed cast technique is that a continuous, qualitative measure of strain rate can be obtained.

Quantitative assessment of the deformation rate of basal sediments can be made using strings of tilt cells inserted into basal sediments. A basic assumption is that, once installed, the tilt cell behaves as a clast within the basal sediment, becoming realigned as the sediment deforms. Thus, as the sediment deforms, the cell is tilted (Figure 2). Tilt cells are installed as "strings" of two or three cells allowing assessment of the vertical deformation profile and differentiation of the tilt data time series allows computation of instantaneous strain rates (Blake et al., 1992).

Tilt cells comprise two main designs. Firstly, leaf spring tilt cells comprise two pendulum weights attached to leaf springs orientated perpendicular to one another to which strain gauges are bonded. As the cell is tilted, the pendulum weights flex the leaf springs causing the resistance of the strain gauges to change. This resistance change can be related to angle of tilt once the cell has been calibrated. The operation and calibration of leaf spring tilt cells are described in detail by Blake et al. (1992).

Secondly, electrolytic tilt cells consist of a series of metal electrodes housed in a chamber containing a suitable electrolytic fluid that contacts the electrodes. Electrodes are arranged around a central common



Subglacial Borehole Instrumentation, Figure 2 Conceptual diagram of a string of tilt cells installed within deforming subglacial sediments. Adapted from Murray (1998).

electrode. In a dual-axis cell, four electrodes are mounted around the central electrode at 90° intervals in a "cross" configuration. As the cell is tilted, the outer electrodes either become immersed in, or emerge from the electrolyte depending on their position with respect to the central electrode, while the level of electrolyte in contact with the central electrode remains constant at all times. This has the effect of changing the impedance between electrodes that can be measured as a voltage change and related to angle and direction of tilt once the cell has been calibrated. Full details of the operation and calibration of electrolytic tilt cells are described by Blake et al. (1992) and Porter and Murray (2001). Strings of tilt cells are inserted vertically into basal sediments using a percussion hammer.

Data obtained from tilt cells installed beneath Trapridge Glacier show that subglacial strain rates vary in amplitude and polarity over short timescales. Observed negative strain rates may be a function of extrusion flow (Blake et al., 1992). A development of the basic electrolytic tilt cell was deployed at Bakaninbreen, Svalbard by Porter and Murray (2001). Here, the lowermost cell in each string was equipped with a pore-pressure transducer to allow relationships between sediment strain rates and water pressure fluctuations within deforming sediments to be assessed. At the time of installation, Bakaninbreen was in the late-active phase of a prolonged surge (Glacier Surging). Tilt cells were installed up- and down-glacier of a surge front. In common with observations at Trapridge Glacier, strain rates at Bakaninbreen fluctuated over short timescales, with periods of both positive and negative strain evident in the time series. Strain rates up-glacier of the surge front were an order of magnitude higher than those measured down-glacier of the surge front. Interpretation of tilt cell records indicated that deformation of basal sediments comprised the dominant mode of basal motion. However, in contrast to observations made elsewhere (e.g., Boulton and Hindmarsh, 1987), no consistent relationship between water pressure within basal sediments and strain rate was observed.

Assessing sediment properties

The ploughmeter is a device that enables assessment of properties of subglacial sediments such as viscosity and yield strength, and may also be used to infer sediment texture and assess glacier sliding rates (Fischer and Clarke, 1994; Fischer and Clarke, 1997b). The device consists of a steel rod onto which strain gauges are bonded near one end. It is hammered into the bed, such that all strain gauges are fully immersed into the subglacial sediment. The upper section of the device then becomes trapped in the ice, while the lower portion is dragged through the underlying sediment, effectively acting as an ice-entrained clast (Figure 3). This "plowing" action sets up stresses within the ploughmeter that cause changes in the resistance of the strain gauges that are monitored at the glacier surface and translated into an applied force by application of

calibration data. A full description of the device and its calibration is provided by Fischer and Clarke (1994).

Ploughmeter data makes it possible to obtain estimates of the rheological properties of basal sediments. If sediment is assumed to behave as a Newtonian viscous fluid, then an estimate of viscosity can be obtained. If sediment is assumed to behave as an ideal plastic solid (Plastic Flow and Plastic Deformation), then an estimate of yield strength (Bed Strength) can be obtained. Viscosity estimates gained from Trapridge Glacier range from 3.0×10^{-9} to 3.1×10^{10} Pa s (Fischer and Clarke, 1994), while estimates from ploughmeters installed beneath Bakaninbreen range from 1.1×10^{10} to $4.3\ 10^{10}$ Pa s (Porter, 1997). Applying an idea plastic solid model, yield strength estimates at Trapridge Glacier range from 48 to 57 kPa (Blake et al., 1992) and at Bakaninbreen they range from 6.6 to 411.6 kPa with high recorded values thought to be caused by ploughmeters moving into areas of frozen bed and by implication, areas of high-yield strength sediment (Murray and Porter, 2001). Comparison of calculated basal shear stress and yield strength data gained from ploughmeters at Bakaninbreen, allowed areas where stress exceeds yield strength to be identified (Porter et al., 1997). By implication, these areas are likely to be experiencing basal sediment deformation, an assertion that is supported by subsequent studies (Porter and Murray, 2001). Ploughmeter data has also been used to estimate glacier sliding rate based on clast collision frequency and associated force variations recorded by the device (Fischer and Clarke, 1997b).

The rheological properties of basal sediments have also been measured using a subglacial borehole instrument that has some conceptual similarities with the ploughmeter, dubbed a "dragometer" (Iverson et al., 1994). The device comprises a conical "fish" attached to a wire that runs up to a load cell installed in a metal tube that is trapped in the base of a borehole. The signal recorded by the load cell varies according to the forces applied to the "fish" which in turn relate to the residual strength of the subglacial sediments through which the "fish" is being dragged. A full description of the dragometer is provided by Iverson et al. (1994).

Data obtained from a dragometer installed in the bed of Storglaciären indicate an average residual strength for subglacial sediments of ~55 kPa (Iverson et al., 1994).

Hydraulic properties

Where ploughmeter data is collected alongside basal water pressure data from borehole pressure transducers, conclusions can be drawn regarding both the functioning of the basal hydrological system (e.g., Fischer et al., 1999; Kavanaugh and Clarke, 2001) and the hydraulic properties of basal sediments (e.g., Fischer et al., 1998; Fischer et al., 2001). Ploughmeter records and associated borehole water pressure records from Trapridge Glacier show good correspondence, with diurnal force fluctuations correlating well with large and rapid fluctuations in basal water pressure (Fischer et al., 1999). However, this correlation was observed to be in phase with one ploughmeter and out of phase with another in an adjacent borehole and was thought to arise from the existence of time-varying "sticky spots" beneath the glacier, whereby one ploughmeter is moving through an area where ice-bed coupling is enhanced (a "sticky spot") in response to a reduction of basal water pressure (Fischer et al., 1999).

Subsequent observations at Trapridge Glacier demonstrated that a series of "spring events" resulted in the failure of borehole pressure transducers and yielded significant force responses on ploughmeters, interpreted to result from strong basal motion associated with the establishment of a connected drainage system (Subglacial Drainage System) beneath the glacier (Kavanaugh and Clarke, 2001).

Ploughmeters installed beneath Unteraargletscher, Switzerland also displayed an inverse correlation with basal water pressure recorded by borehole pressure transducers and a significant time lag between the two signals (Fischer et al., 2001). This lag was thought to reflect the time taken for a pressure pulse in the subglacial drainage system to propagate through basal sediments to the insertion depth of the ploughmeter, thereby reducing sediment strength and associated force exerted on the ploughmeter. Assuming this assertion is correct, the hydraulic diffusivity of basal sediments can be estimated and values from Unteraargletscher range from 1.3×10^{-6} to 2.3×10^{-6} $m^2\ s^{-1}$. A similar ploughmeter force–water pressure relationship was measured at Storglaciären (Fischer et al., 1998) and again, using the propagation velocity of water pressure waves through basal sediments, calculated hydraulic diffusivity was found to range from 1.9×10^{-6} to 3.6×10^{-6} $m^2\ s^{-1}$.

Data concerning the hydraulic properties of basal sediments have also been obtained from pressure transducers installed within tilt cells inserted into basal sediments at Bakaninbreen (Porter and Murray, 2001). Here it was found that pore-water pressure fluctuations, as recorded by pore-pressure sensors installed within tilt cells, lagged borehole water pressure fluctuations by 37–49 h. Because the depth of insertion of tilt cells and integral pore-pressure sensor can be measured during installation, it is again possible to estimate hydraulic diffusivity using the propagation velocity of water pressure waves. Diffusivity values at Bakaninbreen range between 1.2×10^{-6} and 5.0×10^{-6} $m^2\ s^{-1}$ and if a value for specific storage of till is assumed then hydraulic conductivity of basal sediments can also be estimated. At Bakaninbreen, diffusivity ranges from 3.2×10^{-7} to 7.7×10^{-8} m s^{-1} which is in good agreement with values derived elsewhere (e.g., Boulton and Dent, 1974; Fountain, 1994; Iverson et al., 1994; Hubbard et al., 1995; Murray and Clarke, 1995). It is interesting to note, however, that at Bakaninbreen there is no clear relationship between basal water pressure fluctuations and strain rate as measured by tilt sensors (Porter and Murray, 2001). Furthermore, ploughmeters also showed only occasional strong relationships with basal water pressure and in contrast to observations made

elsewhere these correlations were mostly positive (Murray and Porter, 2001). At Bakaninbreen, it appears that there is weak coupling between sediment strength and water pressure fluctuations and that force fluctuations recorded by ploughmeters may arise from variations in granulometry (Granulometry) or ice-bed coupling (Murray and Porter, 2001).

Summary

The installation of subglacial borehole instruments has the capacity to yield much useful information concerning basal motion and the properties of basal sediments. Installation of borehole instrumentation is, however, logistically demanding and given inevitable uncertainties over instrument placement with respect to the ice-bed interface when installing remotely beneath thick ice, careful interpretation of results is required.

Synonyms

Basal drainage system; Subglacial hydrological system; Subglacial hydrology

Definition

Subglacial drainage systems are formed from the hydraulic pathways that contain and transfer water located close to the contact between an ice mass and its substrate. These pathways are commonly considered to be spatially discrete, e.g., flowing through dendritic networks of channels, or spatially dispersed, e.g., flowing through diffuse films. The subglacial drainage system can exchange water with the overlying englacial drainage system and the underlying groundwater drainage system. Extensive reviews of subglacial drainage have been provided by, among others, Flowers (2008), Hooke (1989), Hodgkins (1997) and Hubbard and Nienow (1997).

Introduction and significance

The investigation of subglacial hydrology forms an important branch of glaciology. However, it is important to note that well-developed subglacial drainage systems only exist at the bases of those temperate or polythermal ice masses that are at least partly warm based (i.e., are characterized by a basal interface that is melting).

Reconstructing the nature of, and changes in, subglacial drainage is important for several reasons. First, water located at the basal interface of any ice mass exerts a strong control over the way in which that ice mass moves. In general, the presence of subglacial water acts as a lubricating layer, speeding basal motion up by partially decoupling the ice mass from its (otherwise harder and/or rougher) substrate (e.g., Iken and Bindschadler, 1986). It is not only the presence of water that is important here but probably also the quantity of water stored at the glacier bed and its pressure (e.g., Bartholomaus et al., 2008), both of which change at a variety of timescales both across a single ice mass and between different ice masses. Recent so-called dynamic thinning, caused by a postulated increase in the delivery of surface-derived meltwater to the base of Greenland outlet glaciers (Zwally et al., 2002), is considered to be responsible for their speed up and retreat. Similarly, increases in lubricating basal meltwater may be responsible for at least facilitating, if not triggering, rapid speedups during the surge phase of *surge-type* glaciers (e.g., Kamb et al., 1985). Systematic representations of the links between subglacial drainage and ice mass motion are also important to computer modelers to allow them to improve the realism of their models of ice mass response to climate change.

Second, most of the water delivered from ice masses exits via the subglacial drainage system. In different settings and at different times, this water can represent a resource or a hazard. In terms of resource, subglacial water may be tapped directly from the glacier bed or shortly after it leaves the glacier for hydroelectric power generation and/or potable uses. Downstream extraction for domestic use and agricultural irrigation represents crucial supply issues in many populous but otherwise arid areas of the world. Understanding controls over changes in water delivery from glaciers at a variety of timescales is important for scientists to predict future supplies and to inform planners and policymakers. For example, ~2 billion people are dependent on water supplied by rivers that are fed by Himalayan glaciers – many of which are currently receding and are anticipated to continue to do so over the next several decades to centuries. Subglacial drainage can also be more immediately hazardous. *Jökulhlaups*, for example, probably represent the most visible hazard associated with subglacial water delivery. Taking the name from type events in Iceland, jökulhlaups (literally "glacier leaps") are large floods associated with the catastrophic release of water from subglacial lakes located in areas of high geothermal heating (e.g., Bjornsson, 2002). For example, the Grimsvötn jökulhlaup of 1996 discharged ~3 km^3 of meltwater in just over 2 days across its *sandur* (at a peak discharge of ~45,000 $m^3 s^{-1}$), causing an estimated ~US$15 million of infrastructural damage. Understanding the relationships between subglacial drainage and water delivery is therefore important to modelers, engineers, planners, and policymakers.

Third, water may be stored for long periods in isolated subglacial lakes, allowing distinctive microbiological forms to evolve. There are currently believed to be approaching 300 such lakes beneath the Antarctic Ice Sheet alone (Siegert et al., 2005; Smith et al., 2009), the largest known of which is Lake Vostok with surface dimensions of ~200 km and ~50 km, and an approximate volume of 5,400 km^3. In addition to the biological interest provided by these water bodies, research updates revealing ever-larger numbers of such lakes (e.g., Popov and Masolov, 2007) and the existence of hydraulic linkages between them (Fricker et al., 2007; Wingham et al., 2006) will probably transform our understanding of ice sheet drainage and motion over the next few decades.

Methods of empirical investigation

Revealing the dynamic nature of subglacial drainage represents a fundamental challenge for glaciologists. However, gaining direct access to undisturbed meltwater drainage pathways is at best challenging and at worst impossible. Consequently, researchers of subglacial drainage are continually developing and applying new methods and techniques (summarized in Hubbard and Glasser, 2005). Approaches to studying subglacial drainage fall into five broad categories.

1. *Investigations of the quantity and character of meltwater discharged from ice masses*. Analysis of the meltwater flowing from ice masses can provide important information about the subglacial flow pathways that it has followed beneath that ice mass. Simple discharge records, for example, when compared with the timing of water input to the ice mass, can inform on water transit times and water storage within the englacial and subglacial systems. Similarly, analysis of variations in

the fine sediment particles suspended in the water and of the chemical (ionic) composition of the water itself can also provide information relating to how long that water has spent at the glacier bed and under what broad conditions. For example, water that is routed efficiently through large subglacial channels will have little time to interact with reactive subglacial sediments and will be characterized by a rapid and peaked hydrograph. It will also be solute-poor relative to subglacial water that has been routed via diffuse flow pathways. Changes in the ratio of suspended sediment concentration to discharge of subglacially routed waters can be related to changes in subglacial sediment supply, with increases for example indicating the headward growth of channels or the tapping of new areas of the glacier bed (Fenn et al., 1985).

2. *Tracer investigations*. Tracers such as salt or, more commonly fluorescent dye (which can be detected at far lower concentrations and therefore requires lower dosages), can be added to the glacier drainage system at known locations and recorded as it exits the ice mass. The resulting breakthrough curve of dye concentration plotted against time can provide valuable information relating to the flow pathways followed by the water between the input location and the measuring station. For example, a rapidly-reached, narrow and flashy breakthrough curve will represent flow through a hydraulically more efficient, probably channelized, drainage system than a strongly attenuated breakthrough curve. In addition to such qualitative judgments, breakthrough curve analysis can yield quantitative data such as minimum flow speeds (given by dividing the straight-line distance between the input location and the measuring station by the time separating the tracer injection from the measurement) and dispersion (given by an analysis of the spread of the breakthrough curve relative to its velocity) (e.g., Burkimsher, 1983; Nienow et al., 1998).
3. *Proglacial bedrock investigations.* The methods outlined above provide useful information relating to real-time subglacial hydrological processes, but they are spatially integrated over large, and possibly unknown, flow lengths. In contrast, investigations of drainage-related geomorphic features etched into glaciated surfaces provide excellent spatial discrimination but poor temporal discrimination. Such studies can yield important information relating, in particular, to the structure and morphometry of the former subglacial drainage system and its individual flow pathways (e.g., Walder and Hallet, 1979). This information can be used to approximate former subglacial water discharges and pressures, and this information can in turn be used to inform reconstructions of former ice mass movement (e.g., Sharp et al., 1989).
4. *Borehole-based investigations*. Borehole-based investigations of subglacial drainage systems suffer from neither excessive spatial integration nor excessive temporal integration. However, the approach is logistically demanding, typically requiring multiple boreholes to be drilled to the bed of the ice mass concerned and then instrumented. Such boreholes can be created mechanically, which has the advantage of providing ice cores as well as access to the base of the ice mass (but which is logistically demanding and slow, typically yielding meters to tens of meters of borehole length per day), or thermally by pressurized hot water, which provides no ice core but which typically yields hundreds of meters of borehole length per day. Each such borehole provides direct access to a specific location on the ice mass bed, which can be investigated via several techniques. For example, our understanding of the relationship between subglacial drainage and ice mass motion has been revolutionized by synchronous borehole-based measurements of subglacial water pressure and surface measurements of ice velocity (Bartholomaus et al., 2008; Iken and Bindschadler, 1986). Where arrays of such boreholes can be drilled, spatial variability in multiple hydrological properties can be measured at high temporal resolution, providing the most detailed records available to date relating to subglacial drainage (e.g., Hubbard et al., 1995).
5. *Remotely sensed (geophysical and satellite-based) investigations.* The most widespread spatial coverage of information relating to subglacial drainage is supplied by remotely sensed data. However, while this information does provide good spatial coverage, it commonly yields first-order data that need to be interpreted in terms of specific subglacial properties. Such interpretations are rarely unequivocal, although inversion techniques can be used to infer hydrologically modulated variations in basal motion from satellite-based interferometric synthetic aperture radar (InSAR) (e.g., Magnusson et al., 2007). Ice surface radar also has the capacity to identify the presence of water at the ice-bed contact, and repeated radar measurements at a given site have the capacity to reveal changes in the nature of the interface and the distribution of that water (e.g., Smith et al., 2007). Recently, for example, repeat satellite-derived altimetry has revealed spatial variations in the surface elevation of ice masses pointing to coordinated, episodic water transfer between sub-ice lakes (e.g., Carter et al., 2009).

Configuration and change

Subglacial drainage networks are generally considered to fall into one of two broad categories. *Discrete* drainage systems are formed from a network of channels that may be cut upward into the overlying ice (named Röthlisberger channels or R-channels) (Röthlisberger, 1972) or cut downward into the underlying bedrock (named Nye channels or N-channels) (Nye, 1973). These networks are of broadly dendritic form, composed of small feeder streams

linking to create branch streams that in turn join to create a small number of trunk channels, each progressively flowing at low pressure and therefore drawing water from their smaller feeders. In contrast, *distributed* drainage systems form diffuse or anastomosing networks that do not evolve into progressively larger, lower-pressure channels. Such distributed systems can be formed of films, linked cavities, permeating flow through sub-ice sediments, or so-called canals, cut both upward into ice and downward into underlying sediments. These systems generally transfer water more slowly and at higher pressure for a given discharge than do discrete networks. Switching between the two can therefore raise or lower the pressure of subglacial meltwater, and correspondingly, ice motion (e.g., Fowler, 1987).

Controls over the structure of subglacial drainage systems, and of the individual flow pathways that comprise them, can change at a variety of timescales. Many subglacial drainage systems are correspondingly subject to spatial and temporal changes. For example, a change in the configuration of subglacial drainage pathways – from discrete (operating at relatively low pressure) to distributed (operating at relatively high pressure) – has been closely associated with the initiation of glacier surges (e.g., Fowler, 1987; Kamb et al., 1985 above). However, the most commonly recognized changes in subglacial drainage result from meteorological seasonality. Accordingly, the subglacial drainage system beneath mid-latitude valley glaciers can change from a diffuse network through the winter, when minimal and spatially diffuse water inputs derive from basal melting alone, to the summer, when large fluxes of surface meltwater are delivered to the glacier bed via point sources such as crevasses and moulins. However, this drainage system replacement is not instantaneous but time transgressive, with repeated dye tracer studies revealing that the distributed system is gradually replaced in an upglacier direction (dictated by the retreat of the surface snow line) by the channelized system (Nienow et al., 1998). While such wholesale seasonal changes are improbable at larger ice masses, subglacial drainage change is likely where summer surface melting occurs near the margins of large ice sheets, and over decades to centuries at larger ice masses that are subject to changing climatic conditions.

Conclusions

Subglacial drainage systems are important, diverse, and subject to change at various temporal and spatial scales. They are important because they (a) exert a strong influence on the basal motion of ice masses, (b) represent potential hazards and resource, and (c) can form large subglacial lakes. Subglacial drainage systems are diverse because they are composed of flow pathways that can have different specific configurations, which can in turn exist adjacent to each other and change over time. However, investigating the structure and dynamics of subglacial drainage systems is difficult, requiring major logistical effort and continual development of new methods and technologies. Despite these developments, the most pressing challenges that face researchers in the future are similar to those that have confronted researchers in the past. The most fundamental of these is probably still to obtain high (spatial- and temporal-) resolution records of changes in subglacial drainage systems at the ice mass scale, and to determine the physical controls responsible for those changes. This information would then be applied in a structured manner to allow future drainage system changes and meltwater discharges to be predicted. Additionally, perhaps the most interesting developments in the field of our exploration of subglacial drainage systems will come from obtaining the first direct access to major subglacial lakes, as well as their continued geophysical investigation.

Subglacial lakes: Water-filled cavities located beneath glaciers and ice sheets

Introduction

Visual observations of what appeared to be floating ice by the crews of Russian aircraft flying missions over the Antarctic continent provide the earliest evidence of subglacial lakes. These observations were later verified by airborne radio-echo sounding, seismic data, and satellite imagery. We now know that more than 150 lakes exist beneath the Antarctic continent, and are connected by networks of subglacial streams and rivers, which may initiate and maintain rapid ice flow and should be considered in ice-sheet mass balance assessments (Siegert, 2000; Siegert et al., 2005). Morphometric data indicate that the volume of Antarctic subglacial lakes alone exceeds 10,000 km^3, with Lake Vostok (~5,400 km^3) and Lake 90° E (1,800 km^3) being the largest (Studinger et al., 2003, 2004). Antarctica lakes may hold over 8% of all lacustrine freshwater on Earth, enough to cover the whole continent with a uniform water layer ~1 m thick. Simple balance calculations reveal that the average water residence time in the subglacial zone of Antarctica is equal to ~1,000 years, which is likely a reflection of low liquid water generation rates coupled with slow rates of drainage of liquid water through subglacial environments (Priscu et al., 2008).

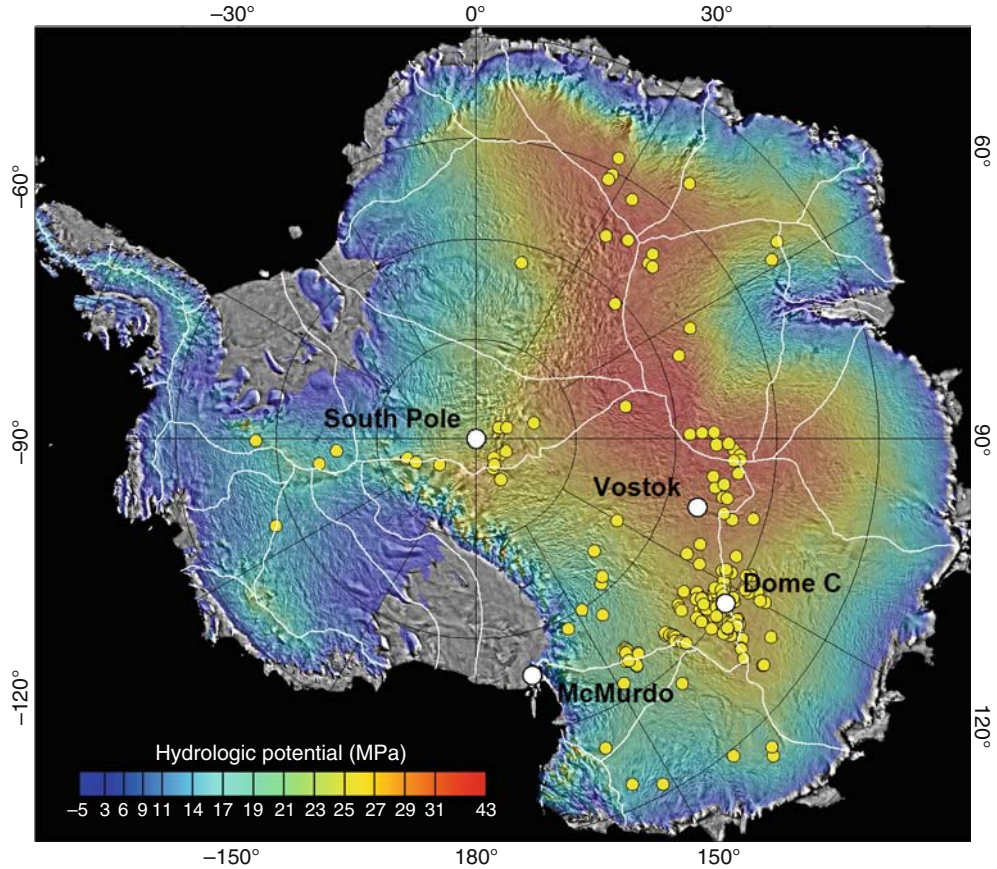
Over 60% of the lakes lie within 50 km of a local ice divide and 88% lie within 100 km of a local divide (Priscu et al., 2008) (Figure 1). The association of subglacial lakes with local ice divides and regions of high hydraulic fluid potential leads to a fundamental question concerning the evolution of subglacial lake environments: Does the evolving ice sheet control the location of subglacial lakes or does the fixed lithospheric character necessary for lake formation (e.g., basal morphology, geothermal flux, or the nature of sub-ice aquifers) constrain the evolution of ice sheet catchments? With the exception of central West Antarctica (where lakes are few), we know little about either the lithospheric character along these catchment boundaries or the history of their migration as discerned from layering within the ice sheet.

Origins of subglacial lakes

Deep subglacial lakes have probably been stable through many glacial cycles and may have developed novel ecosystems, in contrast to the shallower lakes (Dowdeswell and Siegert, 1999, 2002). Although arguments have been made for the tectonic origins of deep subglacial lakes, there continues to be debate about whether subglacial lakes in Antarctica reside in active tectonic basins or along old inactive zones of structural weakness that once provided guidance for subglacial erosion (Bell et al., 2006). Much of East Antarctica, where the majority of subglacial lakes have been found so far, is thought to have assembled 500–800 million years ago. However, our knowledge of the interior of the continent, the distribution of major tectonic boundaries, and old zones of structural weakness is limited due to a paucity of data.

The biology of subglacial systems

Much attention is currently focused on the exciting possibility that the subglacial environments of Antarctica may harbor microbial ecosystems under thousands of meters of ice, which have been isolated from the atmosphere for as long as the continent has been glaciated (20–25 million years). Profiles of prokaryotic cell abundance through the entire Vostok core reveal a two to sevenfold higher cell density in accretion ice than the overlying glacial ice, implying that Lake Vostok is a source of bacterial carbon beneath the ice sheet (Priscu et al., 1999; Christner et al., 2006). Data from the overlying accretion ice have been used to show that bacterial densities within Lake Vostok surface waters should be between 150 and 460 cells mL^{-1}.



Subglacial Lakes, Antarctic, Figure 1 Map of Antarctica showing location of known subglacial lakes (*yellow circles*) in relation to ice divides (*white lines*) and hydrologic potential (*colored contours*). Modified from Priscu et al., 2008).

These values indicate that Lake Vostok is a highly oligotrophic system supporting relatively low levels of biomass. Sequence data obtained from DNA encoding for small subunit ribosomal RNA revealed that the microorganisms within Lake Vostok do not represent an evolutionarily distinct subglacial biota (Priscu and Christner, 2004). The time scale of isolation within Lake Vostok (>15 $\times 10^6$ year) is not long in terms of bacterial evolution compared to their 3.7 $\times$ 10^9 year history on Earth, and studies of species divergence of other bacteria have shown that species level divergence may take ~100 million years. Evidence for the presence of hydrothermal input is supported by the recent interpretation of He^3:He^4 data from accretion ice, which implies that there may be extensive faulting beneath Lake Vostok, which could introduce geochemical energy sources to the southern part of the lake (Petit et al., 2005). If this emerging picture is correct, Lake Vostok could harbor a unique assemblage of organisms fueled by chemical energy. While it seems inevitable that viable microorganisms from the overlying glacial ice, and in sediment scoured from bedrock adjacent to the lake, are regularly seeded into the lake, the question remains whether these or preexisting microorganisms have established an ecosystem in Lake Vostok. If a microbial ecosystem were found to exist within the water or sediment of these subsurface environments, they would represent one of the most extreme and unusual ecosystems on Earth.

Summary

The past 10 years have seen the study of subglacial lakes go from a curiosity to a focus of scientific research. We now know that more than 150 lakes exist beneath the Antarctic ice sheets, some of which rival the largest surface lakes on our planet in terms of size. These lakes appear to play a role in ice sheet dynamics (Llubes et al., 2006; Bell et al., 2007) and may harbor novel microorganisms, the mediate important microbial transformations. Several national programs plan to penetrate the subglacial environment over the next 5 years (Priscu et al., 2005). Data from these expeditions will yield the first samples from these environments and will change our view of polar regions.

Definition

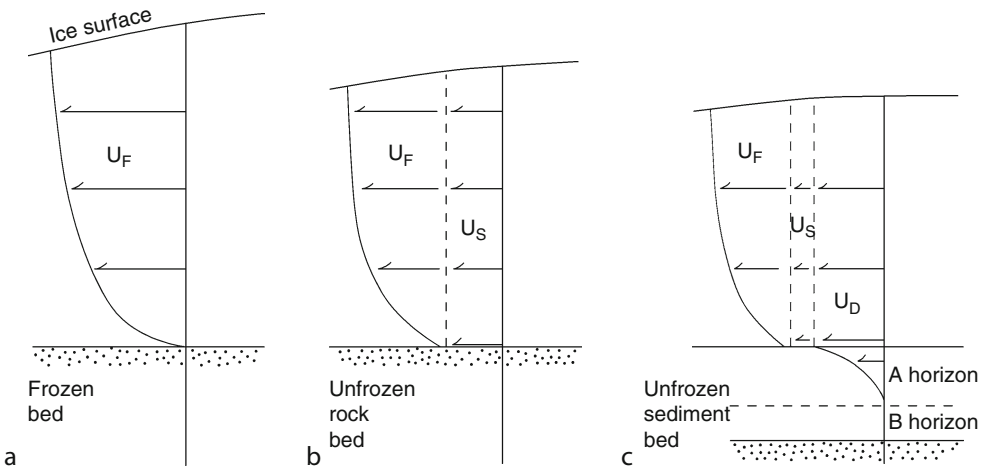
Subglacial processes are the thermal and mechanical processes immediately above and below the boundary between the ice and glacier bed that control glacier motion and processes of erosion, transportation, and deposition.

Introduction

In glaciology the term subglacial processes encompasses the thermal, mechanical, hydrological, and chemical processes that occur a few meters beneath and above the contact between a glacier and its substrate. These processes are of considerable importance because they determine the behavior of glaciers and ice sheets and are responsible for a range of phenomena that are expressed as spatial and temporal variations in the dynamic behavior of glaciers over a range of scales. Consideration of subglacial processes generally excludes processes that occur beneath floating ice masses. A recent, thorough review of subglacial processes was published by Clarke (2005).

Glacier beds

The nature and complexity of subglacial processes are controlled by the thermal conditions at the bed and by the material properties of the bed. The key thermal boundary condition at a glacier bed is the pressure melting point, which is the melting point of ice adjusted for pressure exerted by the weight of overlying ice. If the temperature is below the pressure melting point the ice is classified as cold-based and there is no bulk meltwater at the bed. In contrast, if the basal temperature is at the pressure melting point the glacier is classified warm-based and meltwater is freely available. Bed materials range from hard beds, which are characterized by lithified materials, to unconsolidated sediments such as till, sands, and gravels (soft beds). An additional complexity is that particles eroded from the bed can become entrained within the base of glaciers to form basal ice, which has mechanical properties that are quite distinct from ice of a meteoric origin (Fitzsimons, 2006). The combination of thermal and mechanical conditions, which can be simplified to three schematic velocity structures, are summarized by Figure 1.



Subglacial Processes, Figure 1 Vertical velocity distributions associated with different thermal and mechanical conditions at glacier beds: (**a**) Shows the velocity distribution associated creep of ice above a frozen bed composed of rock or sediment. (**b**) Shows the velocity profile associated with creep and sliding above a warm rigid bed. (**c**) Shows the velocity profile associated with creep, sliding, and subglacial sediment deformation above a warm deformable bed. From Boulton (1996). Reprinted from the *Journal of Glaciology* with permission of the International Glaciological Society.

Thermal and mechanical processes

Most of our knowledge of subglacial processes comes from warm-based glaciers that have hard or soft beds. Warm, hard-bed glaciers are characterized by well-developed subglacial drainage systems, movement by basal sliding, and relatively high rates of erosion by processes of abrasion and plucking. Warm-based glaciers with soft beds are characterized by either rapid sliding that is facilitated by high subglacial water pressures that can uncouple the glacier from its bed, and/or result in deformation of subglacial sediment due to a decrease in shear strength of unconsolidated sediment caused by high pore water pressure.

An experiment conducted by Boulton (1979) beneath an Icelandic outlet glacier concluded that approximately 90% of glacier motion could be attributed to deformation of the uppermost 0.5 m of saturated till that formed the glacier bed. In such a situation, the "effective bed" of a glacier, that is, the surface below which there is no movement, is below the interface between the ice and the sediment. In the 1980s, seismic studies of active ice streams in Antarctica identified the presence of a layer of porous, saturated material beneath the ice, which was likely to be too weak to rigidly support the weight of the overlying ice, and therefore was probably undergoing deformation (Blankenship et al., 1986; Alley et al., 1986). The possibility that ice streams move principally by deformation of subglacial sediment forced a major rethinking of different chapters of glaciology and glacial geology that has been described as a paradigm shift (Boulton, 1986; Murray, 1997). This major shift in thinking has led to a large volume of published research on the nature of subglacial processes associated with warm-based glaciers underlain by soft beds.

A major focus of research into subglacial sediment deformation has involved investigations into processes beneath fast-flowing ice streams that drain the West Antarctic Ice Sheet. Although the ice streams only account for about 10% of the volume of the ice sheet they make up for up to 90% of the ice discharged to the ocean because they reach speeds of over 1,000 m/year, and are up to 60 km wide and 2,000 m thick. Despite numerous investigations into the basal processes associated with the fast flow of Antarctic ice streams it remains unclear whether the high velocities are sustained by subglacial sediment deformation, by fast sliding of ice over the substratum, or by a combination of both. In addition, studies of formerly glaciated landscapes show that ice streams also form on hard beds (Stokes and Clark, 2003), which suggests that the development of fast ice flow cannot be solely attributed to the presence of warm-based ice and a soft bed. A further complexity in our understanding of ice streams is that velocity can vary considerably over a range of timescales. For example, variations in the surface velocity of Whillans Ice Stream have been attributed to a single tidal cycle that is propagated through an ice shelf (Bindschadler et al., 2003), whereas the Kamb Ice Stream appears to have ceased flowing rapidly about 150 years ago. These studies, together with more recent research on the relationship between surface melting and acceleration of glacier flow (Zwally et al., 2002; Rignot and Kanagaratnam, 2006), demonstrate that the temporal variability of ice stream behavior forms an important component of understanding of the response of glaciers to climate change. The increase in velocity has been attributed to an increase in surface meltwater that rapidly migrates to the bed causing an increase in water pressure, which reduces effective normal stress causing accelerated sliding and/or subglacial sediment deformation.

Studying subglacial processes

Despite the difficulties of gaining direct access to glacier beds numerous successful field experiments have been conducted in such environments. The development of rapid hot-water drilling has facilitated the observation of subglacial conditions using cameras. Hot-water drilling has also enabled the deployment of a range of instruments designed to measure subglacial sediment deformation, sliding, bed strength, basal water pressures, and to sample subglacial sediment. Borehole-based instrumentation for observing and measuring subglacial processes has been reviewed by Fischer and Hubbard (2006).

Experiments have been conducted at Svartisen Subglacial Laboratory beneath Engabreen in Norway where Cohen et al. (2000) installed a concrete obstacle to measure bed shear stress. A later study in the laboratory was conducted by Iverson et al. (2003) who blasted a cavity in the bed and filled with it sediment to simulate subglacial till. After the ice closed over the cavity, the effective normal stress was experimentally controlled by changing the pore water pressure. The results showed that the sediment underwent shear at intermediate pore water pressures and that at higher pressures the ice moved over the till by plowing without deforming the sediment.

Uncertainties and questions raised by field experiments have stimulated laboratory experiments on the behavior of subglacial materials. This work has included direct shear tests on sediment collected from the bed of Antarctic ice streams (Kamb, 1991) and the construction of a ring shear device that permitted study of the mechanical behavior of materials under conditions of high shear strains (Iverson et al., 1997). These experiments concluded that the properties of deforming till exhibit the behavior of Coulomb (frictional) plastic material and that resistance to shear varies linearly with effective normal stress. The spatial and temporal variability of such processes has been highlighted by modeling studies, which suggested that local weakening of subglacial sediment could occur due to high pore water pressures in front of objects being dragged through a bed (Iverson, 1999). Similar measurements have been made with a "ploughmeter" to measure force and subglacial water pressure (Fischer et al., 2001). These data suggest that rapidly sliding glaciers might move by plowing through unconsolidated subglacial sediment rather than by penetrative deformation. Although the full complexity of the behavior of warm-based, soft-bed glaciers has yet to be fully understood, there is a clear consensus that the basal hydrological system controls the transient behavior of coupling between the glacier and its bed and whether movement is achieved by sliding or subglacial sediment deformation.

Our understanding of subglacial processes beneath cold-based glaciers with soft beds has also been advanced recently through a combination of field experiments conducted in tunnels excavated in glaciers, laboratory experiments, and modeling (Echelmeyer and Wang, 1987; Cuffey et al., 2000a, b; Fitzsimons et al., 1999, 2000). These studies have shown that cold-based glaciers can slide and ice-rich subglacial permafrost can be deformed and eroded (Figure 2).

Subglacial Processes, Figure 2 A 4.5 m thick excavation in deforming subglacial permafrost beneath Wright Lower Glacier in the McMurdo Dry Valleys, Antarctica. Measurements over 3 years demonstrate that deformation extends more than 3.5 m beneath the ice-permafrost boundary and that most deformation is accommodated by ice-rich layers between frozen sediment layers. The bolts and stakes have been used to measure strain and velocity over a period of 4 years.

Erosion, transportation, and deposition

In addition to acting as an important control of glacier dynamics, subglacial processes are also responsible for the processes of erosion, transportation and deposition that occur at the beds of glaciers. Exchanges of material between the bed and the glacier have two principal outcomes: the formation of a distinctive type of ice at the base of a glacier (basal ice) and the formation of distinctive erosional and depositional landforms. Basal ice is characterized by a relatively high debris content which frequently results in a stratified or banded appearance, high solute concentrations, and distinctive gas and isotopic composition, all of which distinguish the ice from overlying ice that has a meteoric origin. Studies of the chemistry of ice from the beds of glaciers have yielded new insights into the basal boundary conditions when the basal ice formed (Souchez et al., 1993; Souchez and Lorrain, 1991; Sleewaegen et al., 2003). For example, study of the stable isotope characteristics of basal ice exposed at the edge of the Greenland ice sheet suggested that there is considerable spatial variability in ice sheet erosion processes (Sugden et al., 1987). The presence of solid and dissolved contaminants together with associated changes in crystal structure and size result in markedly different mechanical behavior of basal ice from overlying meteoric ice. As a result, the lower few meters of glaciers are characterized by very high strain rates concentrated within the debris-bearing ice. For example, "amber ice" that occurs at the base of glaciers in the McMurdo dry valleys has been recognized as being soft compared to overlying white ice (Holdsworth and Bull, 1970). Later research on amber ice demonstrated that the small crystal size (<1 mm) is directly related to high strain rates (Cuffey et al., 2000b; Samyn et al., 2005).

The landforms left behind by formerly more extensive glaciers during the Pleistocene are testament to the processes that operate beneath glaciers. A wide variety of landforms have been used in a variety of ways to reconstruct the dimensions, behavior, and impact of glaciers on landscapes. However, there remains considerable uncertainty as to the origin of many distinctive landforms such as drumlins. Theories concerning their origin range from subglacial floods to instabilities in deforming beds to episodic erosion and depositional events. The most recent developments in understanding subglacial landforms have been driven by the acquisition of high definition remotely sensed imagery, both terrestrial and marine, that have permitted detailed mapping of glacial landforms such as lineations and moraines associated with ice streams (O'Cofaigh et al., 2002; Stokes and Clark, 2003).

Summary

The last few decades have seen enormous advances in understanding how glaciers interact with the substrates over which they flow. The central issue in our recently acquired understanding is the role of subglacial water as a means of uncoupling glaciers from their beds whether this is accomplished by rapid sliding, or subglacial sediment deformation. However, we have yet to develop an understanding of how spatial and temporal variability in subglacial processes is translated into the behavior of large glacial systems. Such an understanding is a prerequisite for the development of ice sheet models that parameterize subglacial processes.

SUBGLACIAL VOLCANISM

Hugh Tuffen
Lancaster Environment Centre, Lancaster University, Lancaster, UK

Synonyms

Glaciovolcanism; Ice–volcano interaction

Definition

Strictly, volcanic activity beneath ice sheets or glaciers, but used generally to refer to volcanic eruptions where magma interacts with ice in any form, both on Earth and other planetary bodies (Glaciovolcanism). Subglacial volcanism may occur wherever volcanic vents are covered with bodies of ice, which may include small glaciers on the flanks of stratovolcanoes, substantial regional ice sheets, and even the Martian cryosphere (Smellie, 2000; Ice–Volcano Interactions).

Key localities of subglacial volcanism

Beneath past and present ice sheets: Iceland, Western Antarctic Ice Sheet, Antarctic Peninsula Ice Sheet, British Columbia.

At ice-covered stratovolcanoes: Andes, Cascades, Alaska, Aleutian Islands, Kamchatka

On other planets: Mars

Principal styles of subglacial volcanism

Tuya-building eruptions: Sustained, large-volume eruptions that melt through to the surface of ice sheets, forming distinctive "table mountains." Tuyas commonly consist of pillow lavas overlain by fragmental glassy volcanic deposits (hyaloclastites) that were emplaced within englacial lakes, and capped by subaerial lava flows formed when the ice surface was pierced (Smellie, 2000).

Tindar ridge-forming eruptions: eruptions from volcanic fissures beneath ice sheets that generate elongate ridges of pillow lavas and hyaloclastites. Example: Kalfstindar, Iceland (Smellie, 2000).

Magma–ice interaction at stratovolcanoes: interaction between lava or pyroclastic deposits and ice either on the flanks, or in the summit crater of a stratovolcano (Lescinsky and Fink, 2000).

The composition of magma erupted subglacially ranges from basalt to rhyolite (Smellie, 2000; McGarvie, 2009).

Hazards from subglacial volcanism

Melting of ice and snow can generate devastating meltwater floods (Guðmundsson et al., 1997; Glacier Lake Outburst Floods) and lahars (Major and Newhall, 1989). Explosive magma–meltwater interactions can lead to widespread ash fall.

Interesting features of subglacial volcanism

- The products of past subglacial eruptions can be used to reconstruct paleo-ice thicknesses in Iceland, Antarctica, and elsewhere (Smellie 2008; Ice–Volcano Interactions).
- Deglaciation is known to accelerate rates of volcanism in Iceland and other regions (Sigvaldason et al., 1992).
- Subglacial volcanoes may be an important environment for microbial life on Earth and even on Mars.

SUBGLACIAL WEATHERING

Markus Konz
Institute of Environmental Engineering, Hydrology and Water Resources Management ETH Zürich, Zurich, Switzerland

Subglacial weathering is the study of mechanical and chemical changes in soil and rocks due to physical (e.g., grinding) and chemical (e.g., dissolution) processes in glacial environments. The subglacial hydrochemistry governs the rates of biogeochemical denudation and carbon cycling. These processes can have a significant impact on global biogeochemical cycles (Jones et al., 2002). Effluent glacier water transports dissolved and suspended matters that have been mobilized due to subglacial weathering and which can be used to determine nutrient and metal export and cycling (Mitchell et al., 2001, 2006; Mitchell and Brown, 2007).

Hydrologists use chemical analysis of glacier water to infer hydrological flow-paths in glacial drainage systems (Brown et al., 1996; Mitchell et al., 2006). The chemical signature of water samples can indicate the configuration and evolution of subglacial drainage systems.

Subglacial environments feature tough conditions for life due to a combination of low temperatures and lack of energy sources. However, recent investigations indicate an important abundance of bacterial populations in this habitat (see Hodson et al., 2008 for a review). The presence of bacteria is important for subglacial weathering reactions and these in turn supply energy to maintain bacterial populations.

SUBLIMATION FROM SNOW AND ICE

A. K. Singh
DIAT (Deemed University), Girinagar, Pune, Maharashtra, India

The process of ice changing directly into vapor without any intermediate liquid stage is often described by sublimation. The opposite of sublimation is "deposition," where water vapor changes directly into ice. The sublimation of ice or snow is driven by an imbalance between the saturation vapor pressure (or vapor density) at a given temperature, and the vapor pressure in the immediate vicinity of an ice surface. Sublimation process in snow controls the grain shape and size. Snow sublimation rate can be defined as the amount of mass lost per unit time and depends on particle surface area to mass ratio, vapor pressure gradients, and rate of air exchange around the snow crystal surface. Typically, these rates are higher when large vapor pressure gradients exist and rapid air exchange occurs.

It is not easy to actually see sublimation occurring, especially for ice. Sublimation occurs more readily when certain weather conditions are present, that is, on a dry and windy day with low relative humidity. Sublimation also occurs more at higher altitudes, where the air pressure is less than at lower altitudes. Sublimation is fairly slow since it takes quite a bit of energy for an ice molecule to escape the solid rigid structure to a gas. Sublimation will be enhanced under direct sunlight since photons of solar energy will add the energy necessary for solid ice molecules to escape. Sublimation will occur even at low sun angles but the amount of sublimation will be very weak. Since sun angle is a minimum at the start of winter and much higher in late winter, the sublimation power of the sun on surface snow will be much higher in late winter as compared to early winter on sunny days.

The sublimation rate of ice or snow has important implications on surface energy balance calculations, mass balance calculations, and studies of snow metamorphism.

SUMMER ACCUMULATION TYPE GLACIERS

Nozomu Naito
Department of Global Environment Studies, Hiroshima Institute of Technology, Hiroshima, Japan

Synonyms

Summer-accumulation type glacier

Definition

Accumulation. The process of adding of snow or ice to a glacier or its amount. Snowfall is generally the most popular process. In addition, frost, avalanche, refreezing of melt water, and catchment of blowing snow are other possible processes.

Ablation. The process of losing of glacier ice or snow or its amount. Melting is generally the most popular process. Then, evaporation, removal of snow by wind, and calving of icebergs are also possible.

Mass balance. The net mass change of glacier; accumulation subtracting ablation.

Introduction

Classical glaciology was initiated and has been developed through studies on glaciers in Europe and North America, where the main accumulation to the glaciers is snowfall in winter, and the main glacier ablation occurs in summer. The *Mass balance* of the glaciers is usually positive in winter, negative in summer, and then the annual *mass balance* is determined by the deduction of these two seasonal components. On the other hand, glaciers in Asia have been observed to have different characteristics since the 1970s (e.g., Ageta et al., 1980; Xie, 1980). These glaciers receive more accumulation in summer than in winter, and such glaciers have been called as *summer accumulation type glaciers* (Ageta, 1983; Ageta and Higuchi, 1984). In this definition, the periods of summer and winter are not explicitly defined, but they are generally regarded as warm and cold half years, respectively. Because climate in most parts of Asia is influenced by summer monsoon, most of the annual precipitation is concentrated in summer, while winter is cold but is a relatively dry season. Successive studies carried out on glaciers around the Himalayas and Tibetan Plateau have clarified that the *summer accumulation type glaciers* are very sensitive to changes in air temperature, as explained in what follows. Thus, *summer accumulation type glaciers* are considered to be much vulnerable to global warming.

Distribution

Summer accumulation type glaciers are extensively distributed in Asian highland regions influenced by Asian summer monsoon, i.e., the Himalayas, Tibetan Plateau, Qilian Mountains, Kunlun Mountains, Tien Shan, Pamir and so on. The Karakoram, however, is rather influenced by the westerlies, and receives much winter accumulation. In addition to the Asian glaciers, a part of the Andean glaciers are also revealed to be *summer accumulation type*, from an objectively analyzed meteorological datasets (Fujita, 2008).

Characteristics of mass balance

As most of the annual accumulation and ablation occur simultaneously in the same season on *summer accumulation type glaciers*, a change in climatic conditions in summer can induce a more drastic change in the glacier *mass balance* than that in winter. For example, an increase in summer air temperature will usually increase melting of glaciers. On the other hand, it will also decrease the snow fraction in precipitation, thereby decreasing accumulation. Moreover, it will lower the surface *albedo* of glaciers, thereby increasing absorption of solar radiation and melting. Thus, warming in summer has three negative effects on the *mass balance* of *summer accumulation type glaciers* (Ageta, 1983). In usual cases, warming in winter does not have such severe effects on the *mass balance* as warming in summer, because winter temperature is low enough below the melting point of ice.

As follows, the *albedo* effect on *mass balance* is probably the most important feature for *summer accumulation type glaciers*. Snowfall in summer keeps high *albedo* on the glacier surface and depresses melting. Due to this effect, the *equilibrium line altitude*, where the annual *mass*

balance is zero, is quite lowered, compared with a contrasting *winter accumulation type glacier*, which is assumed to have the same climate conditions except for only the seasonality of precipitation (Fujita and Ageta, 2000). In other words, *summer accumulation type glaciers* can exist as they are, owing to summer *accumulation*. In the case of winter accumulation, they should be smaller at higher altitudes or could not exist at all.

Sensitivity to climate changes

The above-mentioned significant characteristics in the *mass balance* of *summer accumulation type glaciers* deduce their high sensitivity to global warming, which have been investigated through numerical experiments. Not only *mass balance* but also dynamical response of *summer accumulation type glaciers* is more sensitive to temperature changes than that of *winter accumulation type glaciers* (Fujita and Ageta, 2000; Naito et al., 2001). On the other hand, the dynamical response to precipitation changes is more sensitive in the *winter accumulation type glaciers* (Naito et al., 2001). Moreover, precipitation seasonality and its concentration have a larger effect on the *mass balance* sensitivity to warming than latitude and the annual amount of precipitation (Fujita, 2008). These results indicate that forecasting the shrinkage of *summer accumulation type glaciers* to global warming requires an adequate consideration of their unique characteristics beyond simply applying any empirical relationship obtained for *winter accumulation type glaciers*.

Summary

Summer accumulation type glaciers receive more snowfall in summer than in winter. They are extensively distributed in Asian highland regions under summer monsoon climate, and parts of Andes. This type of glaciers are likely quite vulnerable to global warming, as decreasing summer snowfall reduces the surface *albedo*, and accelerates melting. In order to evaluate future shrinkages of this type of glaciers, the specific characteristics in their *mass balance* should be taken into account.

SUPER COOLING CLOUDS

P. Pradeep Kumar
Department of Atmospheric and Space Sciences, Pune University, Pune, India

As cloud forms and ascends it may be cooled to temperatures below 0°C. The water drops are expected to freeze, but in natural clouds this may not happen. Whether the water drops will freeze or not depends on the number of ice nuclei present in the cloud. Such drops are called as supercooled drops. For pure water droplets, the homogeneous freezing does not occur till −40°C. Supercooling of clouds till −15°C are not uncommon.

SUPERCOOLED WATER

Simon Cook
Centre for Glaciology, Institute of Geography & Earth Sciences, Aberystwyth University, Ceredigion, Wales, UK

Synonyms

Undercooling

Definition

Supercooled water. Water that remains in a liquid state when cooled below its melting (freezing) point.

Introduction

The freezing point of water (or the melting temperature of ice) varies depending upon the ambient pressure, the solute content of the water, whether the water is kept turbulent, and, where water and ice exist in soils or sediments, the interfacial forces between liquid water and ice. Typically, we think of water as a substance whose phase changes from liquid to solid as we cool it to 0°C, but there are several situations within cryospheric environments where water may exist in a liquid state at a temperature below the ambient freezing point. In this situation the water is referred to as being supercooled.

The transition of water to ice

As Block (2003) describes, the transition of water to ice via crystallization involves three stages: (1) supercooling, (2) formation of an ice nucleus, and (3) freezing to produce an ice crystal and growth of an ice front. Solutions supercool to varying degrees before spontaneously freezing. For example, perfectly pure and still water can remain liquid when cooled to approximately −40°C (Davis, 2001). In this supercooled state, liquid water is thermodynamically less stable than ice but it will remain in the liquid phase unless perturbed beyond a certain threshold. Such perturbations to the system could include further cooling, agitation of the water, or introduction of a freezing nucleus such as a sediment grain (seeding).

Pressure

The pressure dependence of the temperature at which ice melts and water freezes is of fundamental consequence to many aspects of cryospheric science. At atmospheric pressure, water will freeze at a temperature of 0°C, but with an increase in ambient pressure, the freezing point is depressed at a rate of 0.072°C per MPa (1 Pa = 1 N per square meter). So, for example, beneath glaciers and ice sheets, the freezing point of water is depressed by the pressure exerted by the ice thickness. The pressure beneath 2,000 m of ice is ∼17.6 MPa giving a melting point of −1.27°C (Benn and Evans, 1998). This pressure-determined melting/freezing temperature is referred to as the pressure melting point. Water at −1.27°C beneath 2,000 m of ice is not considered supercooled because its temperature is in equilibrium with the ambient pressure, but if that water were to flow from this area of high pressure to an area of lower pressure without freezing then it would be supercooled (e.g., Röthlisberger, 1968, 1972; Röthlisberger and Lang, 1987).

Glaciohydraulic Supercooling (qv) is a process that allows subglacial water to exist in a liquid state beneath ice masses in response to such pressure changes, and subsequently for this supercooled water to freeze to the glacier base to produce *basal ice* (qv *Formation and Deformation of Basal Ice*) and clog subglacial watercourses (e.g., Alley et al., 1998; Lawson et al., 1998; Cook et al., 2006). This mechanism of supercooling is implicitly associated with the flow of subglacial water through topographic basins or "overdeepenings." At the base of the overdeepening, the melting temperature is depressed beneath thick ice. As water is forced along a pressure gradient to ascend the reverse slope out of the overdeepening, the pressure melting temperature gradually rises toward 0°C as the overburden pressure decreases beneath thinner ice at the margin. For the water to remain in thermal equilibrium with the overlying temperate ice, the water must also warm as it moves along the gradient of decreasing pressure. Heat can be provided by a variety of potential sources, including: (a) viscous dissipation associated with water flow, (b) geothermal heat flux, (c) basal sliding, and (d) latent heat release if part of the water freezes. However, thermodynamic calculations suggest that if the adverse bed slope is sufficiently steep (more than 1.2–1.7 times the gradient of the ice-surface slope) then the heat generated and the rate of increase in water temperature will be insufficient to match the changing pressure melting point and it will become supercooled (Röthlisberger, 1972; Hooke, 1991; Alley et al., 1998). The minimum gradient of the adverse slope to allow supercooling varies dependent upon the air saturation state of the water. For the water to remain in thermal equilibrium with the overlying temperate ice, some of it must freeze to release latent heat, resulting in the production of *Frazil ice* (qv) (porous aggregates of lozenge-shaped crystals) and *Anchor Ice* (qv) (ice platelets anchored to the glacier or substrate). Sediment-laden water percolates through anchor and frazil ice until pore spaces freeze shut, and subsequent debris – ice segregation produces debris-laden basal ice (Alley et al., 1998; Lawson et al., 1998). The melting of this basal ice is suggested to have important implications for glacial geomorphology and landscape development (e.g., Larson et al., 2006), although there is still much uncertainty about the controls on the temporal and spatial pervasiveness of the process (e.g., Tweed et al., 2005; Cook et al., 2007).

Solutes

The presence of solutes within water may also depress its freezing point. In glaciers, the presence of solutes has an important impact on ice flow. The influence of solutes on the strain rate of glacier ice is variable as different solutes can either harden, soften, or have no effect on the ice (Nakamura and Jones, 1973). However, in situations where high solute concentrations act to depress the freezing point of water between ice crystals, the *Creep* (qv) of glacier ice may be enhanced (e.g., Wolff et al., 1988). Shreve (1984) demonstrated that glacier sliding could also be enhanced by elevated levels of solutes, in this case by sodium chloride (salt).

The depression of the freezing point by salt is of particular significance to sea ice scientists where supercooling and frazil ice formation occur as a result of differences in the salinities of waters. Martin (1981) explains that water becomes supercooled and produces frazil ice in Arctic river mouths or beneath pack ice where a layer of fresh meltwater at its freezing point (0°C) overlies a layer of

seawater at its freezing point (−1.6°C). Between 0.2 to 0.3 m of fresh water ice can grow beneath melting pack ice during the polar summer. Tsang and Hanley (1985) conducted experiments on ice formation for different supercoolings and initial salinities. Their results showed that the rate of frazil ice production was faster in fresh water than in saline water demonstrating that rates of sea ice formation depend to some extent on local salinity levels.

Block (2003) explains how, for terrestrial invertebrates which live in cold environments, solutes are important in maintaining body fluids in a liquid state. These "freeze avoiding" species may possess thermal hysteresis proteins (THPs) which depress the freezing point relative to the melting point of the body fluids, and which may be present together with compatible solutes that act as antifreezes (e.g., polyhydric alcohols and sugars).

Turbulence

The freezing point of water may be depressed by turbulence. This effect can pose a significant problem in rivers where frazil ice growth from turbulent supercooled water interrupts the operation of hydroelectric power stations (Martin, 1981). At low turbulence, frazil ice will float to the surface where it forms a pan, whereas when turbulence is high, frazil ice can be entrained into the flow and be carried to the bottom where it may attach to the channel bed and form anchor ice (Doering et al., 2001). Anchor ice can therefore alter the hydraulic characteristics of the flow. For example, the upper Niagara River experiences flow reductions of 20–30% as a result of anchor ice growth (Arden and Wigle, 1972).

Martin (1981) described how supercooling and frazil ice formation occur at the ocean surface due to the effect of turbulence. For leads (open water less than 100 m wide) and polynyas (width scale larger than 100 m) frazil ice will form where cold winds blow across regions of open water that is at the freezing point, agitating the water. In leads, frazil ice crystals form throughout the open water and are piled up to depths of 0.1–0.3 m at the edge of the lead due to wind and wave action. In polynyas, frazil ice tends to pile up in streaks aligned with wind direction to depths of around 1 m.

Interfacial effects

Soils and sediments encountered within cryospheric environments (i.e., permafrost and subglacial tills) can comprise a mixture of solid particles, air, ice, and liquid water. Supercooled water may exist in such situations as a consequence of solute content but of additional importance is the effect of premelting which itself can result from three related effects:

1. Ice–water interfacial tension – Interfacial tension results at an ice–water interface because of strong intermolecular forces between liquid water molecules at the interface. Hence a thin layer (on the order of nanometres) of supercooled liquid water will separate an ice lens growing in permafrost from a sediment particle (Rempel et al., 2004). Where the ice surface itself is curved, this will tend to promote the supercooling of pore-water that exists between sediment grains close to the ice front (Rempel et al., 2004).
2. Interfacial curvature – Higher interfacial tension is also promoted by enhanced curvature of sediment grains such that the finer grained a sediment is, the higher the curvature of the interface and the greater the depression of the freezing point (Christoffersen and Tulaczyk, 2003a; French, 2007).
3. Adsorption of liquid water onto a solid particle – The mineral properties of the soil particle also affect the thickness of the water layer that may be adsorbed to it (French, 2007). Adsorption refers to the forces that emanate from the particle surface which reduce the free energy of the water film.

Some important consequences of these effects include ice frost heaving in permafrost environments, and glacier motion. The deformation of the ground level in permafrost environments during winter cannot be fully explained by the volumetric expansion of water on freezing. Instead, it is due to the migration of premelted ice within the permafrost to a freezing front to produce segregation ice. The basic forcing mechanism is the repulsion between soil and water particles across the premelted water film which gives rise to low pressure within the water film (Rempel et al., 2004). Thus water in the surroundings is drawn toward the low pressure ice–water freezing interface where it may be frozen to produce segregation ice. Continued growth of the ice lens in this manner causes the ground to rupture – a process typically referred to as frost heaving (Dash et al., 1995).

Christoffersen and Tulaczyk (2003a, b) described a process of basal freeze-on beneath ice streams analogous to the process of frost heave in permafrost environments. In fine-grained subglacial till, water is unable to freeze due to interfacial effects and insufficient space for crystal growth. In polar ice streams, basal temperatures may be reduced by ice thinning, or by fast downward advection of cold surface ice. Reduced basal temperatures are accompanied by a decrease in water pressure at the ice–water interface producing a hydraulic gradient that drives the supercooled pore-water to the freezing front where it freezes to produce basal ice. Dewatering of the till in this manner causes it to consolidate and hence ice stream motion, which had once been accommodated by deformation of the saturated till layer, slows to the point of stagnation.

The existence of liquid water within glacier ice and subfreezing subglacial sediments is of fundamental importance for glacier motion of *Cold-Based Glaciers* (qv) and their geomorphic potential (Waller, 2001). Andersland and Alnouri (1970) demonstrated that at −12°C, frozen sand is much more resistant to loading than frozen clay because liquid water exists between clay particles due to interfacial effects, whereas water is completely frozen in

the sand sample. Echelmeyer and Zhongxiang (1987) suggested similarly that the existence of liquid water within subglacial sediments beneath Urumqi No. 1 Glacier reduced its creep strength by over 100 times relative to ice at a similar stress and temperature, enabling it to deform. This is contrary to previously held assumptions that cold-based glaciers were effectively frozen to their beds and were hence incapable of performing geomorphic work (e.g., Boulton, 1972).

Droplet size

When water is dispersed as tiny droplets in clouds, it can remain in a supercooled state in supercooled clouds. Clouds consist of water droplets at temperatures down to −12°C. *Rime Ice* (qv) may form from such masses of supercooled vapor or from water vapor carried by wind. On glaciers, rime ice development is most rapid in cool, humid conditions on surfaces that are exposed to wind (Benn and Evans, 1998). Rime ice formation can have a major impact on power supplies and telecommunication towers where it grows around cables and structures until they collapse under the additional weight (Makkonen, 2000). Rime ice accretion is also a major consideration in aeronautical engineering because aircraft must be resistant to rime ice formation since they routinely fly through supercooled vapor (Gent et al., 2000).

Summary

Whilst the transition from liquid water to ice is typically considered to occur at 0°C, there are a number of reasons why water can exist in a supercooled liquid state below this freezing point. Furthermore, the existence of supercooled water in the cryosphere has fundamental implications for important phenomena including frost heave of permafrost, glacier motion and dynamics, sea ice formation, the clogging of rivers and hydroelectric power inlets with frazil ice, and the design of power and telecommunications infrastructure and aircraft.

SUPRA-GLACIAL DEBRIS ENTRAINMENTS

D. P. Dobhal
Wadia Institute of Himalayan Geology, Dehradun, India

Supra-glacial debris entrainments is defined as an unsorted and unstratified accumulation of sediments carried by the glacier along the bed and valley sides and deposited directly on glacier surface. They may occur by regelation or by the ice simply picking up the debris.

SURFACE ENERGY BALANCE

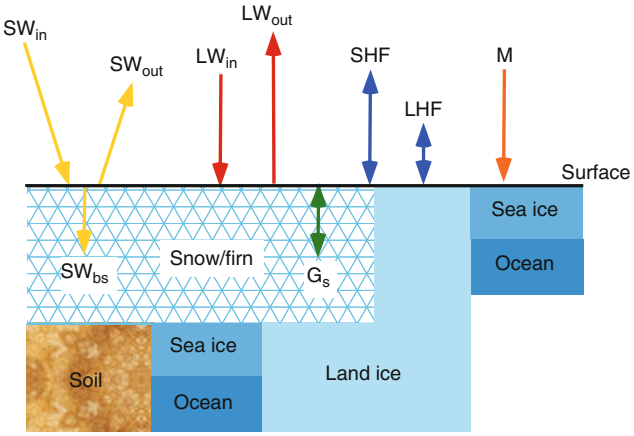
Definition

The surface energy balance (SEB) describes the partitioning of energy fluxes toward and away from the surface. The local SEB determines the surface temperature of the Earth (T_s) and the associated exchange of energy between the surface and the atmosphere on one hand, and between the surface and the subsurface layers (whether it be soil, rock, water, snow, or ice, see Figure 1) on the other. When the surface consists of snow or ice, the SEB also determines the amount of energy that is available for sublimation and melting/freezing. These processes directly couple the SEB to the *surface mass balance* (SMB). In this entry, we describe the components of the SEB, and give six examples of the annual SEB cycle, all with a permanently snow-/ice-covered surface, but in widely varying geographical settings.



Surface Energy Balance, Figure 1 Components of the surface energy balance of snow, sea ice, and land ice. Length of arrows is only indicative.

Components of the surface energy balance

The SEB is defined as the sum of all fluxes of energy passing each second through a horizontal surface of unit area (Figure 1), with units J s^{-1} m^{-2} or W m^{-2}. *We define fluxes as positive when they are directed toward the surface,* i.e., *when they represent an energy gain for the surface.* For an infinitesimally thin surface layer without heat capacity (sometimes called a *skin layer*), these fluxes *balance,* i.e., their sum equals zero. If we neglect the heat added to the surface by falling snow, rain, or fog droplets, the SEB over a snow/ice surface can be written as:

$$M = SW_{in} + SW_{out} + SW_{bs} + LW_{in} + LW_{out} + SHF + LHF + G_s \left[Wm^{-2}\right] \quad (1)$$

In Equation 1, M is the melting flux when T_s equals 273.15 K, otherwise M = 0. Note that the melting temperature for sea ice surfaces can be lower than 273.15 K because the ice is saline in most cases. If $T_s < 273.15$ K and if there is liquid water available at the surface, M represents the freezing flux.

The abbreviations SW_{in} and SW_{out} represent the incoming and outgoing fluxes of shortwave (solar) radiation, SW_{bs} is the amount of shortwave radiation that is absorbed below the surface. LW_{in} and LW_{out} are the incoming and outgoing fluxes of longwave (terrestrial) radiation. Shortwave and longwave radiation are distinguished on the basis of their wavelength domain, determined from Planck's law by the temperature of the body that emits the radiation. If radiation originates from the surface of the Sun ($T_s \approx 5{,}800$ K), either directly or scattered in the Earth's atmosphere, nearly all energy is confined to wavelengths below 3 μm, hence the name *shortwave radiation*. If the radiation originates from the Earth-atmosphere system ($T_s \approx 200$–300 K), nearly all energy derives from wavelengths greater than 3 μm, hence the name *longwave*

radiation. SW and LW radiation fluxes are measured directly with broadband radiation sensors using selective filters.

At a sufficiently small distance above the surface, in the order of one to several mm, sensible heat exchange (SHF) and latent heat exchange (LHF) between the surface and air occurs predominantly by molecular conduction. Higher in the atmosphere, turbulence occurs as eddies (whirls) that vertically mix momentum, heat, and moisture. Turbulence is more effective in transporting scalars than molecular diffusion (Stull, 1988), and SHF and LHF are dominated by turbulent exchange. That is why they are usually referred to as *turbulent fluxes.*

Finally, G_s is the vertical heat flux below the surface, an expression of the molecular conduction of heat along temperature gradients in the snow/ice. The energy coming from the interior of the Earth, the geothermal heat flux, usually does not exceed 0.1 W m^{-2}, and is incorporated in G_s. The major components of the SEB are discussed separately below.

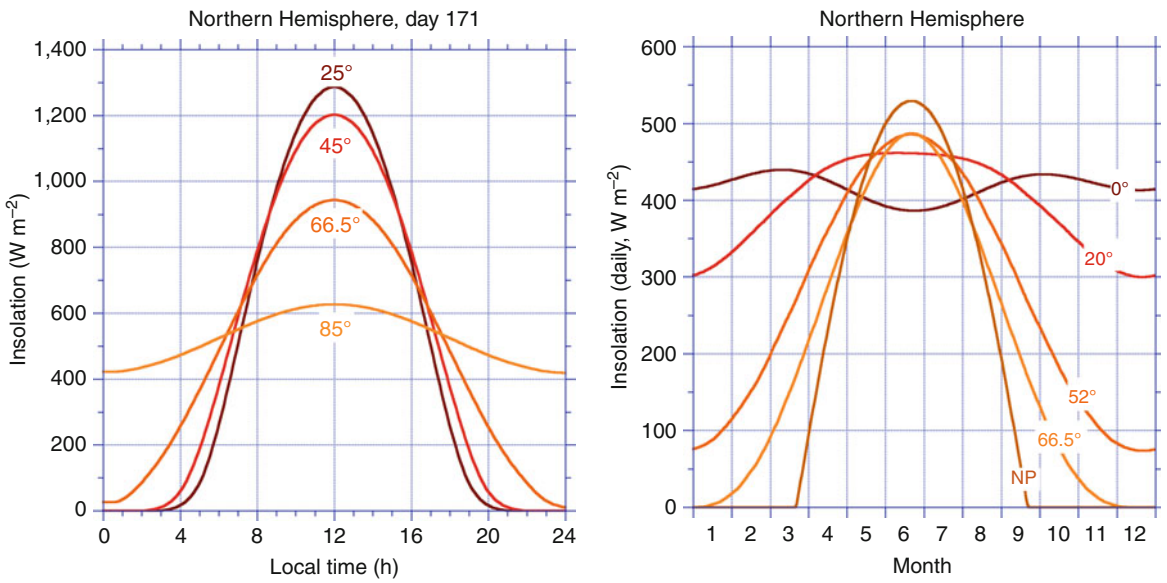
Shortwave radiation fluxes

When solar radiation impinges on the snow/ice surface, a part is absorbed at the surface, another part is reflected back to the atmosphere, and a third part penetrates to deeper layers and is absorbed below the surface. The net shortwave radiation flux (SW_{net}) is the total amount of shortwave radiation that is absorbed at or below the snow/ice surface. SW_{net} therefore equals the sum of downward (SW_{in}) and upward shortwave radiation (SW_{out}), and drives the daily and annual cycle in most SEB components.

SW_{in} is determined by (a) the amount of solar radiation impinging on the top of the atmosphere, (b) the amount of shortwave radiation that is scattered or absorbed in the atmosphere (depending notably on the cloudiness), and (c) the slope magnitude and orientation of the snow/ice surface. The instantaneous amount of solar radiation impinging on the top of the atmosphere (SW_{TOA}) depends on the solar constant, latitude, time of year, and time of day. Averaged over the year, the geographic poles receive about 40% of the insolation at the equator. But the temporal distribution of this energy is very different for different latitudes. As a rule of thumb, high-latitude (polar) regions experience a small daily cycle and a large annual cycle in SW_{TOA}, while tropical regions experience a large daily cycle and a small annual cycle in SW_{TOA} (Figure 2).

The amount of shortwave radiation that is scattered or absorbed in the atmosphere depends on the optical thickness of the atmosphere, which is mainly a function of vertically integrated water vapor mass and liquid water mass (clouds). The vertically integrated aerosol content also is important for shortwave radiation scattering. In the Polar Regions and for highly elevated tropical glaciers, the water vapor and aerosol content of the atmosphere is relatively low, so that the optical thickness is relatively small and the shortwave radiation intensity at the surface high. Explosive volcanic eruptions reduce the amount of solar energy reaching the surface; the El Chichón and Mount Pinatubo eruptions in 1983 and 1991 significantly impacted the SEB of Greenland (Fettweis, 2007). Glaciers or ice caps that are situated in temperate climates usually experience more cloudy conditions, limiting the amount of shortwave radiation that reaches the surface.

The orientation of glaciers with respect to the sun influences the amount of shortwave radiation impinging on the surface. If a glacier surface is steeply sloping and directed toward the sun, this can greatly enhance the amount of



Surface Energy Balance, Figure 2 SW_{in} at the top of the atmosphere. Daily cycle in the northern hemisphere for June 20th (*left*) and annual cycle for the northern hemisphere based on daily means (*right*) of SW_{TOA} for various latitudes.

absorbed solar radiation and hence melting. On the other hand, if the sloping glacier is directed away from the sun, the solar rays hit the surface at an oblique angle, thereby decreasing the amount of shortwave radiation reaching the surface. Moreover, the surface can be shaded for parts of the day, eliminating the direct component of SW_{in}. For glacier melt modeling, the orientation of the glacier surface and the surrounding topography, therefore, needs to be explicitly taken into account (Klok and Oerlemans, 2002).

Part of the absorption (SW_{bs}) takes place below the surface (Grenfell and Maykut, 1977). Typical penetration depths are several cm in fine, dry-grained snow to several decimeters in ice (Brandt and Warren, 1993). This results in heating of the subsurface snow and ice layers (Kuipers Munneke and others, 2009) and may lead to subsurface melting (Van den Broeke and others, 2008b). When calculating the penetration of shortwave radiation in ice/snow, it is essential that the wavelength dependence of shortwave radiation absorption is taken into account, instead of using a bulk-extinction coefficient.

The fraction of shortwave radiation that is absorbed at or below the surface, is determined by the broadband surface albedo α, defined as:

$$\alpha = |SW_{out}|/SW_{in} \quad (2)$$

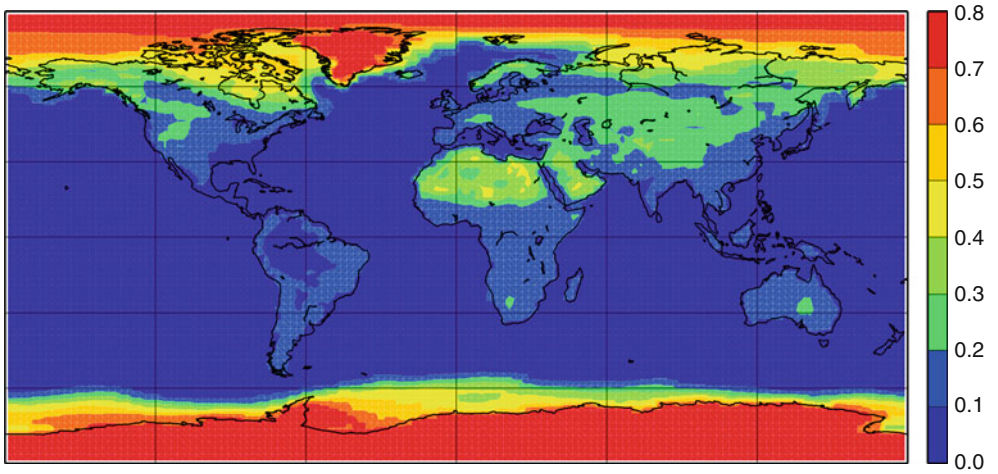
Snow albedo depends on the thickness, aerial coverage, and physical characteristics of the snow (grainsize, wetness, temperature), the thickness of the snow layer over dark soil and the spectrum and direction of the impinging solar radiation (wavelength distribution, solar zenith angle, ratio of diffuse to direct radiation, see Wiscombe and Warren, 1980, and entry on snow albedo). Clean, dry ice has an albedo of approximately 0.55, while clean, fresh snow has an albedo ~0.85. The albedo of water (<0.1) is much lower than that of snow and ice, and meltwater that accumulates at the snow/ice surface can therefore have a significant impact on its albedo (Greuell, 2000).

Melting leads to rapid growth of snow grains and can lower the snow albedo to values near 0.75, i.e., increasing the amount of absorbed shortwave radiation by ~70% compared to fresh snow. This represents the all-important albedo-melt feedback: melting lowers the albedo, which further enhances melt, etc. Typical low-ranging values of albedo (0.15–0.4) are found over ice and snow with a large dust load. The dust could have been melted out from the ice or blown onto it from the ice-free surroundings (Oerlemans and others, 2009). When seasonal snow or sea ice is replaced by the darker soil or sea surface, the amount of absorbed solar radiation may increase severalfold.

Figure 3 shows the global distribution of annual mean surface albedo, as derived from satellite measurements and radiative transfer modeling. The impact of snow and ice at high latitudes is clearly visible. The highest values (>0.8) are found over the interior dry snow zones of Greenland and Antarctica. The Arctic sea ice cover has a lower albedo, because it is melting for part of the year. The gradual transition toward lower values at mid-latitudes takes place over areas that are covered by seasonal snow or sea ice for part of the year. In the entry on snow albedo, the annual cycle of the albedo of Arctic sea ice is presented.

Longwave radiation fluxes

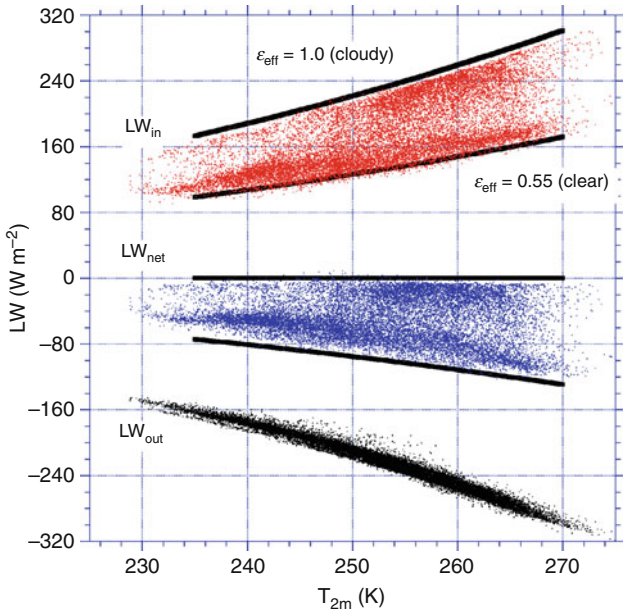
The net longwave radiation flux (LW_{net}) is the sum of incoming (LW_{in}) and outgoing (LW_{out}) longwave radiation fluxes. Over Greenland, LW_{in} appears the most sensitive SEB component for increased atmospheric concentrations of Greenhouse gases (Fettweis, 2007). Apart from exceptional cases, LW_{net} represents an energy loss for the surface, as the surface is generally warmer and has higher emissivity than the overlying atmosphere.



Surface Energy Balance, Figure 3 Satellite-derived surface broadband albedo, annual mean (based on data of Hatzianastassiou and others, 2004).

LW_{in} is determined by the effective emissivity (ε_{eff}) and effective radiation temperature (T_{eff}) of the atmosphere, while LW_{out} is determined by the emissivity (ε_s) and temperature (T_s) of the snow/ice surface. Using the Stephan–Boltzmann law, LW_{net} can be approximated by:

$$LW_{net} = \varepsilon_s \varepsilon_{eff} \sigma T_{eff}^4 - \varepsilon_s \sigma T_s^4 \quad (3)$$



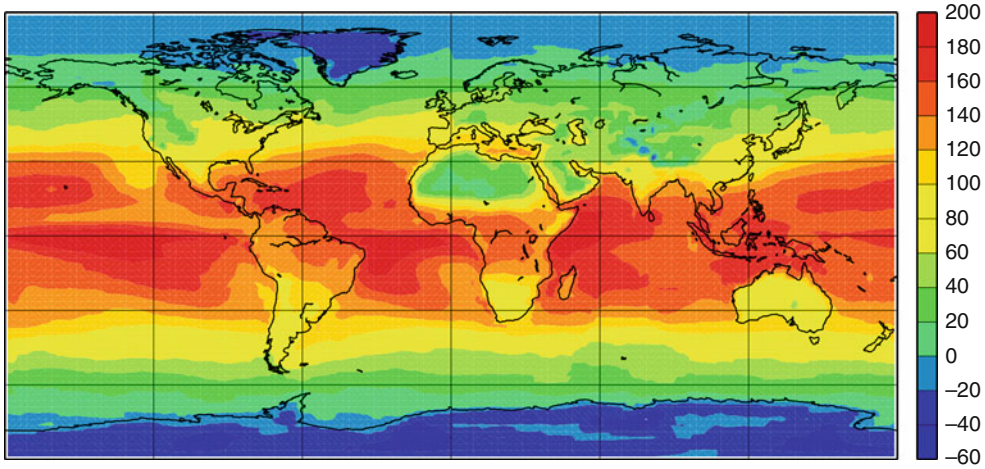
Surface Energy Balance, Figure 4 Observed hourly mean values of LW_{in} (*red dots*), LW_{out} (*black dots*), and LW_{net} (*blue dots*) as well as calculated from empirical formula (black lines, Equation 3) as a function of 2 m temperature for a non-melting location in Antarctica, at 1,100 m a.s.l. The upper and lower bounds of all three cases are for cloudy and clear sky conditions, respectively.

where the Stefan–Boltzmann constant $\sigma = 5.67 \times 10^{-8}$ W m^{-2} K^{-4}.

The surface emissivity of a dry snow surface is close to unity ($\varepsilon_s \approx 0.98$, Wiscombe and Warren, 1980) while the effective emissivity and radiation temperature of the atmosphere are complex functions of the vertical distribution of temperature, moisture, and other atmospheric compounds. In spite of this complexity, some general statements can be made. Under cloudy conditions, $\varepsilon_{eff} \approx 1$, and T_{eff} represents the cloud base temperature. When the cloud base is situated at low elevation, T_{eff} will not deviate much from T_s, so that LW_{net} will be zero or weakly negative. Under clear sky conditions, if 2 m air temperature is used as a measure for effective atmospheric radiative temperature, it is found that ε_{eff} can be approximated by a constant, to be determined empirically. Figure 4 shows an example for a location in Antarctica, where $\varepsilon_{eff} \approx 0.55$ (thick black lines in Figure 4). The resulting expression can be used to estimate LW_{in} and, if T_s is known (or assumed approximately equal to T_{2m}), to estimate LW_{out} and hence LW_{net}. The challenge lies in estimating LW_{in} for partly cloudy conditions, i.e., to interpolate between these two extremes (Kuipers Munneke and others, 2010).

Net radiation flux

Averaged over the year, $R_{net} = SW_{net} + LW_{net}$ is negative over much of the Polar Regions and in some highly elevated plateaus away from the Poles (e.g., the Tibetan Plateau, Figure 5). At these locations, cooling by LW_{net} exceeds warming by SW_{net}. This is remarkable, given that the Sun provides radiative energy for half of the time. The radiation deficit in the Polar Regions can be explained by factors that limit SW_{net}, such as the low Sun angle and the high albedo of the surface that usually consists of snow, glaciers, and sea ice. On the other hand, the snow effectively emits longwave radiation ($\varepsilon_s \approx 1$) while the polar



Surface Energy Balance, Figure 5 Annual average surface net radiation in W m^{-2} (*based on data of* Hatzianastassiou and others, 2004).

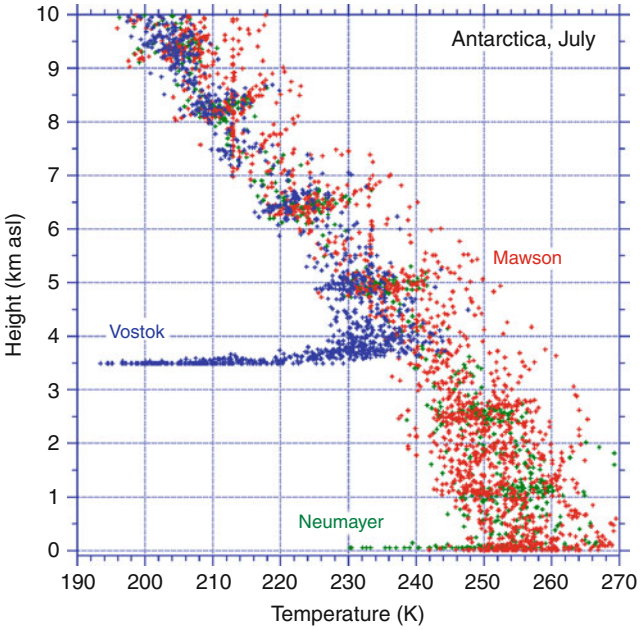
atmosphere is cold and dry, resulting in small ε_{eff}. This results in relatively strongly negative values of LW_{net}. Even at these sites, R_{net} will become positive around noon during sunny summer days, but when averaged over the year, the radiation balance is negative. Over a semi-infinite snow pack, this radiation deficit must be compensated by the sensible heat flux from the atmosphere, as the heat flux from the snowpack equals approximately zero when averaged over the year (see Section Subsurface heat flux). The latent heat flux is also likely to be small at polar sites (see Section latent heat flux), so that the most likely candidate is a flux of sensible heat from the atmosphere to the surface (next Section "Sensible heat flux"). Over sea ice, heat provided by the ocean through the subsurface heat flux compensates an important part of the radiative heat loss. Over open water in winter, much of the radiative heat loss is invested in cooling the upper ocean layers, resulting in the formation of sea ice.

Sensible heat flux

The turbulent flux of sensible heat, SHF (often referred to as the sensible heat flux), describes heat exchange between the surface and the air above it. In the surface layer, SHF can be directly measured using sonic anemometers that measure rapid (turbulent) fluctuations in temperature and vertical velocity. But these instruments are relatively vulnerable and expensive, which is why the sensible heat flux is often calculated, based on measured profiles of wind and temperature, in combination with surface-layer similarity theory (Stull, 1988). These calculations usually give satisfactory results over melting and non-melting snow and ice surfaces.

The sensible heat flux is directed away from the surface (negative) when the surface is warmer than the air, i.e., under statically unstable conditions in the atmospheric surface layer (SL). This upward heat transport is often referred to as convection. In the Polar Regions, convection is rare, and occurs, for instance, when cold polar air flows over open water, forming characteristic convective cloud straits. Weak convection also occurs during summer at highly elevated sites on the Polar Ice sheets, where temperatures are too low for sublimation to be significant (King and others, 2006).

In general, however, the negative net radiation cools the surface, which then becomes colder than the air above. Therefore, over snow and ice, SHF is commonly positive, i.e., directed toward the surface. The associated cooling of the atmospheric boundary layer often results in a surface-based temperature inversion, in which the temperature increases with height. In regions where the radiative heat loss is quasi-permanent during the Polar Night, i.e., the elevated interior plateaus of the Greenland and Antarctic ice sheets, the surface temperature inversion can become several tens of degrees (e.g., Vostok station in Figure 6). In the coastal areas and in the Arctic (Overland and others, 2000), the radiative cooling is weaker because of the more frequent occurrence of clouds, enhancing incoming longwave radiation, resulting in a weaker surface temperature inversion (e.g., Mawson and Neumayer in Figure 6).



Surface Energy Balance, Figure 6 Wintertime (July) vertical temperature profiles from radiosondes measurements at three Antarctic stations. Atmospheric temperature profiles at South Pole are similar to Vostok.

Under these statically stable conditions, wind shear is a prerequisite for the generation of turbulent heat exchange. Wind shear is enhanced over rough surfaces, such as hummocky sea ice (Andreas and Claffey, 1995); over snow and ice surfaces that are relatively smooth, it requires relatively large wind speeds for the wind shear to become sufficiently large. Over ice sheets and glaciers, which have a sloping surface, this wind shear is often provided by *katabatic* forcing. The cold near-surface air is denser than the air in the free atmosphere at the same elevation, which sets up a horizontal pressure gradient over a sloping surface, forcing *katabatic* or downslope winds. Over the large ice sheets, katabatic winds can be very persistent. Because the katabatic forcing acts along the local slope, katabatic winds have a high *directional constancy.* Because of their direct coupling to the radiative cooling of the surface, katabatic winds efficiently generate the turbulence necessary to keep the sensible heat transport going in the stably stratified atmospheric surface layer.

Latent heat flux

Over a snow/ice surface at freezing temperatures, the latent heat flux (LHF) equals the amount of heat extracted from or added to the surface as a result of sublimation (the phase change from solid to water vapor) or deposition (phase transition from vapor to solid, i.e., rime formation). When the surface is melting and liquid water is available, LHF equals the amount of heat extracted from or added to

the surface as a result of evaporation (the phase change from liquid to gas) or condensation (phase transition from gas to liquid, i.e., dew formation). In mountainous areas and over sea ice, frost formation (from liquid to solid) may also be an important process. All these processes exchange not only heat but also mass with the surface, which couples the surface energy balance to the surface mass balance (the sum of all mass fluxes toward and away from the surface).

The LHF can be directly measured using instruments that measure the absorption of light by water vapor at a specific wavelength. Alternatively, LHF can be calculated using simultaneously measured vertical profiles of wind speed and specific humidity. The latter is often determined from relative humidity measurements, which are difficult to perform over snow and ice (Anderson, 1994).

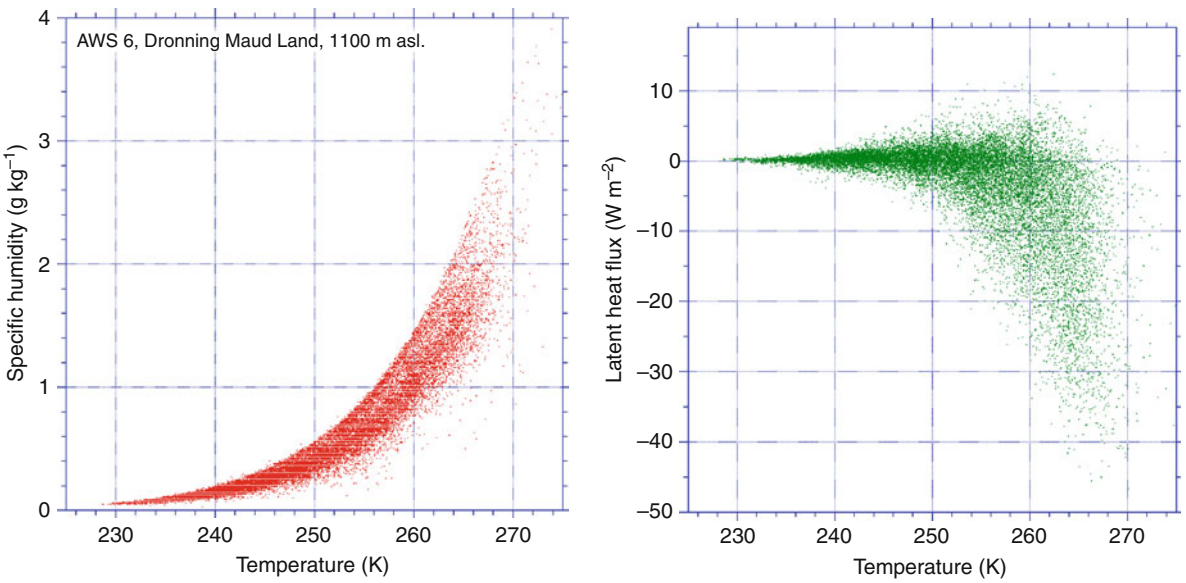
Temperature plays a pivotal role in the magnitude of LHF through its influence on the moisture content of the air. The maximum moisture content of the air, and therewith its vertical gradients, is tightly coupled to temperature through the Clausius Clapeyron equation. Figure 7 (left) shows specific humidity as a function of 2 m temperature for a non-melting location in East Antarctica. Neglecting the temperature difference between the surface and 2 m for the moment and using the fact that the snow/ice surface is always saturated (i.e., the surface-specific humidity is represented by the upper boundary of the point cloud), the distance of individual points to the upper boundary represents the vertical moisture gradient, and therewith the sublimation potential. The undersaturation and therewith the vertical humidity gradient become small at low temperatures, resulting in low LHF values (Figure 7, right).

In summer, when the surface absorbs solar radiation and heats up, significant sublimation does occur at this site (significantly negative LHF). But even under very favorable conditions, the magnitude of LHF usually does not exceed several tens of W m^{-2}, which are small values compared to the mid-latitudes and tropics, where LHF can attain values of several hundreds of W m^{-2}. But this does not mean that LHF is unimportant for the hydrological cycle at high latitudes. An average LHF of only -1 W m^{-2} still represents a surface mass loss of 11 kg m^{-2}. For areas where snowfall and melt are small, such as the interior of the Greenland and Antarctic ice sheets, this potentially represents a considerable fraction of the annual snowfall.

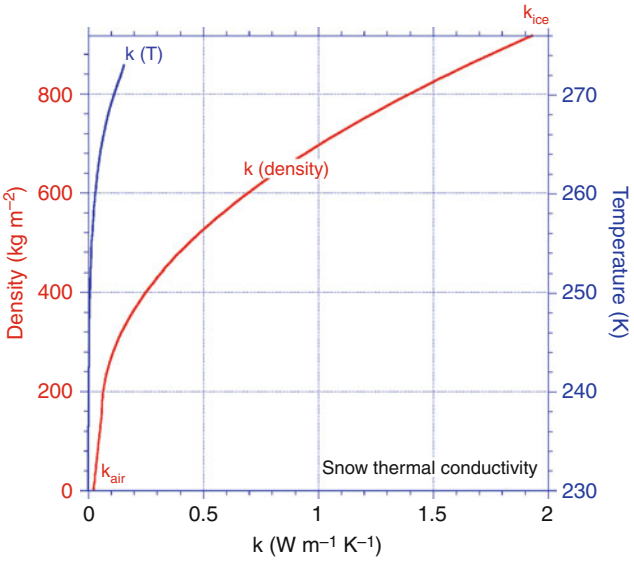
When snowdrift takes place, sublimation from the surface ceases while the sublimation of drifting snow particles takes over. For snowdrift sublimation, which is thought to be an important term in the mass balance of the Greenland and Antarctic ice sheets and the seasonal snowpack at high northern latitudes (Box and others, 2006; Déry and Yau, 2001), no robust measurement techniques are yet available.

Subsurface heat flux

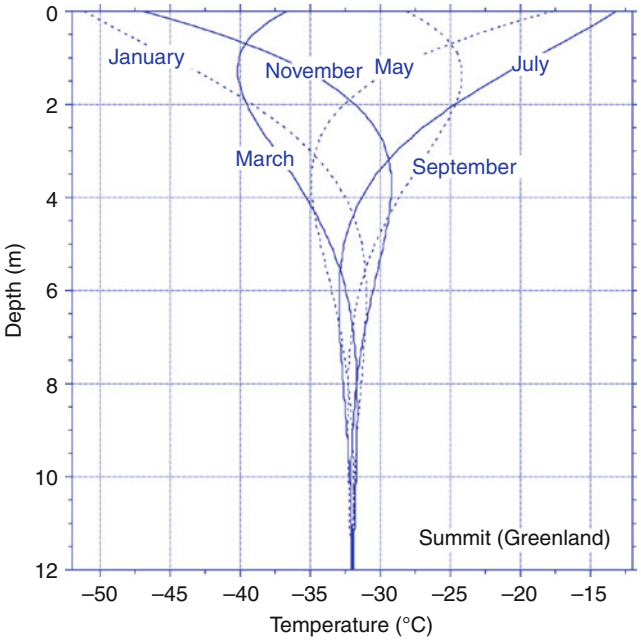
The subsurface heat flux (G) represents the conduction of heat into the subsurface strata; this flux is mainly driven by molecular conduction and therefore occurs along vertical temperature gradients in the snow/ice, following $G(z) = k\, dT(z)/dz$. The heat conductivity (k) of snow is mainly a function of snow density and grain structure, connecting the low heat conductivity of air ("zero" density snow) to that of ice (red curve in Figure 8). Since snow is



Surface Energy Balance, Figure 7 Observations of hourly 2 m specific humidity (*left*) and calculated latent heat flux LHF (*right*) as a function of 2 m temperature at an automatic weather station in East Antarctica.



Surface Energy Balance, Figure 8 Value of heat conductivity k in snow is mainly a function of snow density and grain structure (*red curve*). A small part of the heat transport results from internal convection and from sublimation and subsequent deposition elsewhere in the snowpack, mainly a function of temperature (*blue curve*).



Surface Energy Balance, Figure 9 Theoretical temperature distribution in the snow at Summit, Greenland, forced by a sinusoidal temperature variation at the surface, and assuming a homogeneous snowpack with k = 0.5 W K^{-1} m^{-1}.

a porous medium, a small part of the heat transport results from internal convection and from sublimation and subsequent deposition elsewhere in the snowpack, both processes being a function of temperature (blue curve in Figure 8). This results in an effective heat conductivity that is the sum of conduction and internal convection/deposition.

In the surface energy balance, the surface value of G, G_s, is relevant. Over sea ice, G_s is an important SEB component (see further in this entry). Over a semi-infinite snowpack, G_s will be close to zero when averaged over the year; otherwise the snow layers below the surface would continuously cool or heat up. In the monthly average, G_s will be negative in summer, when the surface is warmer than the subsurface snow layers and heat is transported into the snowpack, and positive in winter, when the temperature gradient is reversed and heat is extracted from the deeper snow layers. But also monthly average values are usually small, typically several W m^{-2}. The real importance of G_s is in the daily cycle of the SEB. At times when turbulence is small, for instance under weak wind conditions, G_s is the only term that can compensate the radiative heat gains/losses; the chain of events is as follows: when the radiation balance becomes strongly positive/negative, and turbulence is weak, the surface temperature will quickly rise/fall. In response, the vertical temperature gradients between the subsurface and the surface will quickly grow, triggering a strongly negative/positive value of G_s, which compensates for the radiative heat exchange.

Because it transports heat, G(z) determines the ice/snow temperature distribution. Figure 9 shows the (theoretical) subsurface temperature distribution at Summit Station at the top of the Greenland ice sheet, as forced by a sinusoidal annual cycle in surface temperature, assuming a homogenous snowpack with constant density. In the absence of melting, the annual temperature variation vanishes below approximately 10 m depth. This means that at those depths, the temperature approximates the annual mean surface temperature. This technique is often used to estimate the annual mean surface temperature in the interior of the large ice sheets, where few observations are available. When melt occurs, the refreezing of the percolating meltwater releases heat into the snowpack and the underlying ice. Under these conditions, the technique of determining annual mean T_s is no longer applicable.

Melting and refreezing

If absorption of solar radiation has heated the snow/ice layers to the melting point, the excess energy produces melting ($M > 0$). The meltwater formed at the surface either runs off (when the surface is impermeable, i.e., ice), or penetrates the snowpack. Sea ice is an intermediate case where the water partly pools at the surface and partly percolates through or flows off the ice into the ocean. In the case of a snow pack, the meltwater may refreeze at some depth where the temperature is still below freezing. This refreezing of meltwater may constitute an important process for the mass balance of glaciers and sea ice

because the ice involved must be melted more than once before it is removed from the glacier. Moreover, upon refreezing, latent heat is released within the snowpack, which alters the subsurface temperature distribution. However, because the heat is released below the surface, as is the case with penetration of shortwave radiation, this heat source is not part of the surface energy balance. It merely influences the SEB through altering the subsurface heat flux by changing the subsurface temperature gradient. Gallée and Duynkerke (1997), for instance, showed that the daily cycle of surface melting and refreezing below the surface significantly impacts the SEB in Greenland. If it is not taken into account, the surface and subsurface temperatures are significantly underestimated.

Annual cycle of SEB over various permanent snow- and ice-covered surfaces

In this section, we discuss the idealized annual cycle, based on monthly means, of the SEB over various permanently snow- and ice-covered surfaces. The coordinates, elevation, surface type and basic climate conditions of these locations during different seasons are summarized in Table 1. For clarity, the annual cycles presented in the following figures have been smoothed using 3-month running means. For details of calculation and variability beyond the mean annual cycle, we refer to the original references.

North pole, arctic basin

While some SEB estimates are available from Russian drifting station and from various US drift stations such as SHEBA (Surface Heat Budget of the Arctic Ocean, Utta and others, 2002; Persson and others, 2002), here we present, for illustrative purposes, the idealized annual cycle of the SEB at the North Pole (90° North, NP), based on model/weather observations combined with an SEB model, assuming 2 m thick sea ice. The NP is situated over a frozen ocean surface that consists of snow-covered sea ice in winter and melting snow/ice in summer (Table 1). The wintertime SEB (Figure 10) is a first-order balance between (longwave) radiative cooling and heating by SHF and G_s. Especially G_s is significant; 30 W m^{-2} is the approximate amount of heat that flows from the warm ocean (−1.8°C) to the sea ice surface (−30°C), when the ice is 2 m thick. Because of the radiative cooling, the sea ice surface is colder than the overlying air, which, in combination with the moderate winds, generates a flux of sensible heat toward the surface. At the sea ice–ocean boundary, a semi-unlimited heat source is available from the deeper ocean. As a result, annual average G_s is significantly positive, driving freezing at the ice/ocean interface.

At these low temperatures, wintertime LHF is negligible. In spring, shortwave radiative heating increases surface temperature and specific humidity, resulting in weak sublimation. At sea level, the summer climate is relatively mild, even this far north, and frequent melting occurs. When melting starts in earnest in summer, the moisture and temperature gradients between the sea ice surface and the overlying air diminish, reducing the magnitude of the turbulent fluxes. Because the temperature gradient between ice surface and ice base also disappears, G_s goes to zero. All the absorbed shortwave radiation is invested in melting. The integrated amount of melt energy represents the removal of approximately 1.5 m of ice, less than the total ice thickness. In spite of bottom melting also taking place, sea ice at the North Pole usually survives the summer melt period, to form multiyear sea ice in the subsequent years.

Ablation zone of the west-greenland ice sheet

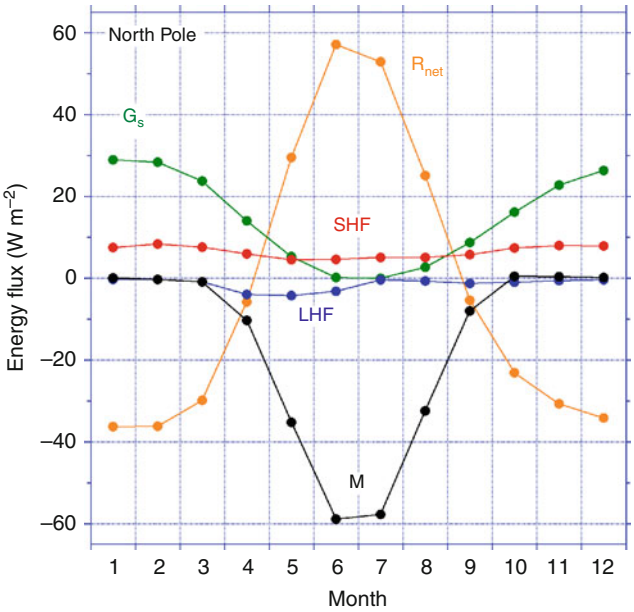
The Greenland ice sheet is the second largest ice mass in the world, and its southernmost part is situated in a subarctic climate. A site was selected in the lower ablation zone of the southwestern ice sheet (Table 1) for which reliable, multiyear meteorological observations are available (Van den Broeke et al., 2008a, b). In winter, surface radiative cooling is compensated in first order by SHF, with small contributions from LHF and G_s (Figure 11).

Surface Energy Balance, Table 1 Surface and climate characteristics of some SEB locations

Location name	Coordinates Elevation (m asl)	Surface type		Temperature (°C)		Wind speed (m s^{-1})	
		Summer	*Winter*	*Summer*	*Winter*	*Summer*	*Winter*
North Pole (Sea Ice)	90° N ~0 m	Melting snow/ice	Snow	−2	−30	6	5
West Greenland ablation zone	67° 06′N, 50° 07′ W 500 m	Melting ice	Snow	+3	−20	5	5
Morteratsch glacier	46° 24′ N, 9° 56′ E 2100 m	Melting ice	Snow	+9	−7	6	6
Neumayer (Antarctica)	70° 39′ S, 8° 15′ W 40 m	(Melting) snow	Snow	−5	−25	7	10
South Pole (Antarctica)	90° S 2830 m	Snow	Snow	−30	−60	5	7
		Dry season	*Wet season*	*Dry season*	*Wet season*	*Dry season*	*Wet season*
Kersten glacier (Kilimanjaro)	3° 05′ S, 37° 21′ E 5873 m	Ice	(Melting) snow	−7	−6	4	5

The subsurface heat flux G_s is heating the surface during winter, when the surface temperature is lower than the deeper snowpack temperature (Figure 9). In summer, the surface at this site is continuously at the melting point while the temperature deeper in the snowpack is several degrees lower than the melting point inducing a negative G_s.

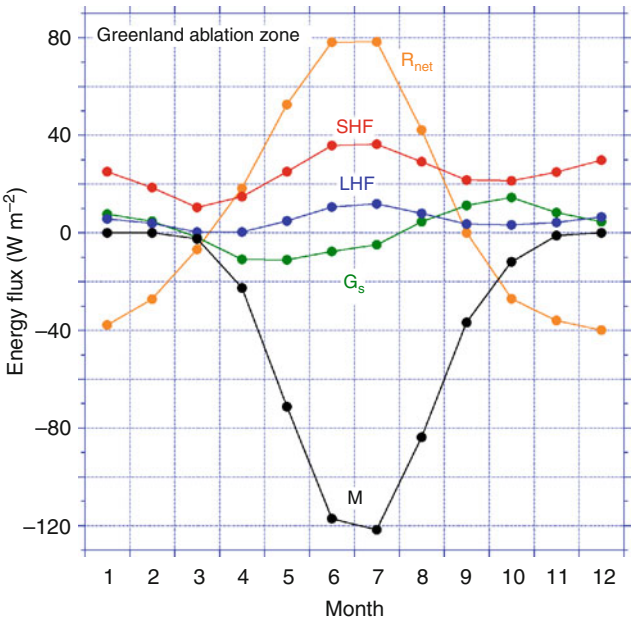
Because in summer the air is usually warmer than 0°C, both SHF and LHF are directed toward the melting ice surface, contributing significantly to melt. Because of the sunny climate and relatively high temperatures in this part of Greenland, the total amount of summer ice melt at this site exceeds 4 m, among the largest values found in Greenland. Both SHF and LHF show a double maximum, one in winter and one in summer, which is caused by the double maximum in wind speed. In both seasons, atmospheric cooling through SHF maintains the katabatic winds. In winter, surface radiative cooling maintains the surface temperature deficit, while in summer the melting surface is responsible for a temperature deficit. Over melting ice surfaces, katabatic winds are sometimes called *glacier winds*.



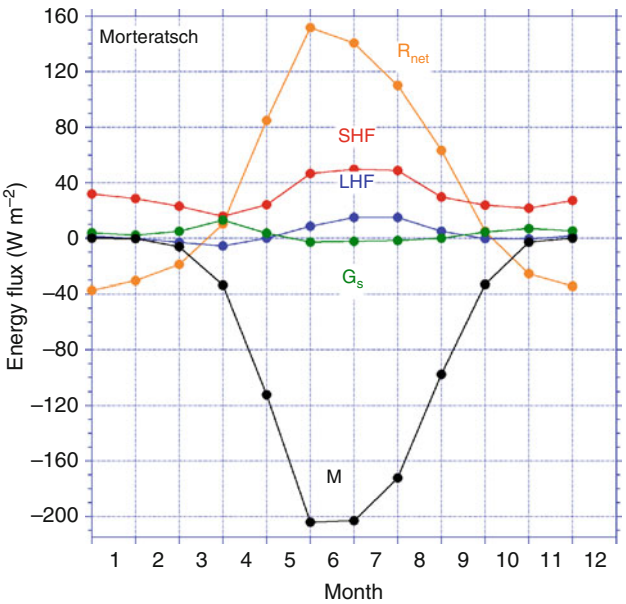
Surface Energy Balance, Figure 10 Annual cycle of SEB components at North Pole in the Arctic basin. Idealized results from model data and observations, assuming 2 m thick sea ice (see text).

Ablation zone of morteratsch glacier, swiss alps

Vadret da Morteratsch is a mid-latitude glacier in Switzerland (Table 1) and has one of the longest uninterrupted SEB records from the surface of a valley glacier (15 years, Oerlemans and others, 2009). The automatic weather station that produced the results shown in Figure 12 is situated in the ablation zone at the tongue of the glacier at 2,100 m asl. The winter SEB (Figure 12) is comparable to the Greenland ablation zone, with radiative heat losses being compensated mainly by SHF. In summer, the glacier tongue is surrounded by ice-free terrain, resulting in high summer air temperatures over the melting ice surface



Surface Energy Balance, Figure 11 Annual cycle of SEB components in the lower ablation zone of the ice sheet in southwest Greenland. SEB calculated from 4 years of automatic weather station observations (see text).

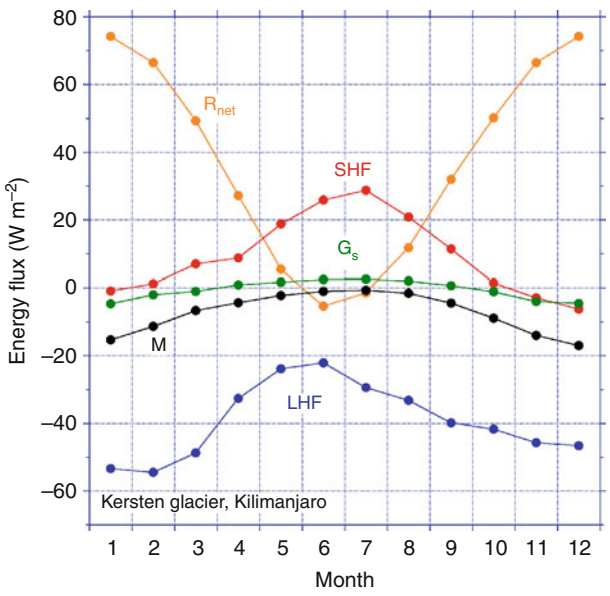


Surface Energy Balance, Figure 12 Annual cycle of SEB components in the ablation zone of the Morteratsch glacier, Switzerland. SEB calculated from 15 years of automatic weather station observations (see text).

(Table 1). This also results in dust accumulation, so that the surface albedo of the ice attains very low values (~0.15). This strongly enhances the absorption of shortwave radiation and therewith surface melting. As a result, R_{net} attains much higher values than in Greenland, while SHF and LHF are comparable, including the double annual maxima. The total melt for this location exceeds 7 m of ice, which has forced a strong retreat of the glacier in recent decades.

Kersten glacier, Kilimanjaro

This tropical glacier is situated between 5,100 and 5,900 m on the southern flank of Kilimanjaro, close to the equator (Table 1). Based on several years of AWS data and distributed energy balance modeling, the SEB, averaged over the entire glacier surface, could be determined (Mölg and others, 2009). The annual cycle (Figure 13) deviates strongly from other locations. As a result of its location close to the equator, the annual cycles in SW_{in} and ambient temperature are small, and thus there is no climatological summer or winter at this site; the seasonal variations are mostly forced by the wet and dry seasons. At these high elevations, the air contains little moisture and sublimation produces an important heat and mass loss year round. In the main wet season (April/May), sublimation strongly decreases. Net radiation is small, because SW_{net} is at a minimum, mainly due to high albedo. At the same time, as the air is moist and cloudy, cooling by LW_{net} is also small, resulting in small net radiation. In the core dry season (June–August) there is hardly any melt and ablation is controlled by sublimation. In these months, cooling by sublimation significantly exceeds warming by R_{net}, so that the surface remains significantly colder than the overlying air and SHF peaks. The most variable part of the year is the wet season around November/December. This season can start in October and last into January/February, but sometimes is totally absent. The occurrence of sublimation and the associated surface cooling is vital for limiting the melt amount throughout the year. Note that, even in the presence of moderate refreezing, melt (575 kg m^{-2} $year^{-1}$) still removes more mass than sublimation (450 kg m^{-2} $year^{-1}$) glacier-wide, because of the much smaller latent heat of fusion compared to evaporation/sublimation. However, at the glacier summit, sublimation dominates and accounts for 75% of the total annual mass loss.



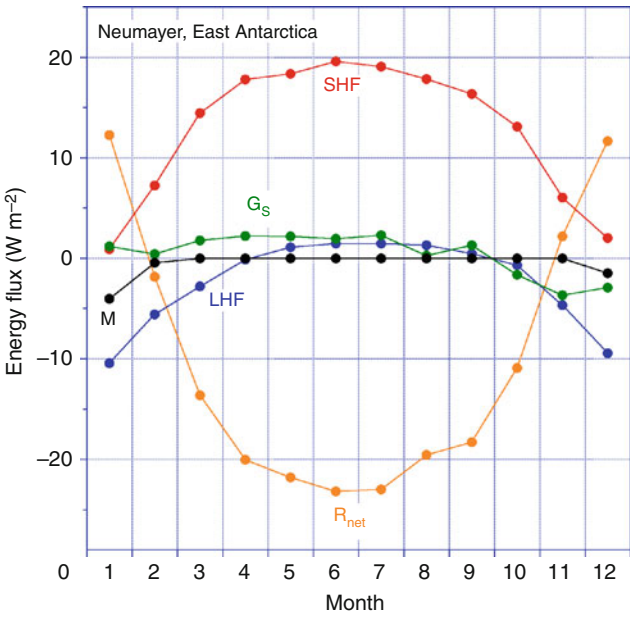
Surface Energy Balance, Figure 13 Annual cycle of SEB components on Kersten glacier, Kilimanjaro, Tanzania. SEB calculated from three years of automatic weather station observations in combination with a distributed energy balance model (see text).

Neumayer, antarctica

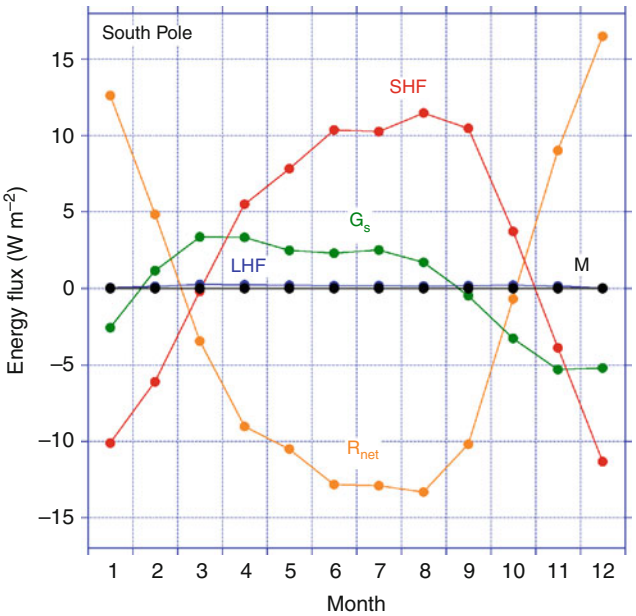
Neumayer station (Germany) is situated on Ekstrøm ice shelf in coastal East Antarctica, at approximately 70°S (Table 1). The station is situated relatively far to the north, at low elevation (40 m asl) and close to the Southern Ocean. The nearby ocean is ice-covered in winter, but ice free in summer. Being situated close to the circumpolar pressure trough, Neumayer experiences strong easterly winds year round with frequent occurrence of snowdrift (~40% of the time). The wind maximum in winter is caused by enhanced depression activity, not by katabatic forcing, because Neumayer is situated on a flat ice shelf, which does not allow for significant katabatic forcing. In spite of the proximity of the ocean, Neumayer has a cold climate with only occasional melting around noon during sunny summer days. The SEB (Figure 14) was calculated using 13 years of high-quality meteorological observations (König Langlo and Loose, 2007; Van den Broeke and others, 2009). In the absence of continuous melting, with slow snow metamorphosis, the surface albedo is high year round. Only after prolonged dry periods with daytime melt in summer does the albedo of the snow surface fall below 0.8; as a result, R_{net} is small and the radiation balance only becomes positive in summer. In combination with mild summer temperatures, this allows for significant sublimation (Figure 14). In winter, longwave radiative cooling dominates and is compensated by SHF and in second order by LHF and G_s.

South pole, east antarctica

The geographic South Pole is situated in the vast interior of the East Antarctic ice sheet at an altitude in excess of 2,800 m (Table 1). The South Pole experiences a wintertime surface inversion similar to Vostok Station in Figure 6. Because it is not situated on a dome, the wind climate shows an appreciable wintertime (katabatic) maximum which, because the surface slope is small, is much weaker than those measured over the steeper parts of the ice sheet closer to the coast. Snow metamorphism is slow at these low temperatures, resulting in a year-round high surface albedo. As a result, summertime net radiation is



Surface Energy Balance, Figure 14 Annual cycle of SEB components at Neumayer, East Antarctica. SEB calculated based on 13 years of surface observations (see text).



Surface Energy Balance, Figure 15 Annual cycle of SEB components at South Pole, East Antarctica. SEB calculated based on 3 years of surface observations (see text).

small, <15 W m^{-2}, and all fluxes are smaller in magnitude than at Neumayer (Figure 15). Summer temperatures are also too low to allow for significant sublimation to occur. In the absence of this heat sink, surface temperature can rise quickly above the air temperature during sunny summer days, allowing weak convection (negative SHF) and a shallow (~100 m) mixed boundary layer to develop (King and others, 2006; Van As and others, 2006). Because all other fluxes are small, monthly mean G_s becomes a significant component of the SEB at the South Pole, in spite of its small magnitude. The wintertime SEB is comparable to Neumayer, i.e., a first-order balance between radiative cooling and heating by SHF.

Summary

This entry describes the components of the surface energy balance (SEB) over snow and ice: shortwave and longwave radiation, the turbulent fluxes of sensible and latent heat, and the subsurface (conductive) heat flux. If the surface is melting, the sum of these fluxes determines the melt rate. We explicitly describe the idealized mean annual cycle of the surface energy balance components at six locations with permanently ice- or snow-covered surfaces, but with widely varying melt characteristics: sea ice at the North Pole, the ablation zone of the Greenland ice sheet, the ablation zone of the Morteratsch glacier in Switzerland, Kersten Glacier on the Kilimanjaro in Tanzania, Neumayer station in coastal East Antarctica, and South Pole station in interior East Antarctica.

Acknowledgments

We thank Gert König Langlo, Rianne Giesen, and Hans Oerlemans for providing data. Thomas Grenfell and an anonymous reviewer are thanked for improving the original manuscript.

SURFACE TEMPERATURE OF SNOW AND ICE

Dorothy K. Hall
Crysopheric Sciences Branch, Greenbelt, MD, USA

Definition

Land-Surface Temperature (LST) – surface temperature measurement from space over land areas, including land ice and snow.

Introduction and background

Thermal infrared (TIR) sensors facilitate surface temperature and melt-condition monitoring over extensive areas of snow and ice (Key and Haefliger, 1992; Stroeve and Steffen, 1998; Comiso, 2006; Hall et al., 2006, 2008a, b), especially when used with complementary satellite-derived passive- and active-microwave data.

The surface temperature (T) is not an intrinsic property of the surface; it varies with external factors such as meteorological conditions. Emissivity *is* an intrinsic property

of the surface and is independent of the temperature (Hook et al., 2007). Emissivity of snow and ice features is far less variable than the range encountered in a wide variety of land surfaces, leading to greater potential accuracies in retrieved land-surface temperature (LST) over snow and ice even when the emissivity is not known precisely. To obtain snow-surface temperatures to an accuracy of 0.01 K, the emissivity must be known to within 0.1% (Stroeve et al., 1996).

Analysis of the Advanced Very High Resolution Radiometer (AVHRR)-derived surface temperature of the Antarctic and Greenland ice sheets, ice caps, and smaller glaciers, available from the early 1980s, provides a method to evaluate melt and general climate trends as a surrogate for, and in addition to, air-temperature records that are obtained from relatively few and scattered in-situ observations (Stroeve and Steffen, 1998; Wang and Key, 2003, 2005a, b; Comiso, 2006). Satellite-derived "clear-sky" surface-temperature data are also useful for the validation of climate models and as input to data-assimilation models. However, AVHRR data, though highly valuable, have been acquired from a variety of instruments over a period >20 years, leading to satellite intercalibration issues. Newer data from the Earth Observation System (EOS) offer promise for validating the overlapping AVHRR record and extending the surface-temperature record over ice-covered areas into the future at a higher spatial resolution with improved instrument calibration.

One way to assess the accuracy of remotely sensed LSTs is to compare the values with in-situ surface temperatures under clear-sky conditions (Hall et al., 2008b). Various factors make that problematic, including the fact that the in-situ observations are point measurements while the satellite-derived observations represent LSTs from a much larger area. Also, in-situ observations from weather stations, and in particular the Greenland Climate Net-work (GC-Net) automatic weather station (AWSs) (Box, 2002) which are generally acquired at some height above the surface so that the measured air temperature must be extrapolated to calculate a surface temperature. That calculation is also affected by meteorological factors such as wind speed, but for higher wind-speed conditions, when the near-surface air is well mixed, near-surface air temperature is very close to the surface temperature. Also the AWS instruments record in-situ data at a "point" while the satellite instruments record data over an area varying in size from: 57 × 57 m Enhanced Thematic Mapper Plus (ETM+), 90 × 90 m Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER), or to 1 × 1 km Earth Observing System Moderate Resolution Imaging Spectroradiometer (MODIS). Surface topography and other factors contribute to variability of surface temperature within a pixel, thus the AWS measurements may not be representative of the LST of the pixel as a whole. Without more information on the local spatial patterns, the AWS LST cannot be considered valid ground truth for the satellite measurements, with RMS uncertainty ~2°C or greater (Hall et al., 2008b; Koenig and Hall, in press).

Satellite-derived "clear-sky" LST products were studied from EOS instruments including the MODIS (Wan et al., 2002), the ASTER (Gillespie et al., 1998), and the ETM+ (Barsi et al., 2005) over snow and ice on Greenland. Satellite-derived LSTs were compared with in-situ air-temperature observations from the GC-Net. Results showed that MODIS, ASTER, and ETM+ provide reliable and consistent LSTs under clear-sky conditions and relatively flat terrain over snow and ice targets over a range of temperatures from −40°C to 0°C. The satellite-derived LSTs agree within a relative RMS uncertainty of ~0.5°C. The good agreement among the LSTs derived from the various satellite instruments is especially notable since different spectral channels and different retrieval algorithms are used to calculate LST from the raw satellite data. However accuracies are lower when LSTs are compared with AWS measurements.

Summary

The accuracy of measuring the surface temperature of snow and ice has been assessed. Difficulties are encountered when attempting to validate satellite data covering a large area (e.g., 1 × 1 km) with a point measurement (e.g., using air temperature data from meteorological stations or AWS), but relative validation between EOS IR sensors has provided accuracies of LST measurements over snow and ice of <1°C. To develop a long-term record of "clear-sky" surface temperature, satellite intercalibration remains an issue.

SUSPENDED SEDIMENT CONCENTRATION

Veerle Vanacker
TECLIM, Earth and Life Institute, University of Louvain, Louvain-la-Neuve, BW, Belgium

Definition

Suspended sediment is generally transported within and at the same velocity as the surrounding fluid (water or wind). The stronger the flow and/or the finer the sediment, the greater the amount of sediment that can be suspended by turbulence.

Only the finer fraction (usually silt and clay fraction) of the suspended sediment can be continuously maintained in suspension by the flow turbulence. This fraction is often referred to as "wash load," and is typically not found in significant quantities at the bed surface. Its concentration is usually related to the sediment supply and is difficult to determine theoretically.

Most sediment particles are not continuously suspended, but are continuously settling through the surrounding fluid and may eventually return to the bed. This part of the total suspended sediment is referred to as "bed-material load," and its concentration can be estimated from the hydraulic parameters of the fluid and the composition of the bed material.

History and current techniques

The first measurements of suspended sediment go back at least to the samplings of the Rhone River (France) in the early 1800s (Garcia, 2008). The earliest suspended sediment samples were collected using instantaneous samplers. Later, more sophisticated samplers were developed that could be filled at a selected depth below the water surface.

The first sediment sampling and analytical methods used to differ strongly between the various monitoring programs (Glysson and Gray, 1997). The creation of the Federal Interagency Sedimentation Project (FISP) was important to standardize sediment samplers, sampling, and analytical techniques around the world. At present, a large number of both manually operated samplers and automatic samplers exist. Information on the use and calibration of these samplers can be obtained from the Federal Interagency Sedimentation Project (FISP, 2009).

In addition to these suspended sediment samplers, rapid progress is being made in developing new techniques for measuring the concentration of suspended sediment in fluids. These new methods are commonly based on optical backscatter, optical transmission, focused beam reflectance, laser diffraction, acoustic, nuclear, spectral reflectance, digital optical, and differential pressure principles to capture specific characteristics of the sediment–fluid mixture (Wren et al., 2000). At the moment, several of these advanced techniques still suffer from technical limitations that render their operation difficult in some environments. Continued technological improvements will undoubtedly lead to improved methods to collect data on suspended sediment concentration in the future.

Factors controlling variations in suspended sediment concentration

There is now a wealth of information from case studies worldwide that exemplify the large temporal and spatial variation that exists in suspended sediment concentration. It is becoming increasingly clear that variations in suspended sediment concentrations cannot be explained by natural biophysical factors only such as climate, geology, or topography.

Various studies have clearly shown that sediment fluxes from anthropogenically altered catchments are significant (Walling, 2006). Research at different spatial scales has indicated that humans have accelerated sediment production by agricultural activities, road construction, and intense logging, but have reduced the global sediment delivery to the oceans because of sediment retention in

reservoirs (Hooke, 2000; Syvitski et al., 2005; Vanacker et al., 2007).

In addition to global-scale analyses, simultaneous research on small catchments may contribute to yield complementary information on suspended sediment dynamics that would be difficult to obtain exclusively through large catchment studies.

Conclusions

In recent years, new techniques have been developed that will provide us a wealth of data on suspended sediment concentrations at spatial and temporal resolutions much higher than previously possible. In the future, this information will undoubtedly contribute to better understand the role of anthropogenic disturbances and climate change on terrestrial sediment fluxes.

Sediment Yield
Suspended Sediment Dynamics

SUSPENDED SEDIMENT DYNAMICS

Tim Stott
Physical Geography and Outdoor Education, Liverpool John Moores University, Liverpool, UK

Definition

Suspended sediment. The fine portion of a river or stream's sediment load which is normally carried in suspension. Suspended sediment is usually finer than 2 mm, although this boundary can vary significantly according to the stream's power and turbulence.

Dynamics. The branch of mechanics that deals with the motion and equilibrium of systems under the action of forces, usually from outside the system.

Introduction

Glaciers alternate between phases of accumulation and ablation. It is during ablation phases that most meltwater is discharged from glaciers. Even at low discharges, the meltwater is usually capable of entraining and transporting fine sediment in suspension. The dominant trend over the past few decades is that most glaciers worldwide are out of equilibrium with the current climate and they are slowly adjusting to seasonal changes in precipitation and higher temperatures by showing negative mass balance, significant volume loss, and retreat in most areas. In terms of landscape dynamics, this widespread and rapid retreat of mountain glaciers is revealing new expanses of fresh glacial debris, the stability, dynamics, and potential fluvial transport of which is beginning to gain the attention of research scientists. Meltwater streams and rivers draining glaciers and flowing across the fore field are called pro-glacial streams. Due to the large supply of sediment deposited beneath and in front of glaciers, pro-glacial streams can have high suspended sediment concentrations (SSC) during the peak (summer) melt season and during rainstorms. They are capable of transporting high suspended sediment loads.

Measurement methods

The most common approach to measuring suspended sediment dynamics in pro-glacial streams relies on retrieving discrete water samples at-a-point over time. This can be achieved by lowering a wide-mouthed bottle (usually 1 L capacity) into the flow and retrieving it when full. The highly turbulent nature of the flow usually means that suspended sediment is extremely well mixed and that values sampled at the stream margin will be representative of the whole cross section (see Gurnell et al., 1992). Water samples are then passed through pre-weighed filters (these are normally glass fiber such as Whatman GF/D 8 μm filters) on which the suspended sediment in the water sample is retained. Filters are then oven dried, and the filter plus dry sediment are weighed. The difference in the pre- and post-weight of the filter is due to the suspended sediment in the water sample. The weight of sediment divided by the volume of the water sample gives the SSC which is reported in mg/L. This method is known as the gravimetric method. However, in order to gain any meaningful understanding of suspended sediment dynamics, samples taken at a minimum of 3-hourly intervals are necessary, and most researchers reduce this time to 1 h or less if possible, which can be very labor intensive. Therefore, automatic pumping samplers (Figure 1) are used to

a

Suspended Sediment Dynamics, Figure 2 Glass fiber 7 cm diameter filters which have been used to remove suspended sediment from a sequence on 1-hourly water samples collected in the Torrent du Glacier Noir, Ecrins National Park in SE France during July 2003. NB. The first sample (*top left*) was taken at 14:00 on day 1 and the last (*bottom right*) at 13:00 on day 2. The *top* row (14:00–17:00 on afternoon of day 1) and *bottom* rows (10:00–13:00 on day 2) show much higher SSCs as these will have coincided with times of highest discharge.

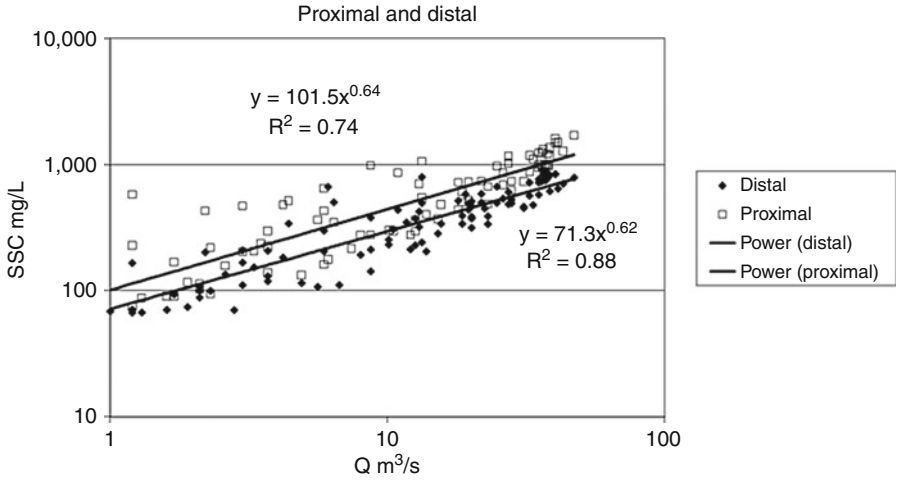
automatically pump water samples from the river via a 5–6 m tube (Figure 1a) into a series of 24 bottles (Figure 1b). The sampler is battery powered and the time interval at which samples are pumped can be determined by the operator. Figure 2 shows 24 filters which were collected from an Alpine pro-glacial torrent.

Since stream discharge has been shown to exert an important control over suspended sediment dynamics, this is normally measured at the same time that water samples are retrieved, or maybe even at greater frequency by means of electronic water level sensors such as a pressure transducer. The relationship between SSC and discharge (Q) shown in Figure 3 is known at a rating curve where $SSC = aQ^b$, where a and b are constants representing the intercept and slope of the rating plot, respectively.

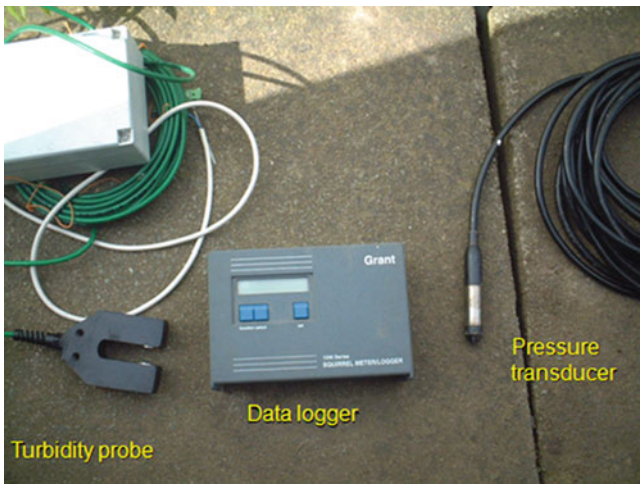
Turbidity has successfully been used as a surrogate for SSC in pro-glacial streams (Clifford et al., 1995; Hodgkins, 1999; Irvine-Fynn et al., 2005; Stott and Mount, 2007a, b; Stott et al., 2008). Partech infrared (IR15C) 0–10,000 mg/L range turbidity sensors are a popular choice (Figure 4).

Turbidity sensors, such as the one shown in Figure 4, work by emitting a beam of light which is detected by a photoelectric cell on the opposite side of a gap. The instrument produces a voltage output which is proportional to the amount of light received by the light sensor. When the instrument is deployed in a stream, the proportion of the emitted light which is received by the light sensor is deemed to be proportional to the color or SSC of the stream water. The voltage output is logged by a data logger at any predetermined time interval (e.g., 10 s to 10 min) giving a far greater insight into the dynamics of the suspended sediment. However, in order to make useful meaning of the turbidity voltage data, gravimetrically determined samples are needed in order to calibrate the voltage output of the turbidity sensor (Figure 5).

The turbidity reading is sensitive to the particle size of the suspended sediment passing through the sensor gap which can scatter the light in different ways, hence the less-than-perfect relationship on Figure 4. So, the use of turbidity in pro-glacial streams can be a useful application to gain a more detailed picture of the suspended sediment



Suspended Sediment Dynamics, Figure 3 Suspended sediment concentration vs discharge rating relationship for proximal (50 m from glacier snout) and distal (600 m from glacier snout) sampling stations in the Ova da Morteratsch, Switzerland (From Stott et al., 2008).



Suspended Sediment Dynamics, Figure 4 Partech turbidity sensor, data logger, and pressure transducer (photo: T. Stott).

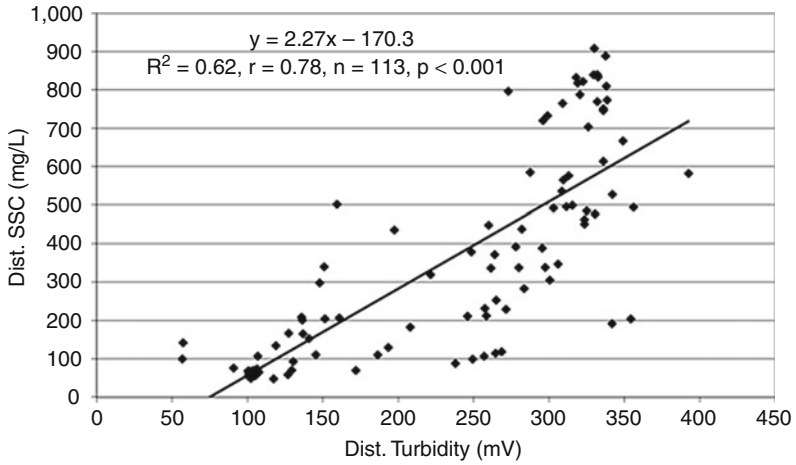
dynamics, but it has limitations due to the difficulties of obtaining strong-enough calibration relationships.

Time series investigations

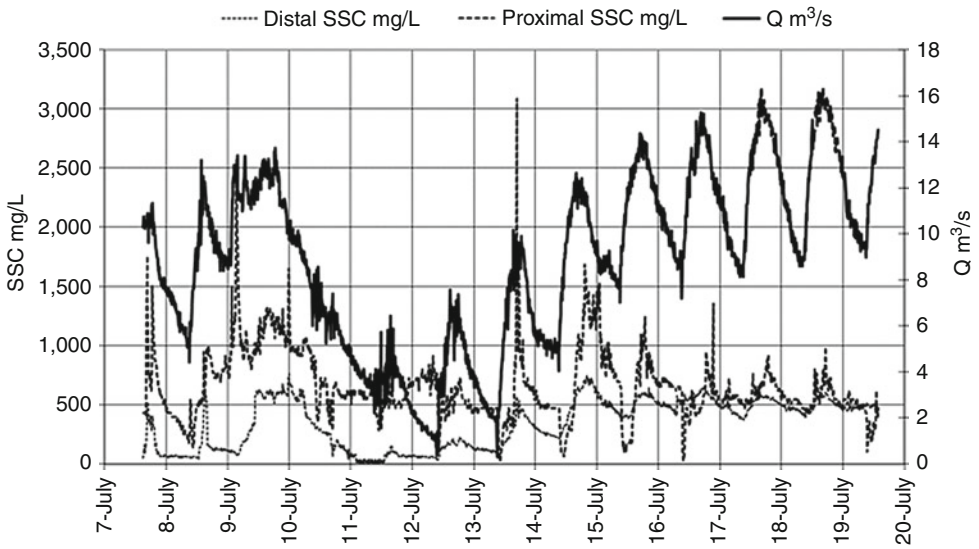
Figure 6 shows a typical time series plot for discharge and SSC predicted from turbidity sensors at two pro-glacial monitoring stations.

The predicted SSC record (Figure 6), while broadly responding to discharge fluctuations, shows SSC to be erratic, particularly at the proximal station. Some of the SSC peaks coincide with discharge peaks but others do not, suggesting that factors other than discharge are controlling SSC variations. One clear diurnal pattern is that discharge minimum consistently occurs at 09:10 each morning, after which it rises rapidly until it peaks sometime between 13:50 (e.g., 8 July) and 18:40 (e.g., 7 July), which seems to depend on the weather conditions (in particular air temperature). The SSC records behave differently, with proximal SSC behaving much more erratically, with greater variation, than the smoother less variable distal SSC. Nevertheless, diurnal variations are clear at both locations. Prior to 12 July, SSC at both stations rises and falls in response to discharge, until a cold weather spell on the night of 9–10 July occurred, when air temperature dropped to almost 0°C followed by cool days on 10 and 11 July causing discharge and SSC to fall. Some rain also fell on 9 and 10 July when daily totals of 24.8 and 1.8 mm were recorded. Warmer temperatures returned on 12 July after which peak discharge climbed steadily each day and a clear SSC exhaustion effect begins to appear. This can be seen clearly in Figure 5 where, following the minimum discharge at 09:10 in the morning, proximal SSC would fall and remain low for up to 6 h, not regaining its 09:10 am level until mid-afternoon, while distal SSC would start and continue to rise from 09:10 am with discharge. This suggests that the suspended sediment source during the morning and early afternoon was the pro-glacial area itself, whereas by mid-afternoon the proximal SSC would overtake the distal SSC suggesting that the suspended sediment source had now switched to the subglacial meltwater once the glacier had started to melt and the supra-, en-, and subglacial conduits had begun to flow. However, despite increasing air temperatures in the latter part of the record (13–19 July), SSC peaks in both proximal and distal records became progressively lower suggesting that the available sediment supply, apparent in the early part of the record, had become exhausted.

Figure 7 shows three examples of hydrographs and sedigraphs (generated using 5-min turbidity data) plotted using data gathered by Stott and Grove (2001) in the



Suspended Sediment Dynamics, Figure 5 Suspended sediment concentration vs turbidity voltage calibration curve for Ova da Morteratsch, Bernina Alps, Switzerland after Stott et al. (2008). Note the large degree of scatter in the relationship.



Suspended Sediment Dynamics, Figure 6 Time series plot for discharge and suspended sediment concentration predicted from turbidity sensors at two monitoring stations in the pro-glacial zone of the Morteratsch glacier, Switzerland in July 2007. The proximal station is 50 m from glacier snout, and the distal station is 600 m from the glacier snout (From Stott et al., 2008).

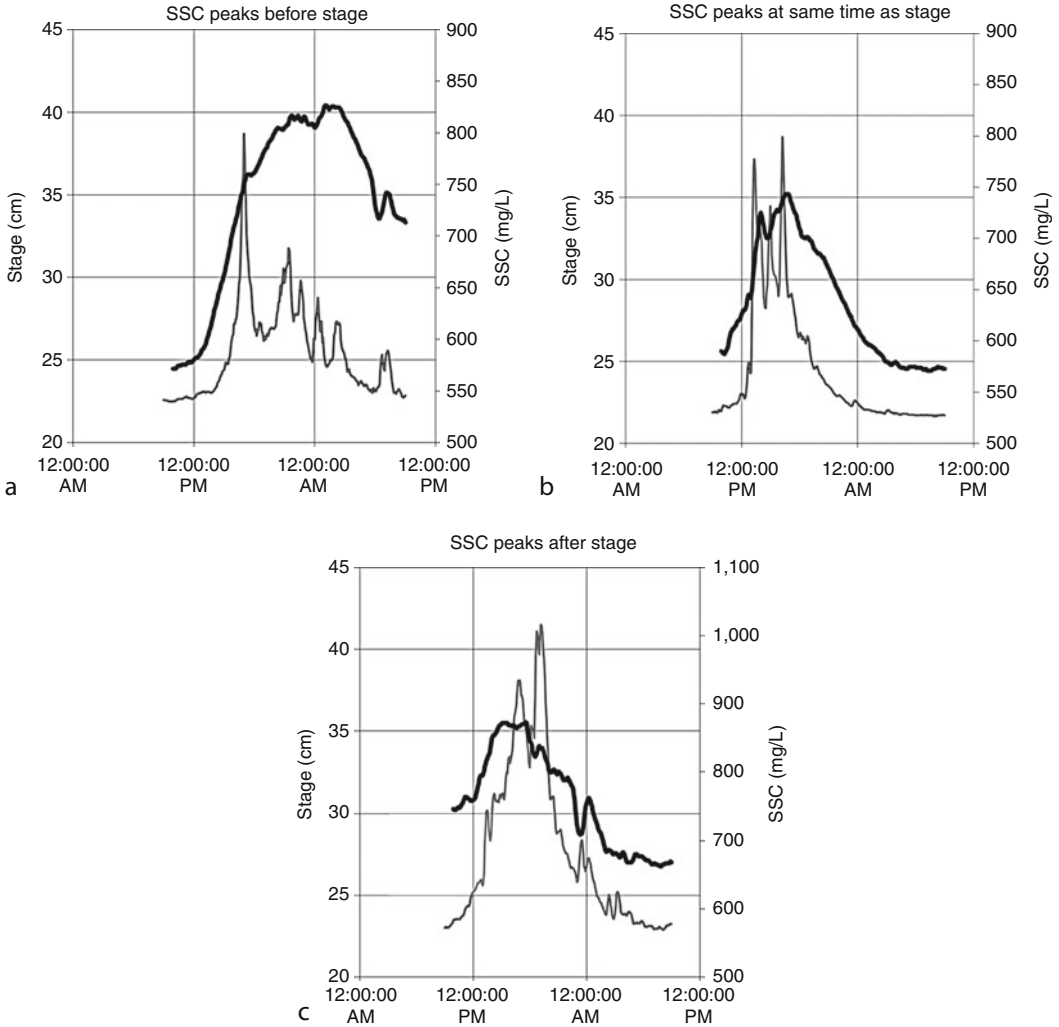
Skeldal River, NE Greenland in the 1998 melt season. At the same monitoring station during the study in August, SSC peaks before (Figure 7a), at the same time as (Figure 7b), and after the main hydrograph peak (Figure 7c).

This means that SSC can have very different values depending on which part of the hydrograph is being examined. For example, in Figure 7a, at a stage of 35 cm on the rising limb of the hydrograph SSC is 750 mg/L whereas when stage is 35 cm on the falling limb, around 10 h later, SSC is 550 mg/L. Where SSC can have different values at the same stage or discharge is known as the hysteresis effect.

Hysteresis

Figure 8 shows two examples of hysteresis loops in the SSC vs Q relationship in the Torrent du Glacier Noir, SE France (data from Stott and Mount, 2007a). Clearly, there is a large amount of scatter in the SSC vs Q relationship during both hydrographs.

However, when the sampling sequence is identified by numbers and the points are traced sequentially by arrows,

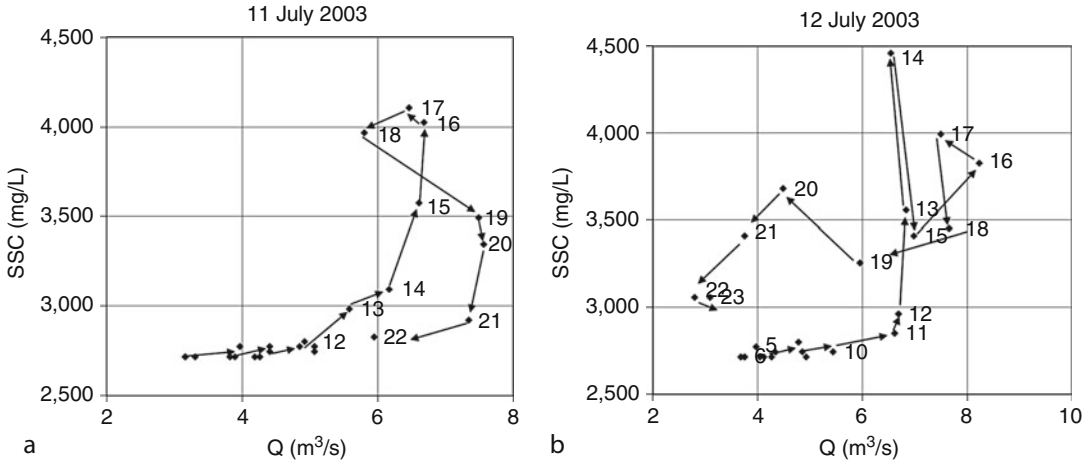


Suspended Sediment Dynamics, Figure 7 River stage (black line) and suspended sediment concentration (gray line) time series plots for the Skeldal River, NE Greenland (5-min data from a study by Stott and Grove, 2001), August 1998.

the loop nature of the hysteresis effect is visible in each of the flood events on 11 and 12 July 2003. While the loops are not perfect (they cross-over), the generally clockwise loop on 11 July (Figure 8a) suggests that SSC peaked before Q, whereas the anticlockwise loop in 12 July (Figure 8b) suggests that SSC peaked after Q.

Current investigations, controversies, and gaps in current knowledge

Future changes in pro-glacial suspended sediment dynamics are likely given the generally agreed forecasts for global warming this century (IPCC, 2007) and the likely continued retreat of glaciers. The consequences are likely to have greatest impact in the less economically developed parts of the world like the Himalaya (Singh et al., 2004) where changes in inputs of sediments to glacier-fed rivers have important implications for water abstraction and drinking water supply. Hydropower (HEP), large and small, is one of the most important of the renewables for electrical power production worldwide, providing 19% of the world's electricity (Paish, 2002) and set to increase. Small-scale hydro which draws water directly from streams and rivers with no dam or water storage, is one of the most cost-effective and environmentally benign energy technologies to be considered for rural electrification in less developed countries. Paish (2002) reports that the European Commission has a target to increase small hydro capacity by 4500 MW (50%) by the year 2010, and notes that turbines need to be protected from all the debris commonly found in rivers. Sediment entering intake pipes can be highly abrasive to turbines resulting in high maintenance and/or repair costs. A better understanding of sediment dynamics, and the likely future, will be important to HEP operators as it will allow planning of sediment flushing events and water intake at times when suspended sediment loads are likely to have least impact.



Suspended Sediment Dynamics, Figure 8 Examples of hysteresis loops in the SSC vs Q relationship for 1-hourly samples in the Torrent du Glacier Noir, SE France (data from Stott and Mount, 2007a), (**a**) clockwise on 11 July 2003, (**b**) anticlockwise on 12 July 2003.

High suspended sediment loads from mountain regions can result in sedimentation in lowland rivers which may affect stream ecology. Silt can clog river-bed gravels (Petticrew and Biickert, 1998), which in certain reaches contain salmon spawn so depriving the eggs of vital oxygen, thus jeopardizing successful salmon reproduction. River sedimentation can also impact channel dynamics in lowland river systems by causing decreases in channel capacity which can increase flood potential and lateral erosion, and may require expensive river dredging programs to avert such problems (Owens et al., 2005).

Summary

Suspended sediment dynamics is concerned with the motion and equilibrium of the fine portion of a river or stream's sediment load which is normally carried in suspension. Most meltwater is discharged from glaciers during ablation phases, and even at low discharges the meltwater is usually capable of entraining and transporting fine sediment in suspension, and at peak discharges pro-glacial streams are capable of transporting extremely high suspended sediment loads.

Changes in SSC are measured by collecting water samples in sequence at-a-point over time, then filtering the water through special glass fiber filters and measuring the weight change, known as the gravimetric method. Samples can be retrieved manually by dipping an empty bottle into the flow, or automatically using pumping samplers. Scatter plots of SSC vs Q are known as rating relationships. Turbidity can be used as a surrogate for SSC and has the advantage of being able to automatically scan at high frequency and log voltages to a data logger. However, SSC vs turbidity calibration relationships in pro-glacial streams, like SSC vs Q, tend to be less than perfect. Nevertheless, they can reveal patterns which might otherwise be missed by water sampling programs, and thereby aide interpretation of suspended sediment dynamics in pro-glacial streams. Examination of time series datasets from NE Greenland for SSC and Q show asynchronous SSC and Q patterns, with SSC peaking before, at the same time, and after the hydrograph peak in different flood events. A hysteresis effect in the SSC vs Q rating relationship is demonstrated for the Torrent du Glacier Noir in SE France.

Future changes in pro-glacial suspended sediment dynamics are likely given the generally agreed forecasts for global warming this century. The consequences are likely to be greatest in the less economically developed parts of the world like the Himalaya where glacier-fed rivers supply a high proportion of drinking water. Elsewhere, hydroelectricity generation often relies on abstracting water from glacier-fed rivers and changes in suspended sediment dynamics will have important implications for the timing and amount of abstraction since sediment-laden water causes problems concerned with increased abrasion and scour of pipes and turbines. Silt from pro-glacial zones can clog river-bed gravels downstream where certain reaches contain salmon spawn so depriving the eggs of vital oxygen, thus jeopardizing successful salmon reproduction. River sedimentation can also impact channel dynamics in lowland river systems by causing decreases in channel capacity which can increase flood potential and lateral erosion, and may require expensive river dredging programs to avert such problems.

Wash load

Definition

Almost all the world's streams carry sediment that originates from erosion processes in the basin that feed the streams. Sediment carried in a stream is classified as either suspended load or bed load. The suspended load is the fine-grained (clay and silt) sediment that remains in water during transportation. The bed load consists of the coarser fractions of the sediment (sands and gravels), moves by rolling, sliding, or saltation actions. Coarser sediments will be deposited first and suspended sediment load moves at approximately with the same velocity of the flowing water. From the general point of view, river is a main component of global water cycle and it plays an important role to transport sediment and other matter into the ocean (Garrels et al., 1975; Martin and Meybeck, 1979). In Himalayas, three major river systems: the Ganga, the Brahamputra, and Indus delivered a combined suspended sediment load of the order of 1.8×10^9 ton/year (Meybeck, 1976), which is about 9% of the total annual load carried from the continent to the oceans worldwide. Suspended sediment load can be satisfactory assessed directly from discharge and sediment concentration. Suspended sediment records are also used to estimating erosion rates in mountainous region, where the eroded material is transported as a sediment load.

Mapping glacier movement

Definition

Glaciers move due to their own weight and the influence of gravity. Information about the movement of the glacier is very important for understanding the climate change, mass balance, and glacier dynamics. The movement can be measured using surveying techniques (stakes and theodolite), laser ranging, and global positioning systems. All these techniques are confined to a point measurement and consumes time and expensive to measure over large inaccessible and inhospitable areas. Remote sensing techniques are very useful and cost effective to map those areas for glacier movement. Synthetic Aperture Radar Interferometry (InSAR) is a powerful technique for measuring the glacier velocity and strain rate (velocity gradient) with centimeter accuracy. In this technique, the phase difference of two or more SAR images acquired from slightly different orbit positions or view angles and at different times is exploited to obtain topography and surface change due to earthquake, volcano, land subsidence, and glacier velocity mapping.

Introduction

InSAR is widely used to map the velocity of glaciers in Antarctica (Goldstein et al., 1993; Frolich and Doake, 1998) and Greenland (Joughin et al., 1995, 1996; Kwok and Fannestock, 1996; Rignot et al., 1995). However, its applicability to map the velocity of temperate glaciers is challenging due to steep topography, melting of snow, and atmospheric changes between two SAR acquisitions. In spite of these difficulties, InSAR was successfully applied to map the velocity of the temperate and alpine glaciers using ERS-1 and 2 SAR tandem data. The advantage with tandem data is that ERS-1 and 2 satellites with similar SAR system acquired data with a 1-day interval between August 1995 and June 1996. Within a 1-day interval, glacier velocity in many parts of the glacier except at terminus is less than the prescribed limit. The upper limit on differential displacement occurs when the phase change is equal to phase sampling rate in range (Vachon et al., 1996). It means that the change in displacement between adjacent resolution cells must be less than $\lambda/2$. This condition sets the upper limit for the detectable velocity gradient. For example, when ice blocks move more than $\lambda/2$ from one resolution cell to the next, phase cycles are no longer detectable on interferogram and phase unwrapping is impossible. However, if the scene coherence is retained, there is no upper limit on absolute displacement measurement. In order to retain the scene coherence, the upper limit on displacement would be roughly half the resolution cell. For ERS system, the value is 4.8 m/day as the slant range resolution is 9.6 m.

Repeat pass InSAR

Glacier velocity can be mapped using 2-pass and 3-pass differential SAR interferometric (DInSAR) techniques. In 2-pass technique, one image is acquired before an event (earthquake, volcano eruption, land subsidence, landslides, glacier movement, etc.) and another one after an event. A typical SAR interferometer is an extension of famous two slit Young's experiment and is shown in Figure 1a. The phase difference between the two images (i.e., interferogram phase) containing both topography and displacement phase can be written as (Rosen et al., 2000, Massonnet and Feigl, 1998; Madsen and Zebker, 1998)

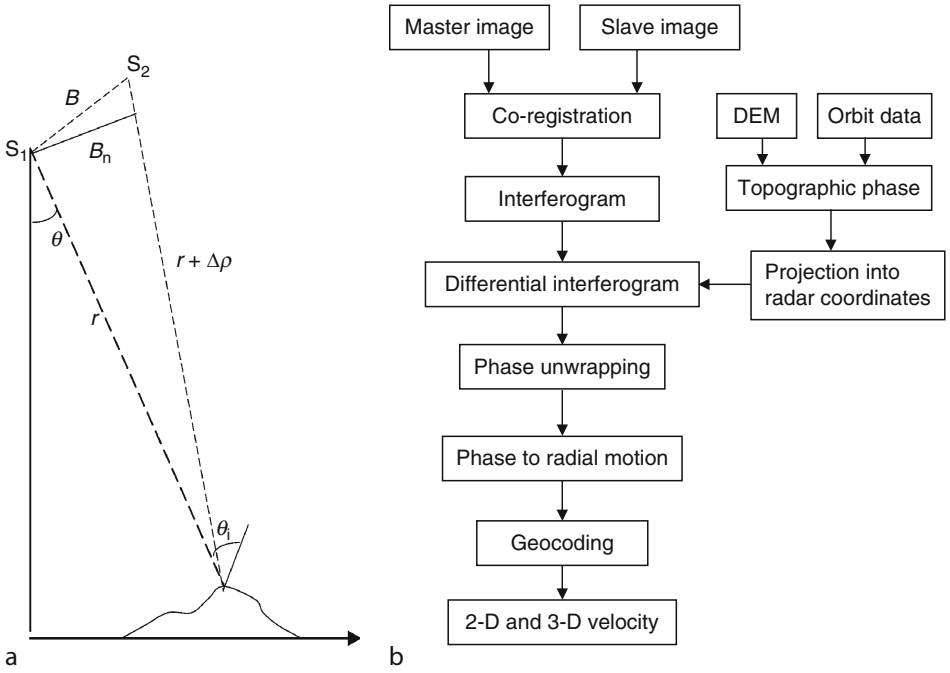
$$\Delta\phi = -\frac{4\pi}{\lambda}\frac{B_n \delta h}{r \sin\theta} + \frac{4\pi}{\lambda}\delta r \tag{1}$$

where $\Delta\phi$ is the interferogram phase after correcting for flat earth surface phase, B_n is perpendicular baseline, δh is altitude difference between two point targets, λ is the wavelength of the SAR system used, θ is the SAR signal incidence angle, r is slant range distance, and δr is the displacement between the two scene acquisitions.

In order to obtain the displacement due to glacier motion, the first term in Equation 1 representing topography phase is to be removed. For this, one has to obtain the accurate topography information. In February 2000, shuttle radar topography mission (SRTM) flew around the globe for around 11 days and collected digital elevation models (DEMs) of the earth surface except the area around north and south poles. The DEMs derived from the SRTM data are freely available to the public. Using orbital parameters of the two SAR scenes and SRTM digital elevation models, synthetic phase corresponding topography can be obtained. The synthetic phase is subtracted from interferogram to get the differential interferogram, representing only phase due to displacement map. After removing the phase due to topography, the Equation 1 becomes

$$\Delta\phi_{\text{defo}} = \frac{4\pi}{\lambda}\delta r \tag{2}$$

From this equation, displacement corresponding to one phase cycle ($\Delta\phi_{\text{defo}} = 2\pi$, i.e., one fringe in differential interferogram) yields $\lambda/2$. This value for ERS-1&2 is 2.8 cm, SIR-C L-band is 12 cm, and TerraSAR-X is 1.5 cm. The entire procedure for obtaining displacement is shown in Figure 1b.



Synthetic Aperture Radar (SAR) Interferometry for Glacier Movement Studies, Figure 1 (**a**) Geometric configuration for InSAR and (**b**) flow diagram for 2-pass differential InSAR for glacier movement.

For typical ERS-1&2 SAR parameters λ = 5.6 cm, r = 850 km, θ = 23° baseline B_n=100 m, the first term (topographic) in Equation 1 becomes

$$\Delta\phi_{\text{topo}} = -0.06756\,\delta h \tag{3}$$

From this equation, the topographic height δh per one phase cycle ($\Delta\phi_{\text{topo}} = 2\pi$) becomes $\delta h = 93$ m. By comparing differential and topographic values, we can say that differential interferometry is 3,321 times greater sensitivity than topography. However, this sensitivity depends on the baseline value and decreases with increasing baseline. That is why DInSAR is better for lower baseline values. If DEM has some error of 30 m, then the error in displacement is about 1 cm (30 m/3,321 ≈ 1 cm).

Error in the baseline also creates an error in differential phase (Vachon et al., 1996). For ERS-1&2 tandem data, the error is about 0.4 cm/day. In addition to these topography and baseline-related errors, atmospheric changes will also affect the accuracy of displacement map (Zebker et al., 1997).

3-pass DInSAR is not useful for mapping the displacement map of temperate glaciers due to large interval (35 days) between two passes and melting of snow. However, this technique was applied by Kwok and Fannestock (1996) and Joughin et al. (1995) with several ERS SAR datasets over Greenland acquired with a 3-day interval to remove motion effects and obtain the topography. In this method, minimum three SAR images are required to form two interferograms. It is important to note that motion should be uniform throughout the acquisition period. By taking the difference of the two interferograms, motion is canceled and the resultant differential phase represents the topography. With this topography information, glacier motion can be obtained after removing the topography-related phase from the interferogram.

Phase coherence

For the analysis of glacier movement using InSAR, information about phase coherence is very important. In the interferometry processing, coherence is one of the products of InSAR technique. Interferometric complex correlation can be written as (Rosen et al., 2000)

$$\gamma = \frac{\langle g_1 g_2^* \rangle}{\sqrt{\langle |g_1|^2 \rangle \langle |g_2|^2 \rangle}}$$

where g_1 and g_2 represent the first and second SAR images, respectively, and angular brackets denote averaging over the ensemble of speckle realizations. The magnitude of the correlation $|\gamma|$ is usually known as coherence and varies from 0 to 1. The causes for the decorrelation between two images are due to temporal, spatial, and thermal noise. The total coherence of the image can be written as (Zebker and Villasenor, 1992)

$$\gamma_{\text{total}} = \gamma_{\text{temporal}}\gamma_{\text{spatial}}\gamma_{\text{thermal}}$$

The spatial decorrelation ($\gamma_{spatial}$) depends on sensor geometry and baseline separation between two acquisitions. The temporal decorrelation ($\gamma_{temporal}$) is due to changes in vegetation growth, snowdrift, snowmelt, glacier motion, permafrost freezing and thawing, soil moisture changes, agricultural practices, etc. that occur during repeat pass acquisition. The decorrelation due to thermal noise is related to signal to noise ratio of the sensor system.

Rignot et al. (1996) observed the coherence over San Rafael glacier, Chile using SIR-C L- and C-band and found that the coherence at L-band is better than C-band with a 1-day interval between two scenes as shown in Figure 2. Coherence is low ($\gamma < 0.4$) on the glacier at C-band, but higher on the plains surrounding Laguna San Rafael. Mountain peaks without vegetation also shows high coherence (γ = 0.7–0.8). The forest area shows low coherence (γ = 0.4–0.6) due to movement of leaves and volume scattering. At L-band, the coherence is high ($\gamma < 0.95$) at low elevations over the forest and also at slow moving part of the ice fields ($\gamma < 0.75$), intermediate over fast moving part of the glacier ($\gamma = 0.5$), moderate ($\gamma = 0.35$) in areas of high shear strain and low ($\gamma < 0.2$) over the open water and shadows. Snowmelting areas also show low coherence.

Using many ERS-1 and 2 tandem datasets, Vachon et al. (1996) and Mattar et al. (1998) observed change in coherence on different dates over Saskatchewan and Athabasca glaciers. It was found that on some dates, coherence is very low even for the tandem data and not useful for InSAR studies. They estimated the coherence using an averaging window size of 50 (azimuth) × 10 (range) samples.

Rao et al. (2008a) observed coherence change over three major Indian Himalayan glaciers, namely, Siachen, Gangotri, and Bara Shigri using ERS-1 and 2 tandem data and ENVISAT ASAR 35-day interval data. Among all these, Siachen glacier showed the highest coherence with ERS-1/2 tandem data acquired in descending pass as shown in Figure 3a. Low coherence was observed over Gangotri and Bara Shigri glaciers using the tandem data and shown in Figure 3b and c. ENVISAT ASAR 35-day interval data also gave good coherence outside glacier area. In glacier area, the coherence is completely lost due to large movement of the glacier within a 35-day interval and also changes in the debris on the glacier due to melting and precipitation. High-resolution TerraSAR-X images over Gangotri glacier with a 11-day interval also give poor coherence for the glacier part due to lower wavelength and fast movement of the glacier. However, good coherence and fringes are observed in the adjacent glacier area.

ALOS PALSAR L-band images over Qinghai-Tebetan plateau with interval 45–90 days also show low coherence over glacier area (Li et al., 2008). But the coherence obtained with a 45-day interval data as shown in Figure 4 is better than that obtained with a 90-day interval data. Due to longer wavelength of PALSAR and winter season, coherence was preserved between images acquired with a 45-day interval.

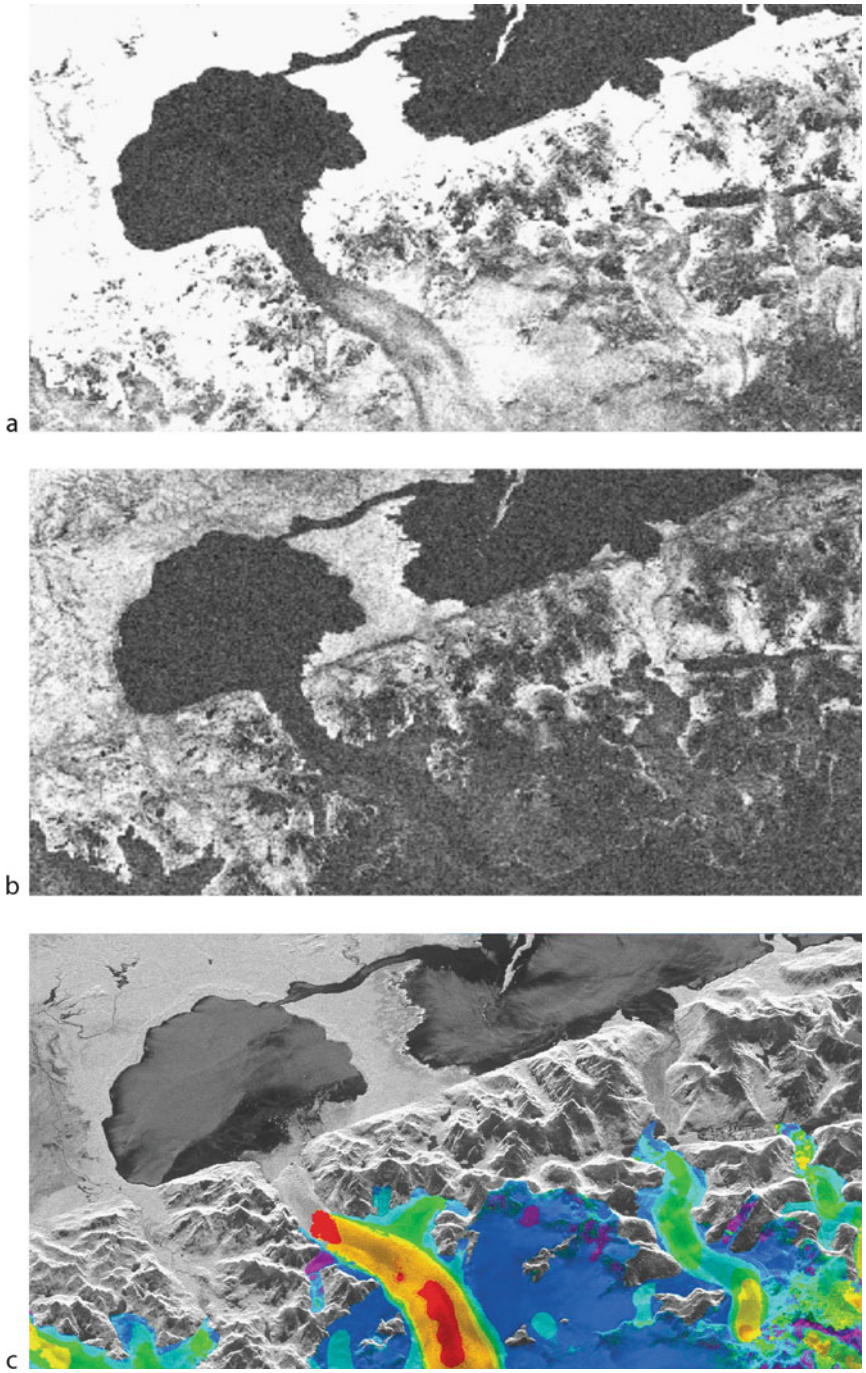
Intensity, coherence, and speckle-tracking methods

When the loss of coherence is high between interferometric SAR images, differential InSAR cannot be applied. An alternative to DInSAR for the estimation of glacier motion is offset tracking (Strozzi et al., 2002; Pattyn and Derauw, 2002). In the intensity tracking, image offsets in the slant range and azimuth directions are calculated using SAR intensity images, whereas in coherence-tracking method single look complex SAR images are used to calculate coherence and maximized the value by shifting the offset. This is done over entire image by tracking small patches of size 8 × 8 pixels which correspond to 160 m in the ground range and 30 in the azimuth direction for ERS SAR system. The offsets obtained through this procedure are due to orbit configurations and glacier movement. The offsets related to orbital geometry are estimated using precision orbit and ground control points and the offsets related to glacier displacement is separated. The accuracy of the offset-tracking methods is two times less than that we get using DInSAR studies (Strozzi et al., 2002). Advantage of offset-tracking method is that we get two-dimensional velocities in azimuth and range direction, whereas the DInSAR gives only in radar look direction (one direction). Rignot et al. (1996) also used intensity-tracking technique for the estimation of movement in crevasse areas.

Speckle tracking is similar to intensity and coherence tracking. Instead of correlating intensity or coherence between two images, it correlates speckle between two images for observing shifts between two images. The condition for this technique is that coherence between two images is necessary (Gray et al., 2001; Joughin, 2002; Short and Gray, 2004).

Three-dimensional flow estimation

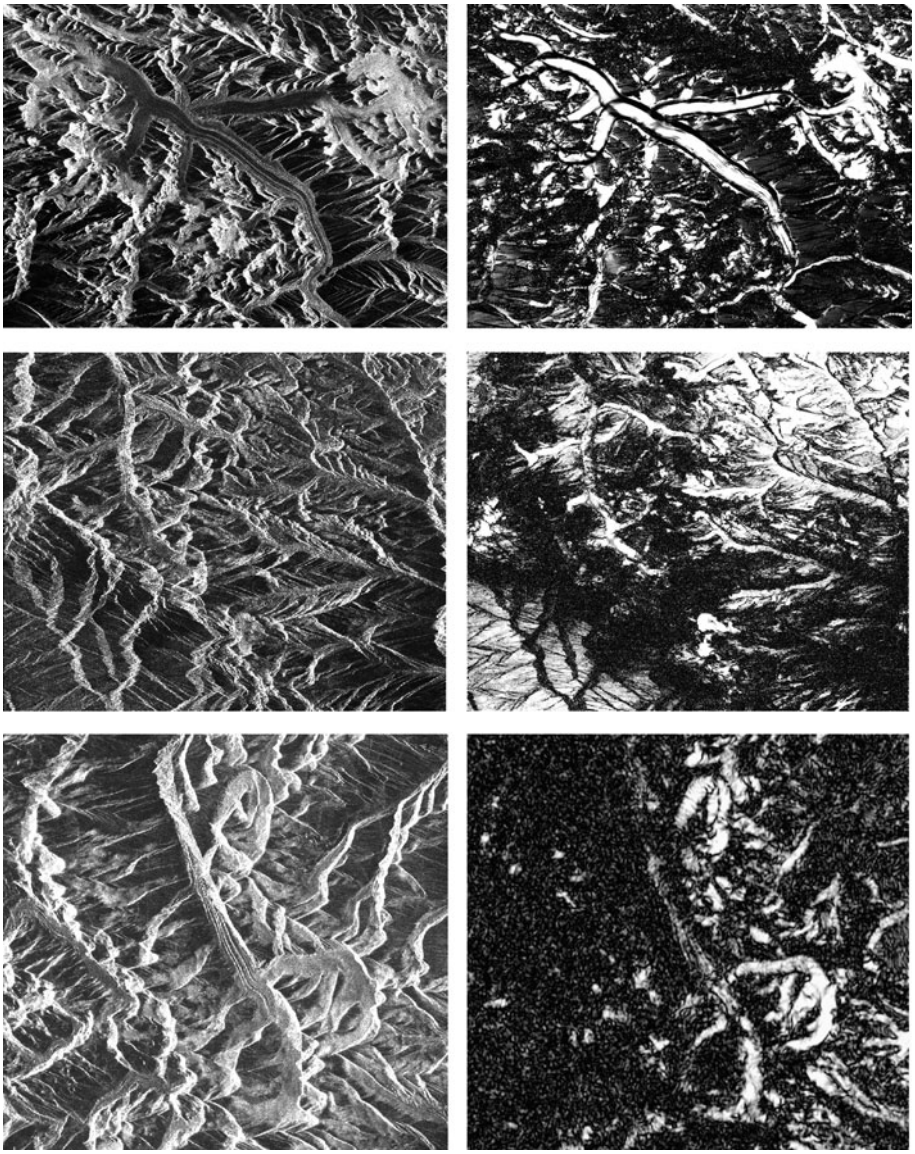
Radar measures the displacement in the line of sight (LOS) direction. One single interferogram gives only one component of velocity. However, the true displacement may lie in any direction. Without additional information, it is not possible to separate horizontal and vertical displacement. Joughin et al. (1998), Mattar et al. (1998), Mohr et al. (1998), and Magnússon et al. (2007) combined the displacements obtained with ascending and descending pass data and surface slope to estimate three-dimensional ice velocity vector. They assumed that glacier flow is parallel to the topographic surface and also ice flows at a steady rate during acquisition of the ascending and descending passes. These assumptions may fail in some cases. The surface-parallel flow assumption fails in the regions of accumulation and ablation areas with bumpy terrain where vertical component motion is large and leads to errors. However, the horizontal component of motion is relatively unaffected by deviations in surface-parallel flow. The required inputs for the calculation of three component velocity vector are surface slope, angular separation of ascending and descending tracks α, and incidence angle (θ_i) which



Synthetic Aperture Radar (SAR) Interferometry for Glacier Movement Studies, Figure 2 (**a**) Phase coherence between October 9 and 10, 1994 SIR-C L-band image pair, San Rafael Glacier, Chile. (**b**) phase coherence at C-band, and (**c**) ice motion derived using L-band data in the direction of radar illumination (Rignot et al., 1996). *Light purple* (<–3 cm/day), *purple* (–3 to –0.5 cm/day), *gray* (–0.5 to +0.5 cm/day), *blue* (0.5–3 cm/day), *light blue* (3–20 cm/day), *green* (20–45 cm/day), *yellow* (45–85 cm/day), *orange* (85–180 cm/day), and *red* (>180 cm/day). Negative sign is movement away from the radar and positive sign is movement toward the radar.

is defined with respect to local normal to the ellipsoid as shown in Figure 1, angle between ascending pass direction and reference x-axis and unwrapped phase corresponding to motion (Joughin et al., 1998).

Using single interferogram also, surface displacement can be estimated using range displacement (Vachon et al., 1996). For certain critical angles of surface slope and the direction of slope, the LOS displacement is



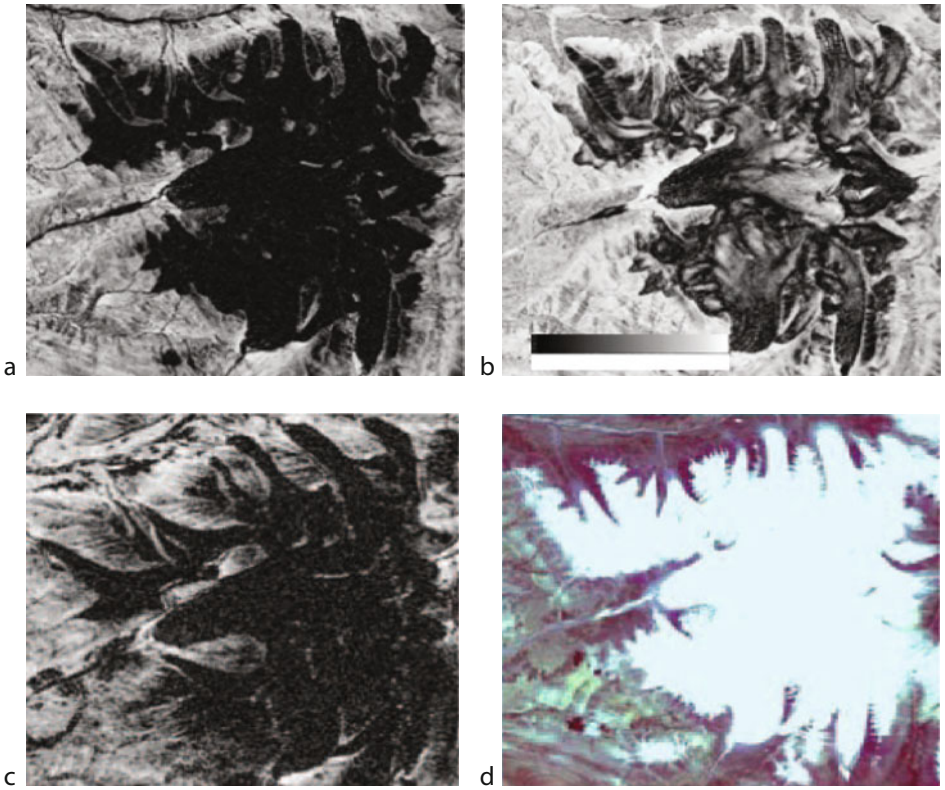
Synthetic Aperture Radar (SAR) Interferometry for Glacier Movement Studies, Figure 3 Interferometric coherence along with SAR intensity images are shown for Siachen (*top*), Gangotri (*middle*), and Bara Shigri (*bottom*) glaciers in Himalaya using ERS-1/2 tandem data.

perpendicular to the glacier displacement and surface displacement tends to infinity. To estimate the displacement from single LOS measurement, the LOS direction relative to displacement is outside the critical range.

Studies on land glaciers

InSAR studies on midlatitude alpine glaciers are very few. Vachon et al. (1996) studied surface displacement of Athabasca and Saskatchewan glaciers using several ERS-1/2 tandem pairs acquired with a 24 h interval. Topography information in the interferogram was removed using the DEM derived using airborne SAR data. The RMS error in their DEM is about 5 m that cause an error of 0.4 cm/day in displacement map at the baseline of 300 m. They also mentioned that the error in the baseline also causes 0.4 cm/day error in displacement map. Mattar et al. (1998) extended the same work and estimated three-dimensional surface flow field using surface-parallel flow assumption by combining ascending and descending passes. The LOS displacement of maximum 18 cm/day was observed for Saskatchewan glacier with ascending pass data, whereas 10 cm/day with descending pass data. The corresponding surface displacement along the center line of the Saskachewan glacier is 35 cm/day.

Rignot et al. (1996) studied San Rafael, Chile glacier using SIR-C L- and C-band October 1994 interferometric



Synthetic Aperture Radar (SAR) Interferometry for Glacier Movement Studies, Figure 4 Phase coherence images over the glacier Dongkemadi in Qinghai-Tibetan plateau. (**a**) ALOS PALSAR pair June 11, 2006 and September 11, 2006 (**b**) ALOS PALSAR pair December 10, 2007 and January 25, 2008, (**c**) ENVISAT ASAR pair July 10, 2007 and August 14, 2007, and (**d**) TM image for the same area (Li et al., 2008).

data acquired with interval of 24 h. Due to shorter wavelength, C-band data did not give good coherence image for this area. However, L-band data preserved the coherence in many parts of the glacier and were used to map the surface topography over the glacier with accuracy of 10 m and measured the ice velocity with a precision of 4 mm/day. The LOS interferometric velocities were converted to surface displacement by assuming a flow direction and complemented by feature-tracking result near the calving front. Ice velocity map in radar LOS direction is shown in Figure 2c. InSAR observed ice velocity at the equilibrium line (1,200 m altitude) is 2.6 m/day (0.85 km/year) and increases rapidly before the glacier enters the narrower terminal valley. Just before 100 m from the calving front, ice velocity reaches 17.5 m/day (6.4 km/year). InSAR could estimate velocities upto 9 m/day. Feature-tracking method was used near the crevasse areas to estimate velocity upto 17.5 m/day. Effective starin-rate map was also generated using velocity map. Forster et al. (1999) studied Europa and Penguin glaciers in Chile using SIR-C L-band data and estimated ice velocity with a precision of 2 cm/day.

Michel and Rignot (1999) used SIR-C L-band October 1994 data to map Moreno glacier in Argentina. Both interferometry and feature tracking based on coherence have been used to map the glacier velocity and found that InSAR can measure ice velocity with a precision of 1.8 cm/day, while feature-tracking method can estimate with an accuracy of 14 cm/day.

Swiss Alpine glacier movement was studied by Strozzi et al. (2003). The glaciers covered in their study were the largest glacier Groβer Aletschgletscher and other glaciers Unteraargletscher, Fieschergletscher, and Grüebu Gletscher. As the ground truth data over Unteraargletscher glacier are available through various methods, interferometric derived LOS displacement map was obtained using ERS-1/2 tandem data for this glacier. The maximum velocity observed at the upper part of the glacier at steeper slopes is 4 cm/day and decreases gradually along the glacier. It was observed that radar is not sensitive to displacement measurement if the glacier flow is perpendicular to the radar look direction. It was suggested that the LOS surface displacement map of the glacier is useful to estimate mass balance distribution using the kinematic boundary condition without the use of ground measurements.

Himalayan glaciers movement

Rao et al. (2004, 2008a, b) mapped the movement of the major Himalayan glaciers, namely, Siachen, Gangotri, and Bara Shigri using ERS-1/2 tandem data. Siachen

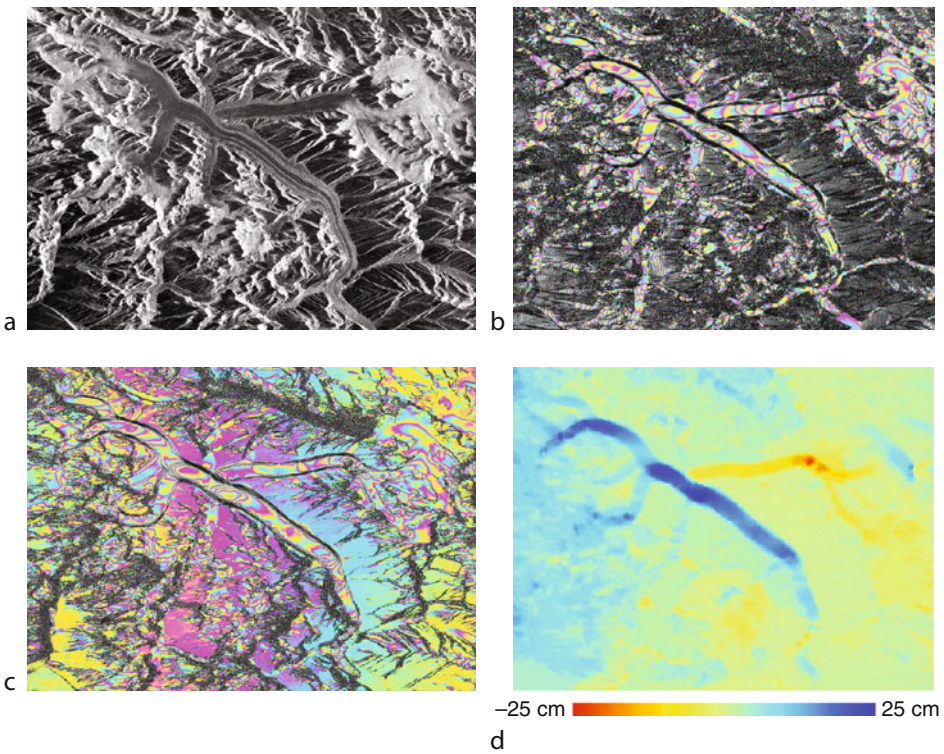
glacier is the largest glacier located at higher elevation. It has a length of about 72 km and with varying width. It is the second largest glacier in the world outside the polar region. It feeds the Nubra river (also known as Shaksgam river) that flows parallel to the Karakoram range before entering into Tibet. The trunk glacier and its tributaries are in the form of a vast ice field. Continuous snowfall can be seen during winter periods. The average winter snowfall is about 10.5 m. The temperature varies from −10°C and −50°C. The elevation varies from the snout (3,620 m) to source of the glacier (i.e., Indira col) (5,753 m).

Gangotri glacier is a major source of water for many states of the North India. It is about 25 km long with varying width of 2.5–0.5 km and having many tributary glaciers. Some of these tributary glaciers are in turn having their own tributaries. The elevation over the main glacier varies from terminus (4,000 m) to the source of the glacier (6,000 m). The temperature at the glacier (terminus) varies from 10°C to –20°C. According to many reports, the glacier is retreating at alarming rates (20 m/year).

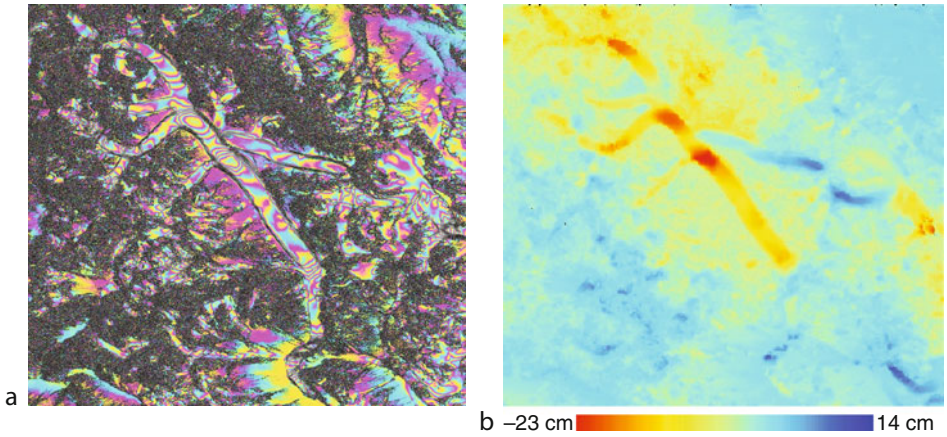
Bara Shigri glacier lies (N32°10'33", E77°40′09″) on Chandra-Bhaga river basin (Pir Panjal range) in Lahaul-Spiti district of Himachal Pradesh. The glacier is the largest in Himachal Pradesh with a length of 28 km (131 km^2) with elevation changing from terminus (4,000 m) to the source of the glacier (5,500 m). There are several glaciers around this glacier (Chhota Shigri, Hamta, etc.). All these glaciers are covered in one scene of the ERS-1/2 SAR data.

ERS-1/2 tandem data acquired on April 1 and 2, 1996 in descending pass with perpendicular baseline of 110 m and May 2 and 3, 1996 in ascending pass with baseline of 114 m were used to map the surface displacement of Siachen glacier. ERS-1/2 tandem pair acquired on March 25 and 26, 1996 in ascending pass with baseline of 75 m was used for Gangotri glacier studies. ERS-1/2 tandem pair acquired on May 2 and 3, 1996 in ascending pass with perpendicular baseline of 110 m was used to study the Bara Shigri glacier.

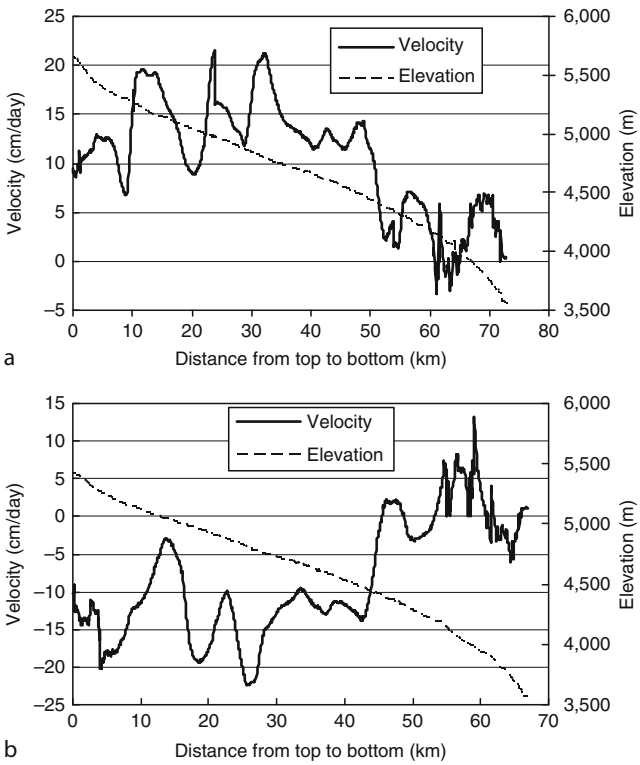
To get differential interferometric fringes, one has to follow several the steps given in Figure 1. Topography information from the interferogram was removed using SRTM 3 arc second DEM. Figure 5 shows ERS-1 SAR intensity, interferoram, differential interferogram and ice velocity in the LOS direction for Siachen glacier. Figure 5d shows velocity of the glacier in color. Negative (−) velocities represent movement away from the radar direction and positive (+) represents movement toward the radar direction.



Synthetic Aperture Radar (SAR) Interferometry for Glacier Movement Studies, Figure 5 Synthetic Aperture Radar (SAR) images of April 1 and 2, 1996 acquired by ERS-1 and 2 satellites were processed using interferometric technique for estimating Siachen glacier movement. (**a**) SAR intensity image, (**b**) Interferogram with each fringe representing topographic height of 85 m, (**c**) Differential interferogram with each fringe representing 2.8 cm motion toward the radar direction, and (**d**) Surface displacement map in cm (*dark blue* represents (25 cm/day) movement toward the radar and red represents (–25 cm) away from the radar).



Synthetic Aperture Radar (SAR) Interferometry for Glacier Movement Studies, Figure 6 (**a**) Differential interferogram and (**b**) ice velocity in the radar direction for Siachen glacier obtained using ascending pass of ERS-1/2 SAR tandem data.



Synthetic Aperture Radar (SAR) Interferometry for Glacier Movement Studies, Figure 7 Ice velocity in the radar direction and surface elevation of Siachen glacier versus the distance from the top to terminus: (**a**) ascending and (**b**) descending pass.

Differential fringes over Siachen are more, particularly at higher elevation and also lower part of the glacier, that is, ablation area. Fringes are not seen at the middle part of the glacier. Above the Siachen glacier, there are small glaciers where fringes are observed. Fringes are also seen at some places where there are no glaciers. It may be due to differences between SRTM DEM and actual elevation present at the ground. At the joining place of tributaries with trunk of the glacier, round-shaped fringes (often called bull eye shape) are observed. It is due to the movement of ice over elevation and through a bump. Maximum number of fringes at the location is about 8 which is equal to 22.4 cm displacement toward the radar direction.

Similarly, differential fringes for ascending pass over Siachen are produced and shown in Figure 6. More differential fringes are seen for this pass particularly at the ablation area indicating that the glacier is moving faster in May than in April. We have also used ENVISAT ASAR datasets with interval of 35 days to 1 year for DInSAR studies. For the 35-day data, complete loss of coherence was observed on the glacier area. To estimate motion using the large interval data, intensity-tracking method can only be used.

Along the middle of the glacier, we took the velocity profile from highest elevation to lowest and shown in Figure 7 for both descending and ascending passes respectively. The X-axis is the distance in pixels down the glacier. Each pixel is about 20 m. In case of Gangotri, we observed positive velocity that indicates the movement of glacier away from the radar direction. For Siachen glacier, the trend of movement along the glacier varies depending on the descending and ascending passes. At the bump of the glacier (525 and 1,000 pixel number), there was steep change in displacement at the glacier. At the bottom of the glacier also, there is variation in the movement. The variation is highest at the ablation zone.

About two to three differential fringes (8.4 cm) were observed for Gangotri area particularly in higher elevation of the glacier. There was also displacement at some other areas due to DEM and baseline errors. Considering the

error in SRTM DEM which is about 30 m, the error in displacement map for Gangotri is less than 1 cm. Although we observed differential fringes for Bara Shigri glacier, we could not obtain displacement map due to phase unwrapping problems. We observed heavy coherence loss at this area. The differential fringes show that the maximum glacier movement is 5 cm/day.

Alaska surge glaciers

Bering glacier is the largest glacier in North American continent with 190 km length. Fatland and Lingle (1998, 2002) analyzed the glacier surge 1993–1995 using intereometric SAR data. Rabus and Fatland (2000) analyzed Black Rapids glacier in Alaska using ERS-1 SAR 3-day interval data. There is not much literature on catastrophic glacier using InSAR.

Summary

InSAR is a power tool for mapping glacier movement with centimeter accuracy at high spatial resolution. All satellite datasets may not be useful for InSAR applications due to large glacier movement, melting of snow, baseline requirements, and atmospheric changes. ERS-1/2 tandem data acquired with a 1-day interval was the best suitable data for mapping glacier movement. Limited data acquired by SIR-C were also used for glacier velocity mapping. For removing the topographic effects in the interferograms, SRTM digital elevation models have been used. Glacier velocity map generated with SAR data is in the line of radar direction. To obtain the three-dimensional velocity map, ascending and descending pass data are combined with an assumption that glacier movement is parallel to topographic surface. As most of the operating satellites give the data at the interval of 11–45 days, applications of InSAR for glacier movement is not feasible. To overcome the difficulty, intensity-, coherence-, and speckle-tracking methods have been used. As the resolution of the present satellites is better than the older satellites, glacier movement of even smaller glaciers can be mapped with greater accuracy.

TALIK

Tingjun Zhang
National Snow and Ice Data Center, Cooperative Institute for Research in Environmental Sciences, University of Colorado at Boulder, Boulder, CO, USA

Definition

Talik refers to a layer or body of unfrozen ground occurring in permafrost regions due to a local anomaly in thermal, hydrological, hydrogeological, or hydrochemical conditions (van Everdingen, 1998/2005). This definition has no time restraint; any layer or body of unfrozen ground for a certain period of time in permafrost regions can be classified as a talik, such as an active layer over permafrost, which is unfrozen ground in summer; however, such a layer is not a talik. With some modification, talik is defined as a layer or body of unfrozen ground existing continuously for more than a year in permafrost region. In Russian and Chinese literature, talik mainly refers to unfrozen ground for more than a year in continuous permafrost regions. When the area of unfrozen ground appears to be comparable with or larger than the area of frozen ground, the unfrozen ground is termed as a talik zone.

Talik types

According to its temperature, taliks can be classified into two major types:

1. Noncryotic talik with its temperatures above 0°C
2. Cryotic talik with its temperature below 0°C and forming part of the permafrost

According to its physical position in response to permafrost, taliks can be classified into five major types:

1. Closed talik: a noncryotic talik located below the seasonally frozen layer and above the permafrost table. Closed taliks usually occur underneath a lake, also called "lake talik," or underneath a river called "river talik." Its temperature remains above 0°C because of the heat storage effect of the surface water. Its thickness varies from less than a meter to tens of meters, depending on the age of lakes or river channels.
2. Open talik: a talik that penetrates the permafrost completely, connecting suprapermafrost and subpermafrost water, usually below large rivers or lakes. An unfrozen ground in discontinuous permafrost regions belongs to an open talik type. It may be noncryotic or cryotic.
3. Lateral talik: a talik overlain or underlain by perennially frozen ground; can be noncryotic or cryotic.
4. Isolated talik: a talik entirely surrounded by perennially frozen ground; usually cryotic but may be noncryotic.
5. Transient talik: a talik that is gradually being eliminated by freezing, e.g., the initially noncryotic closed talik below a small lake which, upon draining of the lake, is turned into a transient isolated talik by permafrost aggradation.

According to the physical mechanism responsible for their unfrozen condition, taliks can be classified into five major types:

1. Thermal talik: a noncryotic talik formed under the effect of local surface energy balance. Thermal taliks mainly occur in discontinuous permafrost regions, especially in the southern limits of permafrost regions. In these regions, ground surface receives much higher solar radiation with higher air and ground surface temperatures, resulting in widespread talik formation and distribution. The insulating effect of seasonal snow cover can cause the mean annual ground surface temperature several degrees higher, if there is a thin or no snow cover, resulting in the northward movement of permafrost boundaries and the talik zone.

Vijay P. Singh, Pratap Singh & Umesh K. Haritashya (eds.), *Encyclopedia of Snow, Ice and Glaciers*, DOI 10.1007/978-90-481-2642-2,

2. Hydrothermal talik: a noncryotic talik formed under the warming effect of surface water bodies. Hydrothermal taliks include taliks above subsea permafrost due to the warming effect of seawater, under an estuary due to the heating effect of river and seawater, and under a lake or river. Taliks may be formed under a flood plain due to the effect of irregular but frequent floodwaters. Taliks may also be formed under cold mountain glaciers due to glacier meltwater.
3. Hydrochemical talik: a cryotic talik in which freezing is prevented by mineralized groundwater flowing through the talik.
4. Geothermal talik: a noncryotic talik formed due to thermal anomalies resulting from processes in the earth's interior. The origin of these geothermal anomalies is associated with connective heat transfer by subpermafrost waters under pressure and conductive heat transfer through geothermal heat flux from the earth's interior along active faults and volcanoes.
5. Artificial talik: a noncryotic or cryotic talik formed in the course of human activities in permafrost regions. These taliks are formed under artificial water reservoirs, spoil heaps, and fills of coal- and sulfide-containing rocks, areas with artificial vegetation removal, and infrastructures such as buildings and roads. Artificial taliks can be easily formed in a discontinuous permafrost zone because a small, often rather short-term, change in hear exchange condition on the ground surface is sufficient for taliks to be formed.

Based on the definition of talik given above, any layer or body of unfrozen ground in permafrost regions is talik. According to the International Permafrost Association (IPA) Circum-Arctic Map of Permafrost and Ground-Ice Conditions (Brown et al., 1997), permafrost regions occupy approximately 22.79 million km^2 or 23.9% of the exposed land area of the Northern Hemisphere (Zhang et al., 1999). The actual area underlain by permafrost ranges from 12.21 to 16.98 million km^2 or 12.8–17.8% of the exposed land area in the Northern Hemisphere (Zhang et al., 2000). In this case, the distribution of taliks ranges from 5.81 to 10.58 million km^2 or 6.1–11.1% of the permafrost regions in the Northern Hemisphere. In reality, the talik distribution is much greater than these values since taliks under water (under lakes, rivers, and seawater) and glaciers are not included in these statistics. Taliks above the permafrost table, especially in discontinuous permafrost zones, are also excluded in these estimates. At present, there is no data or information available about the extent of taliks under water and above the permafrost table.

Under global warming scenarios, permafrost boundaries will move northward, resulting in substantial increase in the areal extent of unfrozen ground or taliks in permafrost regions. Taliks under seawater will also expand due to the sea level rise and rapid arctic coastal erosion. Expansion of thaw lake surface area in continuous permafrost zones will result in more talik development. At the same time, widespread taliks may develop over land due to the thickening of the active layer in summer and less soil freezing in winter because of stronger snow insulation effect and high winter air temperatures.

Development of taliks strongly depends on surface and ground water and on the type of water exchange. It is the water that can be considered as an accumulator and carrier of heat and has most effect on ground temperatures and thus the talik formation in permafrost regions. The nature of groundwater movement and the rate of water exchange directly influence the processes of talik formation. In turn, taliks provide channels for groundwater movement and exchange between super-, intra-, and sub-permafrost waters. Taliks and groundwater are strongly coupled in permafrost regions.

Summary

Taliks provide an excellent environment for soil microbial activities that can produce methane from organic materials, such as dead plants and animals trapped in permafrost. It has been reported that methane released from thaw lakes in permafrost regions is a significant source of atmospheric methane (Walter et al., 2007). Development of taliks also has a dramatic impact on vegetative growth, landscape, surface and groundwater hydrology, and human infrastructure.

TARN

Himali Panthri
Department of Geology, D.B.S (P.G) College, Dehradun, Uttarakhand, India

Synonyms

Cirque lake

Definition

A tarn is a lake formed within a cirque due to excavation by glacier. Greater thickness and enormous pressure of ice mass at the floor of cirque basin are the causes of formation of tarn. A tarn is generally circular, small, and deep with no major inlet. Usually it is fed by the runoff from the slopes surrounding it. Its boundary is often marked by small moraines.

TEMPERATE GLACIERS

Andrew Fountain
Department of Geology, Portland State University, Portland, OR, USA

The term "temperate glacier" originally derives from the geographic classification of glaciers along with tropical, polar, maritime, and so on. While that definition has some currency at the time of this writing, a more nuanced and commonly used definition is that of a glacier that is a "warm glacier" – a glacier that is at its melting temperature throughout except for a seasonal skin effect. This thermal definition of "temperate" is much more descriptive of the glacier than one that defines its geographic zone.

The thermal definition of "temperate glacier" implies the presence of water. If the glacier is at its melting temperature throughout the ice mass then much of its mass loss is through melting. Furthermore, the melt water can be routed through the "warm" body of the glacier, via crevasses and moulins, with minimal freezing, to reach the glacier bed where it is in contact with the substrate of bedrock or sediment. The presence of water at the bed can reach large pressures, often a significant fraction of the weight of the ice, such that it facilitates glacier sliding. A temperate glacier flows by sliding and internal ice deformation at speeds roughly double that of a "cold" glacier that is frozen to the bed and flows by deformation of ice alone.

To accommodate the flux of surface meltwater the glacier evolves a system of passageways through the body of the glacier (englacial) and may be composed of naturally formed conduits and cracks, much like that found in cave systems of karst topography. At the bottom of the glacier, passageways may include conduits and cavities, separations between the ice and bedrock, as well as water flow through sediments.

One can see why the thermal definition of "temperate glacier" has been largely adopted because it explains much more about the glacier and what one might expect, compared to the traditional geographic definition. Temperate glaciers are found from the tropics to the subpolar regions, depending on the elevation of the glacier.

TEMPERATURE LAPSE RATES IN GLACIERIZED BASINS

Shawn J. Marshall, Mira Losic
Department of Geography, University of Calgary, Calgary, AB, Canada

Synonyms

Near-surface lapse rates; Slope lapse rates; Vertical temperature gradients

Definition

Lapse rate. Vertical gradient of an atmospheric variable. Unless specified otherwise, this refers to the rate of change of temperature with altitude, $\partial T/\partial z$.
Free-air lapse rate. Rate of change of atmospheric temperature with height above the ground.
Near-surface temperature. Air temperature measured near the Earth surface, typically at a height of 2 m, using sensors sheltered in a radiation shield. Also known as *screen temperature*.
Near-surface (slope) lapse rate. Rate of change of near-surface temperatures with elevation.

Introduction

Air temperatures at Earth's surface govern many aspects of natural and societal systems. The importance of air temperature in hydrology and glaciology is particularly direct. Snow and ice melt occur when air temperatures rise above 0°C, warm air contributes directly to available melt energy, and the transition from rainfall to snowfall occurs at a temperature close to the freezing point. The spatial and temporal patterns of temperature on the landscape are therefore central to snow hydrology and glacier mass balance.

Despite this importance, there are few long-term measurements of near-surface air temperature in most of the world's mountain regions. It is therefore a challenge to model snow and ice melt in glacierized catchments. Most modelling studies estimate meteorological conditions at the glacier surface based on an extrapolation of station observations from low-elevation (e.g., valley bottom) sites or an interpolation of modelled or reanalyzed climatology (i.e., from regional climate or general circulation models). Because temperature is believed to be more easily extrapolated than other meteorological fields, such as wind and humidity, most large-scale glaciological models are based on temperature index methods such as positive-degree-day (*PDD*) scheme (e.g., Braithwaite, 1995; Jóhannesson et al., 1995). Hock (1999) introduces a combined *PDD*-potential radiation melt model that has come to be broadly applied, while other studies, with a more limited geographic extent, make use of distributed models of the full energy balance (e.g., Arnold et al., 1996).

These models all rely heavily on accurate knowledge of near-surface air temperatures, for both the identification of

the 0°C isotherm (the threshold for melt) and the calculation of melt energy, through cumulative *PDD* or through estimation of sensible and longwave heat fluxes to the glacier surface. There are numerous atmospheric and terrain controls on surface (hence, near-surface) temperatures, such as slope, aspect, and surface type (Carrega, 1995), but elevation is the first-order control. The most common approach in glacier mass balance modelling is therefore based on a constant "lapse rate" correction to linearly extrapolate or interpolate near-surface air temperatures from station data or modelled fields to the site-specific elevations of the glacier surface (e.g., Huybrechts et al., 1991; Jóhannesson et al., 1995; Marshall and Clarke, 1999; Klok and Oerlemans, 2002; Hock, 2003). Calculations of snow and ice melt are extremely sensitive to the choice of lapse rate, and there is frequent confusion between free-air and near-surface temperature gradients with elevation. The next section addresses this, followed by a discussion of some unique properties of the glacier boundary layer. The final section summarizes observations of near-surface temperature lapse rates in glacier environments.

Surface temperature versus free-air lapse rates

There are several mechanisms of heat transfer in the atmosphere and at the surface-atmosphere interface. Absorption of solar radiation drives warming of Earth's surface, giving an average pattern of maximum temperatures at the surface and cooling with height above the ground. Turbulent mixing and convective adjustment processes redistribute this heat through the troposphere. Air mass advection (winds), latent heat exchange (evaporation and condensation of water vapor), and diabatic heating and cooling processes, such as longwave radiation exchange, further distribute this heat energy.

The result of these heat transfer mechanisms is a variable and dynamic temperature structure in the troposphere. Some temporally averaged generalizations are possible, however. Of particular interest here is the vertical temperature gradient in the lower troposphere, classically known as the free-air lapse rate. At the idealized level of an isolated air parcel, the lapse rate is precisely defined by atmospheric thermodynamics. For an unsaturated air parcel that is lifted under free or forced convection, adiabatic expansion gives a rate of cooling of −9.8°C/km. If the air is saturated, cooling induces condensation and latent energy release, which reduces this rate of cooling. The resultant lapse rates vary but are closer to −5°C/km. The amount of warming from latent heat release depends on the extent of condensation, so is greater at high temperatures (e.g., in the tropics or at low altitudes). On average, observed lapse rates in the lower troposphere are −6°C/km to −7°C/km.

These classical values refer to average global conditions. Values deviate from this in specific environments or as a function of the time of day or year. In particular, longwave radiative cooling creates cold surface temperatures overnight and at high latitudes in the winter, setting up near-surface temperature inversions: warming with height above the surface. Horizontal air mass advection and vertical subsidence also affect vertical temperature gradients, introducing a synoptic meteorological influence. The classical values for free-air lapse rates are reasonably representative of free-air conditions for the mean state of the atmosphere. However, the distinction between free-air and surface temperature lapse rates is not always clear in climatological applications (McCutchan, 1983). The change in temperature with elevation is critical in ecological, hydrological, or glaciological studies in mountain regions, but it is the surface or near-surface temperature that is of interest in these applications. The controls of surface temperature are different from those in the free air, however, so it is not clear that the classical free-air lapse rate of −6°C/km to −7°C/km is appropriate.

Surface temperatures are governed by the surface energy balance, with warming or cooling driven by the net radiation balance, sensible and latent heat exchange with the atmosphere, and heat conduction and storage in the subsurface. The terms in the surface energy balance are still sensitive to elevation. For example, incoming longwave radiation and sensible heat generally decrease with altitude, while incoming solar radiation can be higher as a result of less atmospheric absorption. However, the overall surface energy balance does not change with altitude according to, e.g., adiabatic processes in the free atmosphere, so surface temperature lapse rates (also known as "slope" lapse rates) differ. Near-surface or "screen temperature" lapse rates – those that would be measured at, e.g., 2-m height above the ground – closely follow surface temperatures and therefore feel the combined influence of both the surface energy balance and regional free-air conditions. An EOF analysis by Lundquist and Cayan (2007) implicitly isolates these effects in a 2-year study of daily temperatures in the Yosemite Network, an array of stations spanning elevations of ca. 1,200–3,000 m in the US Sierra Nevada.

As observed by Lundquist and Cayan (2007) and many other studies, near-surface temperature lapse rates in mountain environments are highly variable, both temporally and spatially. Based on long-term climatological data (average monthly temperatures) at 589 stations in the Austrian and Italian Alps, Rolland (2003) reports mean annual near-surface temperature lapse rates of −5.4°C/km to −5.8°C/km, with a clear seasonal cycle. Summer values are closer to typical free-air rates, −6.3°C/km to −6.6°C/km. Shea et al. (2004) find similar results in the Canadian Rockies, with a mean annual value of −5.2°C/km, weaker lapse rates in the winter months (−4.6°C/km), and the steepest lapse rates in the spring (−6.0°C/km). In a catchment-scale study in southern Idaho, U.S. Rockies, Blandford et al. (2008)

measure even weaker lapse rates: −2.8°C/km in the winter months, with the strongest monthly lapse rate found in April, −4.9°C/km.

These results imply that, on average, the free atmosphere cools off with altitude more quickly than the surface in mountain environments. There are regional exceptions. For instance, Lundquist and Cayan (2007) report an average annual near-surface lapse rate of −6.8°C/km for stations in the Sierra Nevada, consistent with average free-air lapse rates. Numerous other studies, often based on a small number of stations (e.g., two) or on short-term (e.g., summer) measurements, give widely variable estimates of near-surface lapse rates in mountain regions, with recommended literature values that range from −3°C/km to −10°C/km (de Scally, 1997; Rolland, 2003). de Scally (1997) recommends a summer lapse rate of −7.8°C/km for the Punjab region of Pakistan, steeper than typical free-air values.

Regionally specific values likely need to be measured and applied for most ecological, hydrological, or glaciological applications, but a few generalizations are possible from studies to date. Part of the discrepancy in reported near-surface temperature gradients can be understood as an expected result of the surface environments in question. Where surface environments are similar (e.g., the sites of long-term WMO-standard meteorological stations) and multiyear observations are available, average monthly values of −4°C/km to −6°C/km and the consistent seasonal cycle (weaker winter lapse rates and steeper spring and summer values) appear to be robust results. Winter lapse rates are significantly weaker due to the frequency of low-level temperature inversions, cold air drainage and pooling in valley bottoms, and the weaker influence of solar radiation. Where local lapse rates deviate substantially from these typical rates, this can often be understood in terms of the local surface energy balance. For instance, de Scally (1997) interprets the steep summer lapse rates in the Punjab Himalaya as a result of surface warming on vegetated, snow-free surfaces at the lowest elevations, vs. cold, snow-covered (i.e., high-albedo) environments at the highest elevations. The relatively strong spring lapse rates reported in the North American Rockies (Shea et al., 2004; Blandford et al., 2008) may result from the same effect.

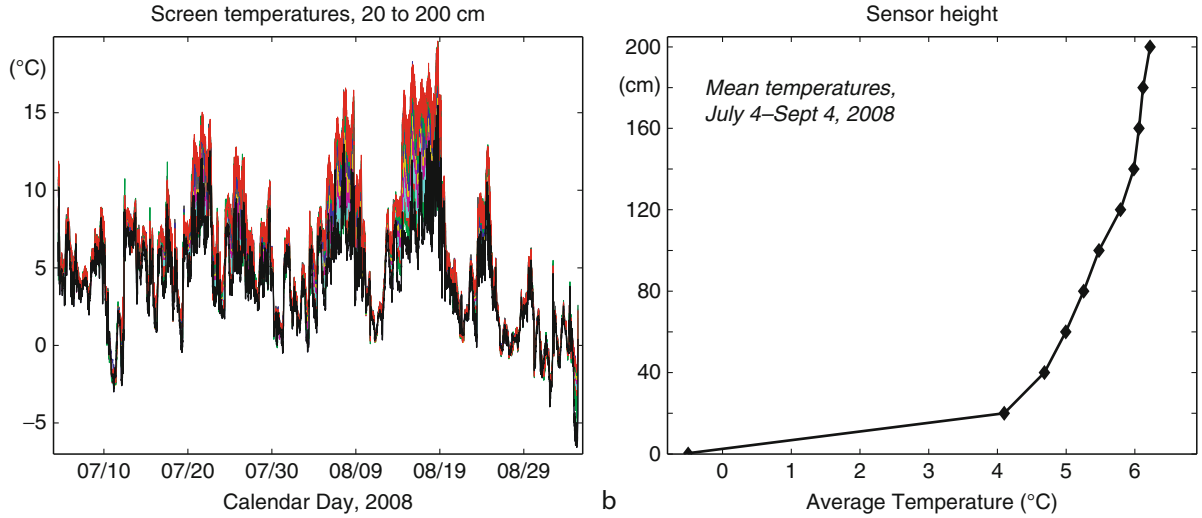
In addition to seasonal cycles, there is substantial diurnal and synoptic variability in near-surface lapse rates (Pepin and Losleben, 2002; Pepin et al., 2005; Marshall et al., 2007; Lundquist and Cayan, 2007; Gardner et al., 2009). Weaker lapse rates are more frequent overnight, again due to the occurrence of cold air drainage and the change in the dominant terms in the surface energy balance, from incoming shortwave radiation during the day to outgoing longwave radiation at night. Consistent altitudinal gradients in the net radiation budget drive greater daytime warming at low elevations, particularly where snow and ice are present at high elevations. The next two sections examine these relevant energy balance processes and their implications for near-surface lapse rates on glaciers.

The glacier boundary layer

For much of the year (and year-round at the world's highest elevations and latitudes), glacier surfaces are snow covered and a glacier's surface environment is generally undifferentiated from that of the surrounding area. The surface energy balance and the atmospheric boundary layer behave similarly to non-glacierized snow-covered regions, although the specific topographic setting of valley glaciers often gives rise to strong, channelized winds in the near-surface boundary layer. This is particularly true for glaciers that drain icefields or ice sheets, as the high-elevation plateaus in such settings are conducive to the formation of cold air masses. Gravitational drainage of this cold air produces downslope, katabatic winds year-round in many glacial settings. This cold-air advection can produce anomalously cool temperatures at low elevations on a glacier, weakening the near-surface lapse rates. Warming from adiabatic compression of the descending air counteracts this effect but does not usually offset it.

In the summer season, glacier surfaces become more interesting and distinct from the surrounding environment. van den Broeke (1997) discusses the meteorology of the "glacier boundary layer" – the near-surface atmospheric conditions on a glacier. Greuell and Bohm (1998) examine temperature variability in this boundary layer on a mid-latitude valley glacier, while Steffen and Box (2001) discuss near-surface meteorological conditions on the Greenland Ice Sheet. On an intermediate scale, Marshall et al. (2007) consider mesoscale patterns of temperature variability on a polar ice field in Arctic Canada.

Several general properties of the glacier boundary layer emerge from these studies. Katabatic winds and the relatively smooth surface of glaciers give the frequent occurrence of a low-level wind speed maximum, within a few meters of the glacier surface, which affects the turbulent heat fluxes and generally cools the lower altitudes of a glacier and weakens near-surface lapse rates, as discussed above. Beyond this influence, near-surface temperatures are primarily governed by the radiation balance and synoptic weather systems. On most ice bodies, spring and summer warming leads to rapid "ripening" of the snowpack to the melting point (0°C), after which point the glacier surface can no longer warm. Overnight refreezing is common on glaciers, with temperatures dipping slightly below 0°C on many nights and for short periods of the summer when cold weather systems pass through, but surface temperatures remain close to 0°C throughout the summer melt season. This acts to limit the atmospheric warming over glaciers, such that they are usually colder than the surrounding environment (e.g., adjacent moraines or rock ridges) during the summer.



Temperature Lapse Rates in Glacierized Basins, Figure 1 Screen temperatures in the glacier boundary layer, Opabin Glacier, Canadian Rockies. (**a**) Ten-minute temperature data at ten vertical levels (20–200 cm), July 4–Sept 4, 2008. The heavy black line (bottom trace) is at the 20-cm level and, in general, temperatures increase with height. (**b**) Profile of average temperatures at each level for the 62-day period.

In spite of this thermal buffering effect, 2-m temperatures on mid-latitude valley glaciers can warm to temperatures as high as 20°C during the day. Figure 1a illustrates this for a 2-month time series of temperature measurements in the ablation area of the Opabin Glacier in the Canadian Rockies (51.3°N, 116.3°W). This figure plots 10-min data from a set of 10 temperature sensors deployed at heights of 20–200 cm (with 20-cm spacing) in the glacier boundary layer (Losic, 2009). Temperatures increase with height above the surface, as seen in the average temperature profile for the 2-month period (Figure 1b). The sharp, buoyantly stable temperature gradient is typical of the glacier boundary layer during the daytime. This gradient weakens and can reverse overnight.

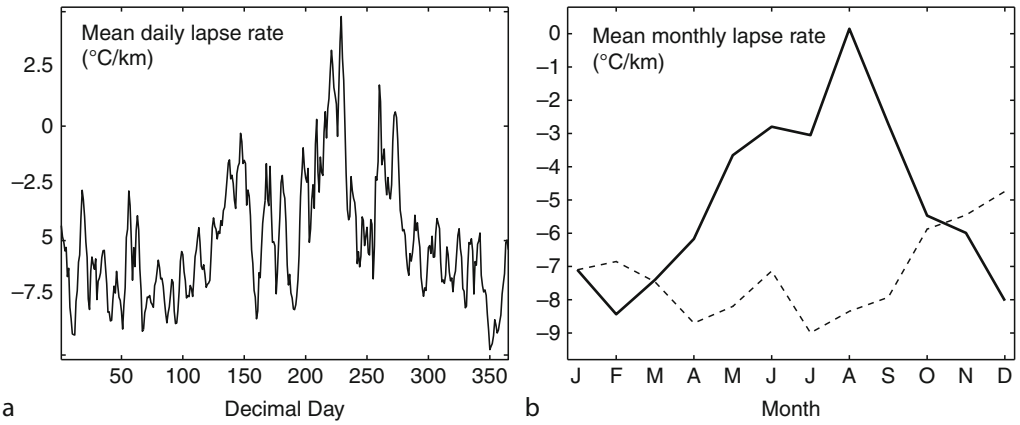
Near-surface temperature lapse rates in glacier environments

Temperature gradients in the glacier boundary layer have been the subject of several studies, as the near-surface lapse rate is a critical parameter in glacier mass balance models. Braun and Hock (2004) examine this on King George Island, Antarctica and report the frequent occurrence of shallow and inverse (positive) lapse rates, giving average near-surface lapse rates that are well below average free-air values. Jóhannesson et al. (1995) adopt a value of −5.3°C/km for mass balance modelling in Iceland. Steffen and Box (2001) measure −4.0°C/km for the ablation area of Greenland in the month of June, while Box and Rinke (2003) give an updated June–July estimate of −5.0°C/km. Marshall et al. (2007) report on 2 years of data from a network of 25 temperature sensors on the Prince of Wales Icefield, Ellesmere Island, Arctic Canada. The mean annual lapse rate in this study was −3.7°C/km, with a summer value of −4.3°C/km. Similar to non-glacial settings, there is a large degree of synoptic and seasonal variability in daily lapse rates, with a seasonal cycle that reflects that of Rolland (2003).

Gardner et al. (2009) extend this work through an analysis of regional near-surface temperature lapse rates over several icefields in the Canadian high Arctic for the period 1988–2007. They report a mean ablation season (JJA) value of −4.9°C km^{-1} at all sites, along with substantial regional correlation in daily lapse rates. Winter season lapse rates and their regional correlation are weaker. Gardner et al. (2009) also report a correlation between weaker lapse rates and anomalously warm atmospheric conditions, generally associated with southerly air masses and anti-cyclonic flow (ridging over the Canadian Arctic). The seasonal and synoptic variability in near-surface lapse rates may be sufficiently systematic to incorporate in regional-scale snow and ice melt models, although the patterns of variability are certain to be specific to the meteorological and energy balance regime of a particular region.

A multiyear study of near-surface lapse rates in the glacier boundary layer at a mid-latitude valley glacier, the Haig Glacier in the Canadian Rockies (50.7°N, 115.3°W), also reveals average near-surface lapse rates that are weaker than free-air values, but with the opposite seasonal cycle and extreme summer lapse-rate weakening. Figure 2a illustrates this, based on regressions of daily mean temperature vs. elevation from six temperature sensors along the centerline of the Haig Glacier for the period 2001–2009. Shea et al. (2005) and Sinclair and Marshall (2009) describe the field site and instrumentation in detail.

The buffering effect described above – limited heating in the glacier boundary layer due to the maximum surface



Temperature Lapse Rates in Glacierized Basins, Figure 2 (**a**) Daily average near-surface temperature lapse rates (2001–2009), Haig Glacier, Canadian Rockies (five-point moving average). Values are based on regressions of daily average temperature from a transect of six temperature sensors along the glacier centerline (elevations of 2,530–2,760 m). (**b**) Mean monthly near-surface temperature lapse rates for this period. *Solid line*: the glacier boundary-layer lapse rate, based on the centerline transect. *Dashed line*: calculated from automatic weather stations on the glacier (2,670 m) and in the glacier forefield (2,360 m).

Temperature Lapse Rates in Glacierized Basins, Table 1 Mean seasonal and annual near-surface temperature lapse rates measured on the Haig Glacier, Canadian Rockies, August 2001 to May 2009, °C km^{-1}

	DJF	MAM	JJA	SON	Annual
AWS data	−6.2	−8.1	−8.2	−6.4	−7.2
Glacier transect	−7.9	−5.7	−1.9	−4.7	−5.1

temperature of 0°C – tends to create a more homogeneous boundary layer, weakening summer lapse rates. Downslope winds reinforce this tendency. Mean monthly lapse rates are plotted in Figure 2b (solid line), while seasonal values are given in Table 1: −5.1°C/km annually, weakening to −1.9°C/km in the summer (JJA). The entire glacier surface is at the melting point through this period, and the lapse rates are weakest, with frequent inversions, late in the summer (August) when most snow has melted off the glacier, exposing bare glacier ice. Over the period of record, 2001–2009, the upper accumulation area has been snow-free in August in 5 of 9 years.

Also plotted in Figure 2b are the near-surface lapse rates as determined by the "classical" method of differencing temperatures from two automatic weather stations (AWS sites), one on the upper glacier and one in the glacier forefield. Average daily average temperature gradients through this method are much steeper: −7.2°C/km annually and −8.2°C/km in the summer (Table 1). This is a fundamentally different measure from the lapse rates in the glacier boundary layer; the glacier AWS is on the snow/ice surface, while the forefield AWS is on glacier moraine and is subject to intense summer radiative warming. As discussed by de Scally (1997) for the Punjab Himalaya, this comparison of temperatures on rock vs. a snow/ice surface produces a systematically steep gradient in the summer season.

Caution is needed when interpreting reported lapse rates in glacierized catchments, to ensure that meteorological station environments are comparable. In addition to the different albedo and thermal properties of rock and ice in the example above (i.e., rock can warm above 0°C), stations can be affected by cold air drainage or other microclimatic effects, creating an unrepresentative lapse rates. Regression-based analyses from multiple sites are recommended to minimize this problem. If one is extrapolating temperatures from an off-glacier site, the latter (AWS-derived) lapse rates are probably more appropriate than those measured in the glacier boundary layer. In this case, one needs to differentiate between near-surface lapse rates measured in the valley, forefield, and glacier environments.

Summary

Mean near-surface temperature lapse rates in mountain regions and in the glacier boundary layer are weaker than typical free-air lapse rates. Mean annual values of −4°C/km to −5°C/km are typical of mountain regions and also appear to be representative of summer lapse rates in polar regions. These rates can be much weaker on a melting glacier (bare-ice) surface, as occurs on mid-latitude glaciers in the summer months, as the glacier surface is held at a temperature close to 0°C and relatively homogeneous conditions prevail in the glacier boundary layer. Summer values of ca. −2°C/km are measured on the Haig Glacier and have also been reported on the John Evans Glacier, Ellesmere Island, in the melt season (Gardner et al., 2009).

There is substantial seasonal and synoptic variability in near-surface lapse rates, governed by the surface energy balance, evolution of the surface environment

(e.g., albedo) through the melt season, and the seasonal and synoptic variability of atmospheric conditions. Although the controls and patterns of lapse-rate variability are regionally specific, it is likely that much of the seasonal and synoptic variability in near-surface lapse rates is deterministic and may be possible to include in hydrological and glaciological modelling. Tests of the sensitivity of mass balance models to the choice of lapse rate indicate that this is a first-order control on modelled snow and ice melt, and that application of a fixed, free-air lapse rate can lead to large underestimation of summer melt (Gardner et al., 2009; Marshall and Sharp, 2009).

TEMPERATURE PROFILE OF SNOWPACK

Charles Fierz
WSL Institute for Snow and Avalanche Research SLF, Davos Dorf, Switzerland

Synonyms

Snow temperature distribution

Definition

Snow temperature profiles are records of snow temperatures, T_s, taken within the snowpack along a line vertical or perpendicular to the base, including both snow surface and base temperature, T_{ss} and T_g, respectively (Fierz et al., 2009). Measurement spacing is independent of layer boundaries, usually denser near the surface. Ground surface is in general taken as the base, but on firn fields and glaciers, base refers to the level of either the firn surface or glacier ice. Ground surface temperature, T_g, corresponds to Bottom Temperature of Snow BTS in the field of permafrost.

Significance

A snow temperature profile reflects the temperature distribution within the snowpack at one point in both space and time. Temperature distribution is a consequence of (1) the *snow–atmosphere interactions* at the surface and (2) of ground heat fluxes at the lower boundary (or base) of the snowpack. In addition, energy sinks (melting) and sources (freezing, shortwave radiation) effect temperature distribution and hence the internal energy of the snowpack. In absence of melt-freeze processes, temperature distribution is a signature of the cold content of the snowpack and snow surface temperature reflects the energy balance of the dry snow surface.

Within the snowpack, thermal properties of snow govern the shape and time evolution of the temperature profile. As heat transfer in snow is complex, an "effective" thermal conductivity is usually used to embrace all processes involved. Thermal diffusivity then controls the speed and attenuation of heat waves initiated at or near the surface and propagating through the snowpack. These and other thermal properties of snow are well described in literature (see, e.g., Gray and Male, 1981; Jones et al., 2001; Kaempfer et al., 2005; Armstrong and Brun, 2008). As a result of layering and densification within the snowpack, nonuniform temperature gradients are established that induce water vapor gradients, which in turn drive *snow metamorphism*. Indeed, dry seasonal snowpacks are hardly ever found to be isothermal. Percolating water, however, either from rain or melt at the surface, very efficiently warms up subfreezing snow as it releases latent heat during refreezing. In the end, percolating water leads to an isothermal snowpack at the melting point, that is, the snow temperature reaches 0°C throughout the snowpack. Note that percolating water is seldom an important energy input after this state has been reached.

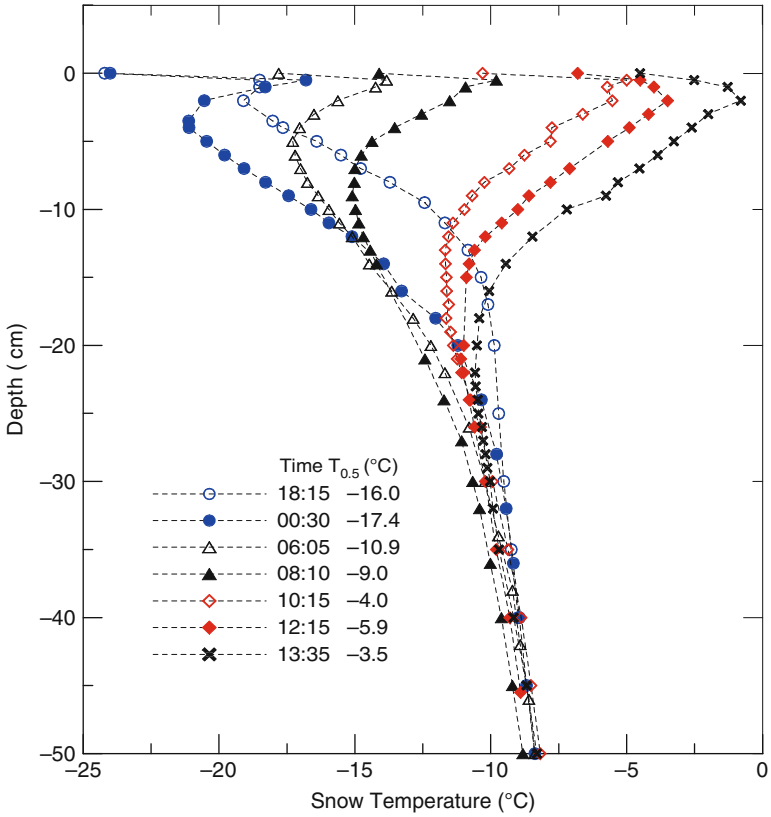
Finally, spatial variability of the snow cover, e.g., variations in snow depth, strongly influences temperature distribution. This variability mostly results from the interaction of external causes like precipitation and redistribution of snow by wind with topography and vegetation (Schweizer et al., 2008). For example, snowpacks under trees may be shallower than in clearings due to snow interception. Such variations induce lateral heat fluxes within the snowpack, but these are rarely considered in general.

Description of snow temperature profiles

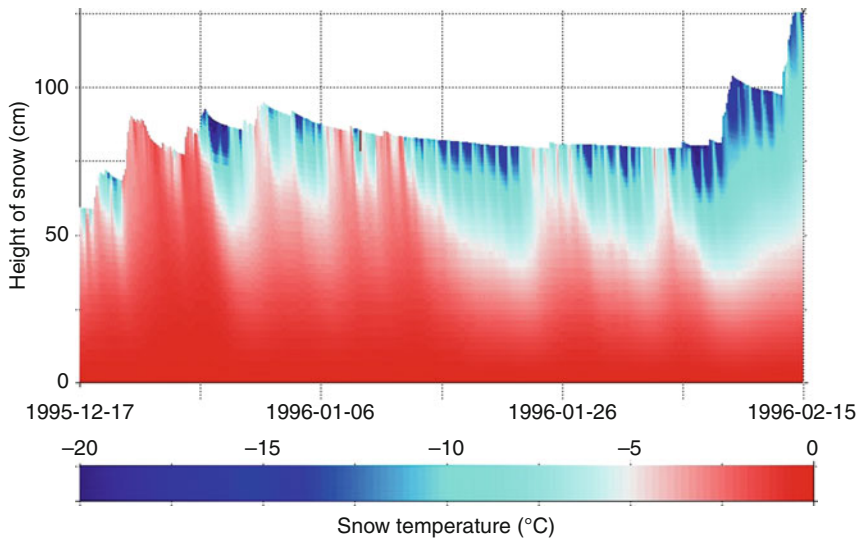
The snow temperature profiles in Figure 1 nicely show the influence of *snow–atmosphere interactions* on the top 50 cm of the snowpack. Starting 18:15 on 23 February 2000, the measurements were done with a specially designed vertical probe pushed downward from the snow surface. IR-thermometers recorded snow surface temperature. The sky was clear up to late in the morning the next day. Under such conditions, one would expect the topmost snow to cool during the night due to long-wave radiation loss. Accordingly, the temperature profile then becomes convex and temperatures near and at the surface are the lowest just before sunrise. In our case, however, the profile recorded around midnight reflected warming of the surface snow. This was due to wind along with raising air temperatures, that is, increasing turbulent heat fluxes, particularly sensible heat. This heat then diffused into the snowpack from the surface. At the surface, however, long-wave radiation losses counterbalanced warming, resulting in a typical Z-shaped profile with a temperature extreme located right below the surface. At 06:05, the heat wave penetrated deeper in the snowpack. In addition, ventilation may also have played a role in this unexpected warming up of the topmost snow made up of decomposing and fragmented precipitation particles.

After sunrise, short wave radiation penetrated the snowpack until about 11:00. The net flux entering the snowpack depends on snow *albedo* that is determined by the properties of the top centimeters of the snowpack. The net shortwave energy then diffused through the snow from the depth at which it was absorbed. The sky being still clear, a Z-shaped or swan-like profile (from French "col de cygne") resulted again. Note, however, that the upper warm extreme of the profile was located somewhat deeper in the snow than the one observed at night. This is a signature of the different energy-delivering mechanisms: heat diffusion in the latter and instantaneous release at depth in the former case.

These temperature profiles also clearly exemplify that heat only slowly penetrates the snow and that heat waves are strongly attenuated with depth. Therefore, below about 30 cm, temperature profiles showed only low-amplitude diurnal cycles that almost disappeared further down. As a consequence, snow is an excellent insulator, a well-known property of this fascinating material.



Temperature Profile of Snowpack, Figure 1 Snow temperature profiles measured 23–24 February 2000, on the study plot of the WSL Institute for Snow and Avalanche Research SLF, Weissfluhjoch, 2540 m a.s.l., Davos, Switzerland. The temperature probe was inserted vertically down from the surface.



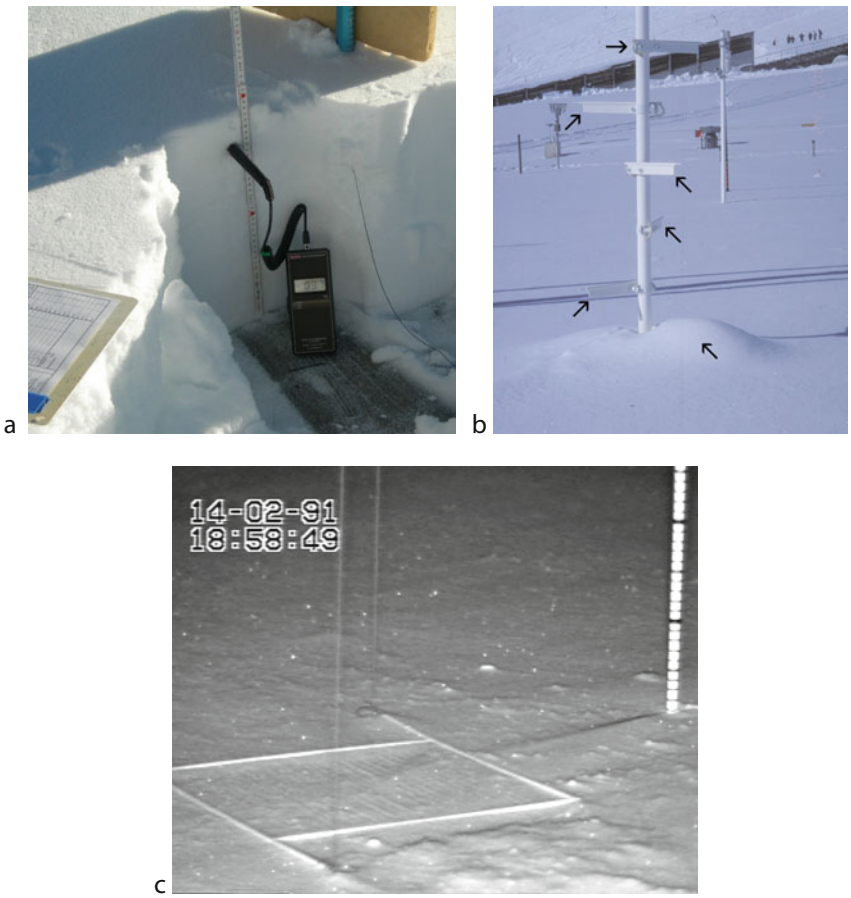
Temperature Profile of Snowpack, Figure 2 Numerical simulation of the temperature distribution within the snowpack. Input data originate from the Weissfluhjoch study plot, 2540 m a.s.l. The model used is SNOWPACK, developed at WSL Institute for Snow and Avalanche Research SLF, Davos, Switzerland.

Modeling the temperature distribution of a snowpack

Snow temperature distribution over time is often simulated with numerical models like SNOWPACK (see, e.g., Lehning and Fierz, 2008). Figure 2 presents one such simulation for part of the winter 1995/96 at Weissfluhjoch, Davos, Switzerland (2540 m a.s.l.). Note that the white "band" in Figure 2 corresponds to about −5°C. The simulation nicely reproduces the characteristic warm and rather slowly varying temperatures near the ground, while close to the surface, the snow experiences the influence of daily changing meteorological conditions. The time delay with depth is also clearly visible as well as the alternation of cold and warm waves travelling through the snowpack.

Measuring snow temperatures

There are various ways to measure temperature profiles in the snowpack. Most of them require first digging a pit and then placing suitable temperature sensors from the side wall (see Figure 3a). If measurements are done manually, the sensor is displaced by the observer and the record represents one point in time. This is the classical way to measure snow temperature profiles. A vertical resolution of a few centimeters can be reached with some uncertainty in the positioning. Furthermore, as seen in Figure 3a, measurements have to be shadowed to avoid the sensor picking up shortwave radiation and reading erroneous temperatures due to self-heating. This problem affects all types of snow temperature measurements down to 20–30 cm, at which depth almost all shortwave radiation will have been absorbed by the snow. Infrared thermography can also be used to take instantaneous shots of temperature profiles. However, the pit wall must be freshly dug out as snow temperature on the pit wall will quickly equilibrate to air temperature prevailing in the pit. Snow surface temperature, however, is best measured with contactless IR-thermometers, avoiding radiation pickup and positioning of sensors at the surface of the snowpack.



Temperature Profile of Snowpack, Figure 3 Different ways to measure snow temperatures. (**a**) Conventional manual measurement. Note that the surface need to be shaded during measurements performed within the top 10–20 cm of the snowpack. (**b**) Temperature sensors at fixed heights shown by arrows on the pole in the middle of the photo. Note that sensor readings may be effected by the settling snowpack or vice versa. (**c**) Snow harp seen just before being snowed in by the ongoing snowfall. This device records simultaneously height and temperature (Fierz and Lehning, 2001). The fine tungsten wire recording temperature is still visible.

To avoid digging a pit, vertical probes can be used. For example, a specially designed probe was used to measure the profiles shown in Figure 1. In particular, the material supporting the measuring thermocouple has to be chosen such as to avoid heat diffusion from the part of the probe exposed to air and radiation to the probe tip.

If measurements have to be continuous over longer time scales, several sensors can be placed in the pit wall and the pit backfilled. For example, this is often done in polar snowpack studies, for which either several single sensors or strings of either thermistors or thermocouples are used. To measure accurately snow temperatures near the surface, however, careful sensor design is required to reduce both shortwave radiation pickup and differential settling of both snow and sensors (see, e.g., Bakermans and Jamieson, 2006). To know the real position of the sensors during measurements requires back-calculations after removal.

Mounting sensors on fixed structures such as poles avoids the uncertainties in position. However, the supporting structure and the fixed sensors will disturb the free settlement of the snowpack (see Figure 3b) and a perfect contact to the surrounding snow is often questionable. In general, measurements of such sensors not covered by at least 10 cm of snow measured from the undisturbed surface should be discarded. Because of the difficulties involved, few attempts have been made to design sensors capable of recording both their position and the corresponding snow temperature as shown in Figure 3c (Fierz and Lehning, 2001).

Summary

Temperature distribution, more precisely its evolution with time, illustrates what processes are at work within the snowpack. It reflects the current state of the internal energy of the snowpack as a result of energy exchanges at the interfaces with both ground and atmosphere and the interplay with internal heat sinks and sources. Snow temperature profiles are snapshots of snow temperature distribution, both in time and space. Measuring snow temperature profiles over longer period of time requires careful experimental design to be useful for further analysis.

Snout

Definition

Glacier terminus (snout) is the end of a glacier at any given point in time (Figure 1). Although glaciers seem motionless to the observer, in reality they are in very slow motion and the glacier terminus is always either advancing or retreating. The location of the terminus is often directly related to glacier mass balance. The position of a glacier terminus is also affected by localized or regional temperature change over time. Changes in location of a glacier terminus with time are determined by monitoring a glacier's movement. The difference in location of a terminus as measured from its fixed position at different time intervals provides a record of the glacier's movement. Another way of detecting changes in the movement of terminus of glacier is comparing satellite imageries of the glacier's position at different times.

The form of a glacier terminus is determined by many factors. If the glacier is retreating, it is usually gently sloping in form because a melting glacier tends to assume this shape. But there are many conditions that modify this typical shape, including the presence of thermal fields and

Terminus, Figure1 View of Terminus (Gaumukh) of Gangotri glacier in Himalayas.

various stresses that cause cracking and melting response resulting in glacial calving and other diverse forms.

TERRACES

Amit Kumar
Department of Geology, Centre of Advanced Study in Geology, Chandigarh, Punjab University, India

Synonyms

Kame terrace

Definition

Terrace is generally a series of surfaces in a stream valley, flanking and more or less parallel to the stream flow direction. These surfaces originally formed at or below the level of the stream, and now higher than the present stream. They represent the former valley floors and dissected remnants former flood plain. The melt water from glaciers carries immense amounts of sediment: clay, sand, gravel, and rock fragments. It deposits these sediments, creating a riverbed at the height of the terrace. As the glacier ice recedes, the river transports sediments. The kame terrace is termed as the distinctive landform that is formed when the glacier retreats, the former stream bed is left perched above the deglaciated valley floor.

THAW WEAKENING

Divya Dudeja
Department of Geology, DBS (P.G.) College, Dehradun, Uttarakhand, India

The ice located in the frozen, frost-susceptible soils of cold regions is subjected to thawing when seasonal or diurnal temperatures rise. Thawing causes saturation of soil by excess water that is restricted from draining due to frozen underlayers. This saturation reduces soil strength due to generation of excess pore pressure and the saturated active

layer becomes substantially weaker and tends to lose bearing capacity. This is called thaw weakening.

Occurrence of thaw weakening depends on frost-susceptible soil, its permeability, poor drainage conditions, and rate of thaw. Knutson (1993) categorized soil in high to low frost-susceptible soils. High frost-susceptible soils are typically coarse silts with less than 40% of particles smaller than 0.002 mm, more than 12% of particles smaller than 0.02 mm, and more than 50% of particles smaller than 0.2 mm.

Depending upon the surface temperature conditions, thawing can proceed downward from the top, or upward from the bottom, or in both directions. During a sudden thaw, melting will proceed almost entirely from the surface downward. This type of thawing leads to extremely poor drainage conditions.

Thaw weakening adversely affect stability of pavements, slopes, and other engineering structures in cold regions. Traffic on thaw-weakened pavements may cause permanent damage onto the surface like rutting, widening of the pavement, cracking, and failure of the pavement.

In order to mitigate the detrimental effects of thaw weakening, the assessment of depth of thawing is a prerequisite that depends in part on the magnitude and duration of the temperature differential below or above freezing at the ground surface. For the depth of thawing, thawing index (TI) is estimated. The air thawing index is the annual summation of the thawing degree-days. A thawing degree-day is defined as the mean daily temperature minus freezing temperature multiplied by 1 day, when the mean daily temperature is above freezing.

$$\mathrm{TI} = \sum (T - T_f) \cdot d$$

where T = mean daily temperature T_f = Thawing temperature (typically 0°C).

The calculated TI can be used to estimate the depth of thawing by modified Berggren formula given as

$$x = 13.15\lambda\left[(k_{avg} n \mathrm{TI})/L\right]^{0.5}$$

Where x = depth of freeze or thaw (m) λ = dimensionless coefficient that takes into consideration the effect of temperature changes in the soil mass k_{avg} = thermal conductivity of soil, average of frozen and unfrozen, W/(m °C) n = surface correction factor for TI, TI = air thawing index or freezing index (°C days), L = Specific volumetric latent heat of fusion (kJ/m^3).

These estimations are helpful in structure designing and mitigating adverse affects of thaw weakening by limiting depth of frost penetration, replacing or modifying frost-susceptible soils, and providing effective drainage.

THERMAL INFRARED SENSORS

Anju Chaudhary
Water Resources System Division, National Institute of Hydrology, Roorkee, India

Definition

All matter radiates energy at thermal infrared wavelengths (3–14 μm) during day and night. The infrared radiation region representing the wavelengths from 3–14 μm is called the thermal IR region. Photographic films do not detect thermal IR radiation. Thermal infrared sensors detect and record this thermal radiation as images. Majority of satellites have thermal infrared sensors on board. These sensors operate in the same fashion as visible and near infrared sensors. The signal from thermal IR range of spectrum is significantly weak and presently available sensors are typically less sensitive to it. This leads to sensors with lower resolution and longer dwell time to increase the energy that is integrated. While it is easier to distinguish clouds from the land by visible sensors, more detail inside the clouds is obtained by the infrared sensors. This is useful for studying cloud structure.

Thermal IR images generally record broad spectral bands, typically 8–14 μm for images from aircraft and 10.5–12.5 μm for images from satellites.

Applications

Thermal infrared sensors are used for infrared imaging for both military and civilian purposes. Military applications include target acquisition, surveillance and night vision, homing, and tracking. Nonmilitary uses include thermal efficiency analysis, remote temperature sensing, and weather forecasting. The main advantage of infrared sensors is that it can take images at night, allowing a continuous sequence of weather to be studied.

Thermal infrared sensors are used in the field of climatology. In this field, atmospheric infrared radiation is monitored to detect trends in the energy exchange between the earth and the atmosphere. These trends provide information on long-term changes in the earth's climate. It is one of the primary parameters studied in research into global warming together with solar radiation.

Weather satellites equipped with thermal infrared sensors produce thermal infrared images, which can be used to determine cloud heights and types, to calculate land surface water temperatures, and to locate ocean clouds of gas and dust in our galaxy.

THERMAL REGIME OF ICE-COVERED LAKES

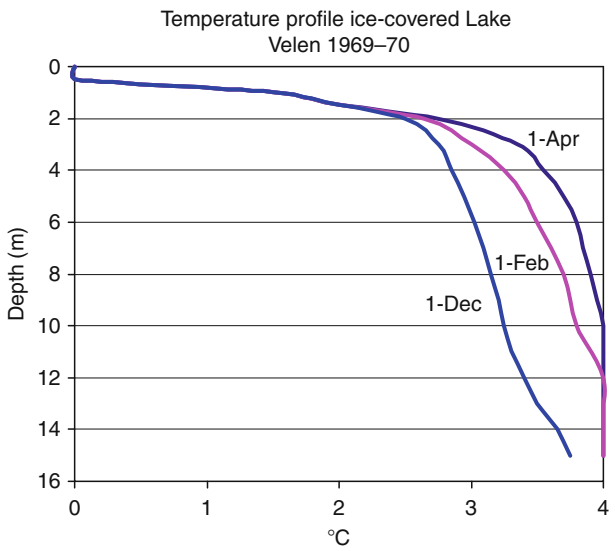
Lars Bengtsson
Department of Water Resources Engineering,
Lund University, Lund, Sweden

Definition

Thermal regime of ice-covered lakes considers the heat fluxes to and from a water body without direct contact with the atmosphere, the temperature distribution over the depth, and how it changes during the ice-covered period.

In the autumn after the surface water is cooled to 4°C and the water has turned over, the warmest water in a lake is that of the highest density. The surface water is colder than the bottom water. If there is a very cold period shortly after turnover, a wind-sheltered lake may freeze-over when the water not far from the surface and downward is still 4°C. In another year, the turnover may be followed by an extended windy period with air temperatures fluctuating around 0°C, resulting in a reduction of the lake water temperature down to considerable depths. The initial temperature profile after freeze-over is quite different for the two situations.

Once a lake has a stable ice cover, the lake water is more or less insulated from the atmosphere. The heat lost to the cold atmosphere is taken from the latent heat released from the ice growth. There is a small sensible heat flux from the water to the underside of the ice. The major heat flux in an ice-covered lake is that from the sediments to the lake water. Heat stored in the sediment from summer to winter is released. The lake water temperature increases in course of the winter (see Figure 1) from Lake Velen in Sweden. Lakes in cold long winter climate tend to be warmer than lakes in milder climate with less stable winters. In the milder climate, the lakes freeze-over later, when they have cooled down throughout the vertical, and also in the milder climate the lake ice may break up several times during winter, allowing wind mixing and heat losses directly to the atmosphere. The bottom temperature is often 4°C already at the time of freeze-up; if not, because of the contribution of heat from the sediments this temperature is approached in the course of the winter. The bottom temperature may even be slightly higher than 4°C, due to diffusion of solutes from muddy sediments.



Thermal Regime of Ice-Covered Lakes, Figure 1 Temperature in ice-covered Lake Velen, mean depth 6.5 m, maximum depth 17 m, lake area 2.8 km^2.

The sediments gain heat from the lake water during summer. The sediments are warmer at low water depth than at larger depths, since the surface water is warmer than the bottom water during summer. The heat budget of the sediments in Swedish lakes that develop a thermocline during summer is of the order 10^8 J/m^2 (e.g., corresponding to 2.5°C temperature change in 10 m of water). In the ice-covered period, the surface water is colder than the bottom water. Thus, when heat is released from the sediments to the water during winter, the heat flux is considerably higher in the shallow parts of a lake than at the deeper parts. As heat is released the sediments cool down and the lake water slowly becomes warmer, so the heat flux from the sediments is reduced in course of the winter. The sediment heat flux at shallow water may be in the range 4–10 W/m^2 in early winter and reduce to 1–3 W/m^2 in late winter. At the deep part of a lake it is smaller, 2–3 W/m^2 in early winter, and less than 1 W/m^2 prior to breakup. The warming of the lake water temperature profile over an ice-covered period is shown for Lake Velen in Sweden, Figure 1.

The heat balance of an ice-covered lake is

$$\text{Heat content change} = \text{sediment heat flux} - \text{heat loss to ice} + \text{solar radiation} + \text{heat loss with through} - \text{flow}$$

The heat advection with the through-flow is very small in most lakes, since the river through-flow per unit lake area is small and the temperature of the inflowing river water is very close to 0°C. When the outflow and inflow both are 1 m^3/s in a 5 km^2 large lake, the inflow temperature being 0°C and the outflow temperature 0.5°C, the heat loss is 0.4 W/m^2. In narrow fjord-lakes the flow may be substantial. However, in such lakes a thermocline develops so that the river runs through the lake within a top layer of 0°C temperature.

The sediment heat flux is already mentioned as the most important heat flux. The only heat loss, except the heat loss with outflowing water, is the sensible heat flux from the water to the underside of the ice. A pronounced temperature gradient develops close to the underside of the ice. A viscous sublayer develops. Temperature measurements very close to the ice have shown that the heat flux is 1–2 W/m^2 in most lakes but can be rather much higher

in late spring. Higher midwinter values have been reported from small very shallow lakes.

In spring when the snow on the ice melts, solar radiation can penetrate the ice and heat the water below. The surface water becomes instable. Convection is initiated and a mixed top layer is formed. The temperature gradient next to the ice sharpens and the heat flux to the ice increases. The transmissivity of snow ice is low, but much solar radiation can pass through black ice. Although only a small fraction of the solar radiation reaches the lake water, the flux is higher than the other fluxes in an ice-covered lake. Depending on the ice character and the ice thickness and time of year the solar radiation penetrating the ice is 10–40 W/m^2, partly compensated for by increased heat transfer from the water to the ice.

The knowledge of the thermal conditions in lakes is essential when planning for water intakes, so that desirable water is provided, or planning for discharge of effluents, so that recirculation is avoided. Withdrawal and release of water may affect the thermal conditions. Also regulation of rivers causing winter flows to be higher than the natural ones may influence the temperature in an ice-covered lake; large river flows may result in advective heat losses and cooler lakes.

Definition

Karst: The term Karst is usually associated with a characteristic topography formed due to groundwater dissolving sedimentary rocks such as limestone. These characteristics of the topography are usually channels, shafts, caves, tunnels, and sinkholes. The land thus becomes fragile and is susceptible to erosion and pollution.

Thermoerosion: Thermoerosion refers to erosion by water combined with its thermal effect on frozen ground. Small channels can develop into gullies up to several kilometers in length, growing at rates of 10–20 m/year, and in sandy deposits, as fast as 1 m/h. The main climatic factors controlling the intensity of thermoerosion are snow melt regime and summer precipitation. (Source: http://www.cartage.org.lb/en/themes/Sciences/Earthscience/Geology/WaterCycles/Frozenground/Frozenground.htm.)

Thermokarst: Thermokarst refers to a range of characteristic landforms features created in areas of low relief underlain by permafrost with excess ice thaws. These are unevenly distributed and include subsidence of ground with massive ice, water-filled depressions, "drunken" forests, new fens, and other forms of thaw settlement that account for many of the geotechnical and engineering problems encountered in periglacial landscapes. Even where repeated ground freezing takes place, thermokarst features, once formed, are likely to persist. The occurrence of thermokarsts is thus limited to high latitudes or at times in high altitudes of the earth. These features render the land to be susceptible to erosion and degradation. (Source: http://www.cartage.org.lb/en/themes/Sciences/Earthscience/Geology/WaterCycles/Frozenground/Frozenground.htm.)

Introduction

Thermokarst has been described as characteristic landforms that result from thawing of ice-rich permafrost or the melting of massive ice (French, 1976; Washburn, 1980; van Everdingen, 1998). Thermokarst topography forms as ice-rich permafrost thaws, either naturally or anthropogenically, and the ground surface subsides into the resulting voids (Brown and Grave, 1979; Hinzman et al., 1997). The important processes involved in thermokarsting include thawing, ponding, surface and subsurface drainage, surface subsidence, and related erosion. These processes are capable of rapid and extensive modification of the landscape and predicting, preventing, or controlling thermokarst is a major challenge for northern development (Lawson, 1986). The depression formed by thaw settlement is at times occupied by what is termed as a thermokarst lake (also called thaw lake). Typically, such lakes may expand by thermokarst forming processes (Wallace, 1948; Hopkins, 1949; Williams and Smith, 1989; Grosse et al., 2006). Even small disturbances, especially on the surface, that affects the soil thermal regime can initiate thermokarst processes and create related lakes. Many thermokarst ponds and depressions have been

observed across Interior Alaska and Canada in regions of discontinuous permafrost (Jorgenson et al., 2001; Osterkamp et al., 2000; Burn and Smith, 1990).

Permafrost thawing has profound implications for two major reasons. First, large areas of permafrost (about 50% in Alaska) are ice-rich. Permafrost underlies 20–25% of the northern hemisphere land area (Brown et al., 1997). Ice that forms during periods of cold climate frequently constitutes a high proportion (20–30%) of the volume of these frozen soils (Brown et al., 1997). Consequently, melting of permafrost can lead to surface collapse of soils forming thermokarst. When this ice melts, the ground above can subside dramatically. Since these ice deposits are erratically distributed, permafrost thawing can disrupt a level ground surface into a jumble of trenches and pits. Thaw settlement related to permafrost degradation is presently responsible for damage to houses, roads, airports, military installations, pipelines, and other facilities founded on ice-rich permafrost (Osterkamp et al., 1997).

The primary control on local hydrological processes in higher latitudes of the earth is dictated by the presence or absence of permafrost, but it is also influenced by the thickness of the active layer (layer of soil above the permafrost and below the ground surface that freezes and thaws annually) and the total thickness of the underlying permafrost (Hinzman et al., 2001). The permafrost underlying the active layer poses an extremely low permeability barrier and may be compared to poorly drained soils underlain by shale or clay. The inability of soil moisture to infiltrate to deeper underground zones under poorly drained conditions and the previous pore volume expansion due to ice result in super saturated soil moisture regimes in the active layer during the thaw season. Thermokarst can thaw the upper portion of permafrost, the intermediate layer, which is super saturated with ice. The added water and lack of soil structure can lead to highly unstable ground in areas where the super saturated soils could easily detach (active layer detachment slide) and displace the soil from its matrix due to either high hydraulic gradient (or due to high hydrostatic pressure), due to action of gravity on a slope, or a combination of both.

A disturbance to a permafrost environment such as removal of the surface organic layer and installation or removal of a road will modify the surface energy and water balances and change the ground thermal regime often resulting in a deepening of the active layer (Klinger et al., 1983; Waelbroeck, 1993). If during this process ice-rich soils are thawed, catastrophic settling may occur causing formation of a thaw lake or thermokarst (Carter et al., 1987). It has been reported by Greenpeace (http://archive.greenpeace.org/climate/arctic99/reports/perma.html) that thermokarst formations in Alaska have forced the abandonment of a hospital in Kotzebue, are ruining homes and the local schoolhouse in Kipnuk, have required the reconstruction of roads in Fairbanks and airport runways in Deadhorse, and have created large landslides and ground collapse near Tuktoyaktuk and many other places in the Arctic. The second reason for concern is that organic material in thawing permafrost decays rapidly, releasing large quantities of carbon dioxide and methane (Khalil and Pusmussen, 1989; Kvenvolden and Lorenson, 1993; Walter et al., 2006). Moreover, large summer methane releases are closely correlated to warming temperatures.

Hydrology and the related processes of heat and mass transfer are vital linkages between the atmospheric, terrestrial, and aquatic ecosystems. If we do not physically understand this coupling, we will never reach the point where we can understand and predict the impact of disturbance (such as initiation of thermokarsts) or restoration (such as incorporation of the thermal effects of revegetation) (Hinzman et al., 1997). There is a significant lack of understanding of the degree to which the surface energy balance changes in response to disturbance that causes initiation and growth of thermokarsts. Equally important is the impact of alterations in the thermal regime of soils on physical stability and consequently, surficial morphology. This lack of understanding stems from the complex nature of the formation of thermokarsts (Nixon, 1975; Jorgenson et al., 2001).

As a result of the warming of soil temperatures, long-term permafrost degradation has already started at some sites (Federov, 1996; Osterkamp et al., 2000; Jorgenson et al., 2001; Federov and Konstantinov, 2003; Gavriliev and Efremov, 2003) forming thermokarsts in the process. Changes in permafrost regime probably reflect undocumented changes in the thickness or thermal conductance of snow or vegetation, in addition to changes in air temperature (Osterkamp and Romanovsky, 1999). Thermokarst features are developing actively in the zone of discontinuous permafrost (Osterkamp and Romanovsky, 1999), particularly in association with fire and human disturbance, but there are no long-term records from which to detect trends in the regional frequency of thermokarst.

The large observed and predicted future climatic changes will inevitably change the energy and mass fluxes at the land surface and, as a result, the near-surface and subsurface physical conditions in the Arctic and Sub-Arctic. This will trigger changes in ecosystems, hydrology, and infrastructure because the stability of these systems in the north relies on the stability of ice that, so far, holds these systems together. In losing permafrost, we are losing the stability of systems. Thermokarst and related lakes are closely linked to the ground thermal regime and, thus, especially sensitive to changes in boundary conditions. The existence of thermokarst lakes is a clear expression of ground conditions (e.g., thermal regime and ice content). Even small changes in boundary conditions such as climate can be made clearly visible by thermokarst processes. Thermokarst lakes can, therefore, be seen as geo-indicators (Romanovskii et al., 1996).

Phases of a thermokarst

According to Black (1969), "The genesis and evolution of thermokarst depressions and thermokarst lakes remain

some of the least understood cryogenic processes" (Toniolo et al., 2009). The evolution to maturity of a thermokarst has three stages: (1) the origination or initiation, (2) the progression or growth, and (3) the stable formation and expansion of a thaw lake.

Thermokarst initiation

Perhaps the least understood and studied aspect of the thermokarst is its initiation. While it is known that thermokarsts are initiated due to changes in the thermal regime of a permafrost underlain soil due to the thawing of the ice-rich permafrost, these features only occur in certain regimes of the soil and not in all places where thermal imbalance has occurred. This origination or initiation of thermokarst is yet a mystery to scientists and engineers, although such initiation has direct impact on soils, structures, and other engineering aspects of areas underlain by permafrost. Having stated such, it is also difficult to study the initiation of thermokarsts because the process can originate quite suddenly and at times in remote and inaccessible locations. Hence, to our knowledge, there has been no record of the cause of the origination of a thermokarst. Nonlinear processes are similar to the flap of a butterfly, which can cause the formation of a hurricane, and a foot print of a caribou that can cause the formation of a lake. One of the necessary components is ice-rich permafrost close to the surface in the intermediate layer. Further study of these ice-rich layers is necessary to understand catastrophic change in the arctic landscape.

Thermokarsts are crucial to study because they form suddenly and the reason for their initiation is still not well understood. However, some scientists are of the opinion that these thermokarsts could form quickly or may take decades (Hinzman, 2004, Personal Communication). They may respond to disturbance or to a warming climate or some interaction of both. They do have very important implications for engineered structures in higher latitudes, but they are also indicative of a warming climate with broad impacts to huge geographical areas. Whether anthropogenic activities are responsible for such initiation is not well known. With the new highways, bridges and railroads that are being built consistently and the existing structures that influence the permafrost as well as the ground, it is crucial to understand the initiation, progression, and potential impact of the thermokarst.

There are several aspects of the initiation and development of a thermokarst that are not well understood. For example,

- What soil conditions are responsible for initiation of a thermokarst?
- What thermal regime is responsible for such initiation?
- What are the bounding factors that either allow or prohibit progression of a thermokarst?
- What are the factors that contribute to the process and quantity of erosion from a thermokarst?
- What is the quality of the water that emanates from a thermokarst?

It has been hypothesized that the soil gradient (slope) (cf. Strang, 1973), percent of fine materials in soil, the soil bulk density, depth of active layer, and change in thermal regime are variables that affect the initiation of a thermokarst. Additionally, the supersaturation of soil and connectivity to remote groundwater source provides the hydrostatic head and the hydrodynamic force to detach the soil from its matrix and transport it downstream, thus developing the eroded gully.

Although it has not been established, however we hypothesize that the thermokarsts are initiated due to preferential thaw settlement at the top and with a constant source of water at the bottom such as the ones observed in laboratory conditions (Figures 1 and 2). The figures illustrate the time scale thaw settlement in a silty-loam soil with approximately 50% fines. The experimental set up was designed such that we have only top down freezing with a constant source of water from the bottom. Figure 1 shows the completely frozen soil at 9:15 am. Figure 2

Thermokarst, Figure 1 Soil completely frozen at 9:15 am.

Thermokarst, Figure 2 Preferential thaw settlement at room temperature after 5 h of thaw.

shows preferential thaw settlement and channel development at 2:15 pm.

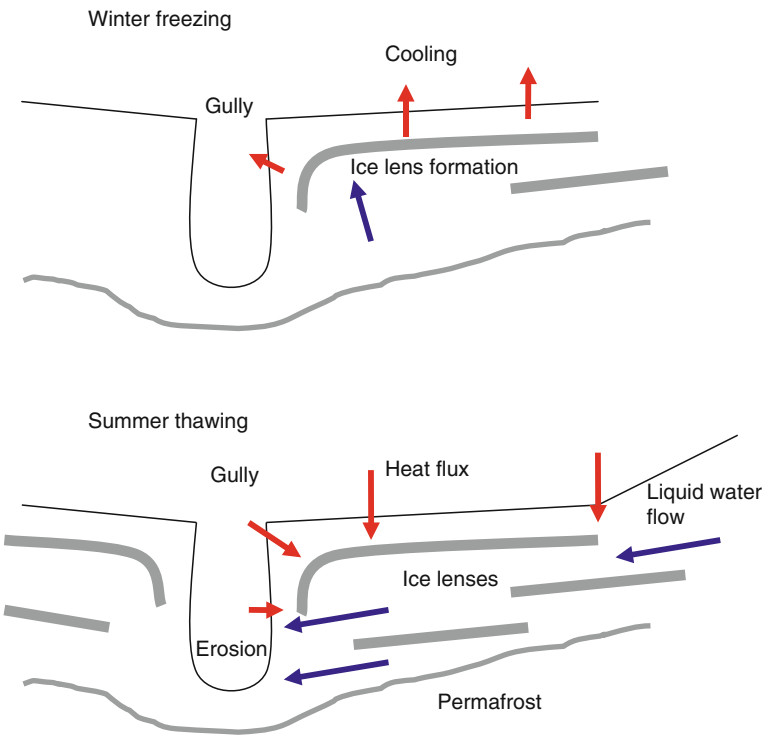
The aspect of underlying permafrost degradation has not been included in the laboratory studies in Figures 1 and 2. However, once the thaw settlement is initiated, the groundwater finds a path to remove the fines from these settled zones to create a gully. This gully is next expanded with more groundwater action and surface abrasion. Sediments removed are transported downstream of the gully thus creating a permanent topographic depression. This aspect or stage of the thermokarst has been studied, although in a very limited context (see Toniolo et al., 2009).

Thermokarst growth

The rapid growth of a thermokarst in Alaska has been studied by Kodial (2005) and Kodial et al. (2005), perhaps for the first time. They speculated that the initiation of the thermokarst was directly related to a major rainfall event with 90 mm of precipitation that occurred over a 2-day period, which triggered the thermal erosion. The thermokarst subsidence occurred when the energy balance at the ground surface was modified, which increased the heat flux to the subsurface layers, thus initiating the thaw of permafrost ice wedges and formation of terrain depression. Toniolo et al. (2009) state, "These depressions may grow due to subsidence over successive summers. When conditions are favorable for water storage, ponding can be significant. The presence of subsurface formations such as pipes and sinkholes may lead to drainage of the stagnant water, depending on the groundwater static level. Gradually shorelines stabilize as the ground subsides. Erosion and sedimentation are final steps in the thermokarst formation process."

The development or growth of a thermokarst is also observed from other physical indicators such as drunken trees, slumping of banks, and submergence of vegetation (Burn, 1992). Dingman (1976) states that rapid and extensive degradation of landforms occur in northern latitudes when significant amount of flowing water comes into contact with ice-rich soil. This subsidence and subsequent increased thermokarst development are amplified by the thermal erosion associated with the flowing water (U.S. Arctic Research Commission Permafrost Task Force, 2003). This process can be best illustrated in Figure 3.

Associated with growth of thermokarst is the yield of higher sediment loads, especially beginning with removal of finer sediments due to melting of ice and the resulting viscous slurry flow out of the soil matrix that would weaken the soil structure followed by abrasion due to ground water or surface water flow through the gully that would remove the coarser particles. Toniolo et al. (2009) report, "The probability that this disturbed terrain will recover to its original stable configuration on the time scale of decades to perhaps centuries is very low, as seen in three intensive study sites located in the National



Thermokarst, Figure 3 Schematic representation of Thermokarst growth.

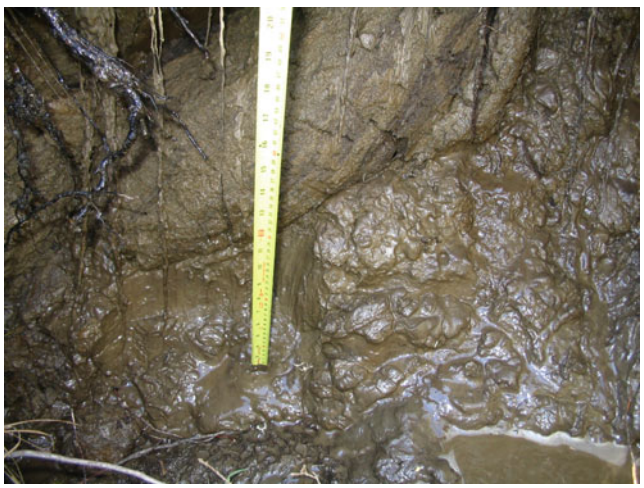
Thermokarst, Figure 4 Photograph of the Caribou-Poker creeks research watershed thermokarst showing profiles from where soil samples were collected and temperature was measured.

Petroleum Reserve-Alaska (Lawson, 1986). Recently, Fortier et al. (2007) observed rapid changes in landscape due to gully evolution in the Bylot Island (Canada). The formation of sinkholes initiated gully evolution in the area. Carey and Woo (2000) described the importance of cryogenic piping in slope runoff. High velocity flows inside the pipes could cause soil destabilization and gully formation."

In order to develop a better understanding of the growth of thermokarst, we collected temperature data and soil samples from the Right and Left Bank profiles of the same thermokarst that was studied by Kodial (2005), Kodial et al. (2005), and Toniolo et al. (2009). A photograph with description of the thermokarst on June 9, 2004 is shown in Figure 4.

At the time (June 9, 2004) the data and samples were obtained, the right bank showed signs of erosion wherein slurries of water rich mud were being pushed out of the bank as shown in Figure 5. As opposed, the left bank at both the locations did not show any sign of erosion due to soil water movement. Rather, the channel carrying the water downstream perhaps had a shearing effect or simply melting of the pore ice at the bottom of the left bank profiles that relieved some of the sediments from the very bottom of the gully. The left bank profiles are shown in Figure 6.

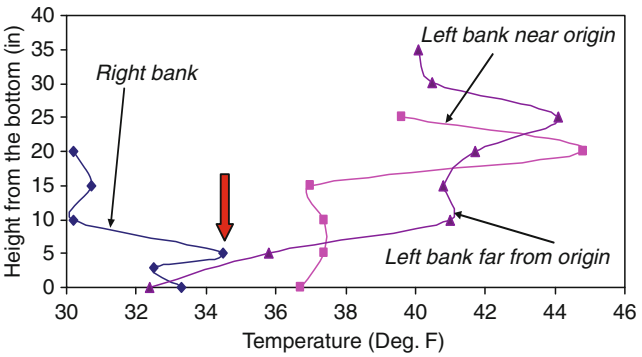
We plotted the temperature (Figure 7) and the percent of fines that passed sieve # 200 (Figure 8) for all three profiles along the depth. While the left bank temperature profiles were all above 32°F, the right bank showed a layer approximately between 5″ and 10″ from the bottom that was above 32°F with the rest being below. The same layer showed a huge decrease in the percent of fine material that has been perhaps removed from the profile due to the flow of water through this zone of the soil. We had observed the slurry in Figure 5 emanating from this layer of the soil. A decrease in the fines from the bottom layer of the left bank near the origin might be due to simple shear action of the stream.



Thermokarst, Figure 5 Soil profile of the right bank eroding face of the gully demonstrating supersaturated soil conditions and slurry detachment from soil matrix under high fluid pressure. (Photograph taken on June 9, 2004 after a few days without any precipitation.)

Our field observations and the results obtained have been extremely helpful in asserting that the process of erosion and sedimentation is driven by the following two factors: (a) the soil gradient and (b) the hydrostatic head in combination with some hydrodynamic force. Degradation of permafrost being a major cause has already been ascertained by many authors as referenced above. The

Thermokarst, Figure 6 Soil profile of the (**a**) Left bank near origin and (**b**) Left bank far from origin. Both the pictures show no supersaturated condition along the profile. Each profile is host to the surface runoff from the gully that out-springs from the vicinity of the Origin and the Right Bank close to the origin. (The photographs were taken on June 9, 2004.)



Thermokarst, Figure 7 Temperature of soil layers as sampled on June 9, 2004.

thermal regime undoubtedly plays a major role in the development of the thermokarst. Our field observation of the temperature profile on July 13, 2004 of the right bank of the thermokarst (Figure 9) revealed a completely thawed profile from bottom up. We also did not observe any flow or erosion taking place on that date.

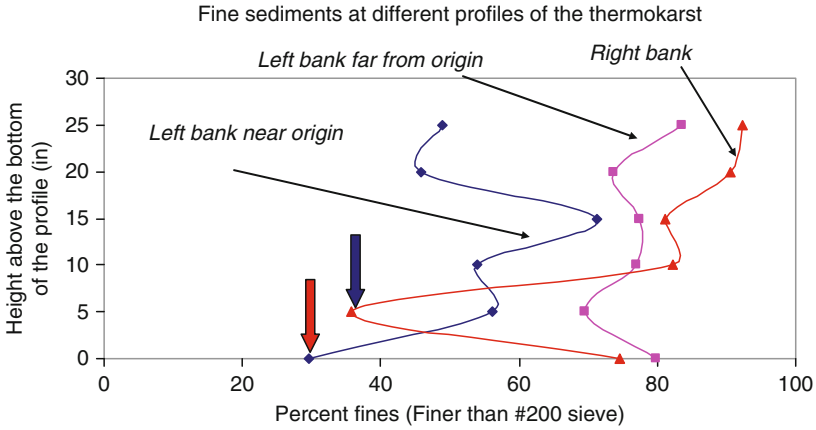
More detailed description of the thermokarst growth and process of sedimentation, fluvio-thermal erosion, interflow, cryogenic piping, and gully development through stabilization is provided in Toniolo et al. (2009). This thermokarst study is to our knowledge the only study that has been done on possible initiation but a detailed growth of an infant thermokarst.

Thaw lake

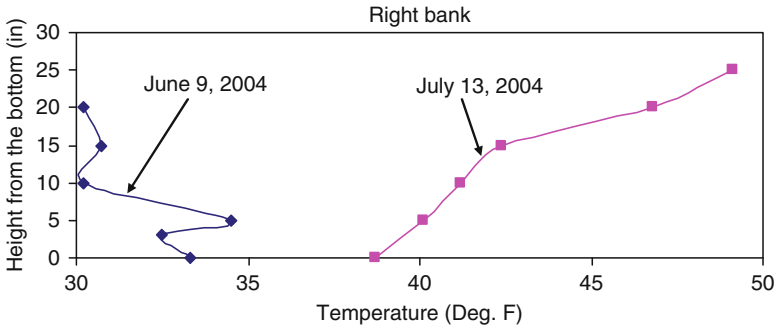
Thaw lakes or thermokarst lakes are formed once the permafrost underlain soil is completely thawed and the gully is eroded and developed into a permanent lake. This aspect of thermokarst has been quite well studied from an ecological and environmental perspective. Thaw lakes may not develop at all if the topography is not conducive for such development (Kääb and Haeberli, 2001). Thermokarst lakes have been studied for past climate change studies (Bohncke et al., 2008; Walter et al., 2007). The initiation and cause of expansion of thaw lakes were studied extensively by Boiskov (2003). Edwards et al. (2009) studied the impact of thermokarst lakes on carbon and methane cycle in the Arctic. The influence of environment on thermokarst lakes was studied by Kirpotin et al. (2008). There are many more studies on thermokarst lakes in the recent years (e.g., Yoshikawa and Hinzman, 2003).

Summary

Thermokarsts are formed due to degradation of permafrost (increase in active layer thickness) as a result of increase in soil temperature in the Arctic and the sub-Arctic. Soil temperatures are increased due to an increase in air temperature as a result of global warming. However, forest fires and other anthropogenic disturbances may also elevate the soil surface temperature. Thaw settlement related to permafrost degradation is presently responsible for damage to houses, roads, airports, military installations, pipelines, and other facilities founded on ice-rich permafrost.



Thermokarst, Figure 8 Percent of fines (finer than #200 sieve) at various depths of the thermokarst as collected on June 9, 2004.



Thermokarst, Figure 9 A comparison of the temperature profiles of the right bank of the thermokarst on two different dates.

There is a significant lack of understanding of the degree to which the surface energy balance changes in response to the disturbance that causes initiation and growth of thermokarsts. Equally important is the impact of alterations in the thermal regime of soils on physical stability and consequently, surficial morphology. This lack of understanding stems from the complex nature of the formation of thermokarsts. There are no long-term records from which to detect trends in the regional frequency of thermokarsts. So far, most thermokarst-related studies have focused mainly on well-developed lakes and related water quality. From the field evidence gathered, we hypothesize that the soil gradient (slope), percent of fine materials in soil, the soil bulk density, depth of active layer, and the change in thermal regime initiates a thermokarst. Additionally, the supersaturation of soil provides the hydrostatic head along with the soil moisture movement providing the hydrodynamic force to detach the soil from its matrix and transport it downstream, thus developing the eroded gully. The thermokarst formation and the sediment moved due to the process cause water quality (both sediment and dissolved organic carbon), hydrologic, and ecological disparity issues. Understanding the physical processes in development and formation of thermokarsts in a climate changing environment and/or in areas of increased anthropogenic disturbance and forest fires is crucial because the understanding developed and the parameters measured could help reduce potential impact on engineered structures or the ecosystem in northern areas.

THINNING OF ARCTIC SEA ICE

Ron Lindsay
Polar Science Center, Applied Physics Laboratory, University of Washington, Seattle, WA, USA

Definition

Sea ice is frozen ocean water that floats on the surface of the sea.

Introduction

In the northern winter, sea ice is found over the entire Arctic Ocean and the peripheral seas such as Hudson Bay, Davis Strait, Barents Sea, and the Bering Sea. More southerly seas also have some ice in the winter such as the Sea of Okhosk or the Gulf of Bothnia. In the summer, ice is found just in the Arctic Ocean and the seas within it, such as the Beaufort, the Chukchi, the East Siberian, the Laptev, and, to a lesser extent, the Kara and Barents seas. It is also found in the passages of the Canadian Archipelago, and along the east coast of Greenland. The typical extent of all winter sea ice in the northern hemisphere is 15.6×10^6 km^2 and in the summer it is 6.7×10^6 km^2 (1979–2008, NSIDC Sea Ice Index, Fetterer et al., 2002). Major changes have been observed recently in the age, thickness, extent, and circulation of Arctic sea ice.

Typical age and thickness

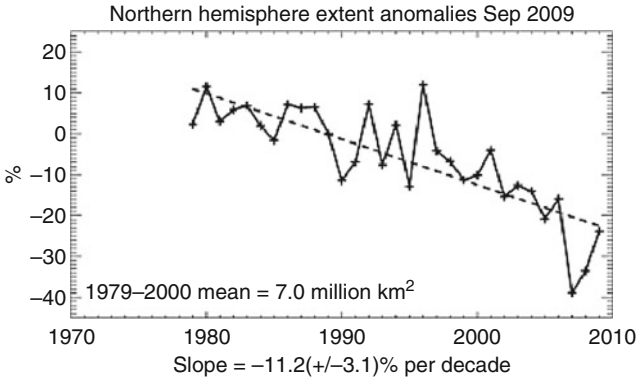
Sea ice ranges in thickness from a few centimeters in newly frozen regions to 30 m or more in pressure ridges, where the ice has been compressed and broken by the force of the winds and currents. The mean thickness in the Arctic Ocean in the winter is 3–4 m and in the summer it is 2–3 m. The ice often fractures to form linear features called *leads* of open water in which thin ice soon forms. The much thicker ice of the *pressure ridges* are formed from the rubble of broken ice floes. The age of ice in the Arctic Ocean ranges from *first-year ice*, less than 1 year old, to ice more than 10 years old, *multiyear ice.* First-year ice is commonly less than 2 m thick except where it has ridged, while multiyear ice is typically 4 or 5 m thick, again except where it has ridged. Ice age is a good proxy for ice thickness for ice less than 4 or 5 years old (Maslanik et al., 2007). Changes in the ice age distribution in the Arctic is a major contributor to the observed thinning trend.

Movement

Sea ice is highly mobile, pushed by the winds, currents, and the *Corriolis force* (from the earth's rotation). In the Arctic Ocean there is a clockwise rotation of the ice in the Pacific sector, called the *Beaufort Gyre* that changes in size and strength from year to year. The *Transpolar Drift Stream* takes ice across the *North Pole* and through *Fram Strait* between Greenland and Svalbard. This is the major point of export of ice from the Arctic Ocean. The ice that moves south along the coast melts before reaching the southern tip of Greenland. Changes in the circulation of the ice have major impacts on the mean ice thickness. In the late 1980s and early 1990s, the wind circulation patterns shifted dramatically as represented by the *Arctic Oscillation* (AO) index. The AO is a hemispheric pattern of variability of the atmospheric sea level pressure that is characterized by relatively low surface pressures in the North Pole region when the AO index is high (Thompson and Wallace, 1998). The AO index shifted to a highly positive mode for several years starting about 1989 and continuing to 1995. This change in the wind circulation patterns caused a large amount of the old thick ice that is normally found north of the Canadian Archipelago and north of Greenland to be flushed out of the Arctic Ocean and south along the east coast of Greenland (Rigor et al., 2002). This change in the circulation was the beginning of an extended period of change for Arctic sea ice in which the ice has grown thinner and the summer extent has been reduced (Lindsay and Zhang, 2005; Lindsay et al., 2009), a change that has continued to the present day.

Recent trends in extent

We have good records of the sea ice extent since the era of passive microwave measurements from satellites began in 1979. The sea ice concentration is measured from thermal emissions from the surface in the microwave region of the spectrum with a spatial resolution of about 25 km for the older instruments. For the first two decades after the beginning of the satellite record, the decline in the late summer ice extent was about –6.9%/decade (in September, the month with the minimum extent, 1979–2000). But in recent years, the decline has accelerated. For the period 1979–2008, the rate is –11.1%/decade (based on data from NSIDC Sea Ice Index, Fetterer et al., 2002). The rate of decline in the winter is less, –2.8%/decade in March from 1979 to 2008 (NSIDC Sea Ice Index, Fetterer et al., 2002) because of the geographical constraints on ocean areas in the Arctic. In 2007, the September mean ice extent fell to 4.3×10^6 km^2, far below the trend line.



Thinning of Arctic Sea Ice, Figure 1 Northern hemisphere sea ice extent for September (National Snow and Ice Data Center, Sea Ice Index, http://nsidc.org/data/seaice_index).

The large decline in 2007 was due both to the very thin nature of the ice pack after years of thinning and to unusual winds that blew the remaining ice to one side of the Arctic Ocean (Lindsay et al., 2009). The last 2 years have seen a partial recovery with the September 2009 ice extent very near the trend line, but there is large year-to-year variability in the total ice extent (Figure 1).

Recent trends in thickness

Ice thickness in the Arctic can be measured by several different methods. Moored *upward looking sonars* (ULS) measure the ice draft (depth of the bottom of the ice) as the ice passes by above, while submarines use a ULS instrument to measure the draft as it conducts a transect under the ice. The thickness of the ice can also be measured from a satellite using either a laser or radar altimeter. Airborne electromagnetic instruments are also used to measure the ice thickness. The methods used and time periods and areas sampled by the various instruments are quite different.

Ice draft data from U.S. submarines dating back to 1958 have been declassified for a Data Release Area (DRA, see Figure 1) that includes most of the central Arctic Ocean outside of the exclusive economic zones of foreign countries. It covers about 38% of the Arctic Ocean. Within this DRA, Rothrock et al. (1999) found that sea-ice draft data acquired on cruises between 1993 and 1997 was 1.3 m thinner at the end of the melt season than similar data acquired between 1958 and 1976, a decrease of 40% from greater than 3 m to less than 2 m over a roughly 28 year period. Rothrock et al. (2008) analyze a more extensive submarine record for the DRA from 1975 to 2000 (34 cruises). Multiple regressions are used to separate the interannual change, the annual cycle, and the spatial field. The annual mean ice draft declined from a peak of 3.42 m in 1980 to a minimum of 2.29 m in 2000, a decrease of 1.13 m (1.25 m in ice thickness).

Sea ice freeboard (distance of the top snow or ice surface above the surface of the water) and, hence, thickness is measured from space by a laser altimeter on ICESat (Ice, Cloud, and land Elevation Satellite). Kwok et al. (2009) use ICESat-based ice freeboard measurements in the Arctic Ocean to produce basin-scale ice thickness estimates from 1-month-long fall and spring ICESat campaigns from a period of 5 years (2003–2008). They report a basin-wide decline of –0.17 m/year over this period. The ICESat data (for the DRA only) shows that the ice continues to thin at an accelerated rate when compared to the submarine data of Rothrock et al. (2008). Figure 2, from Kwok and Rothrock (2009), shows the winter and summer mean ice thickness for the submarine period (1975–2000) and for the ICESat period (2003–2008) for the DRA.

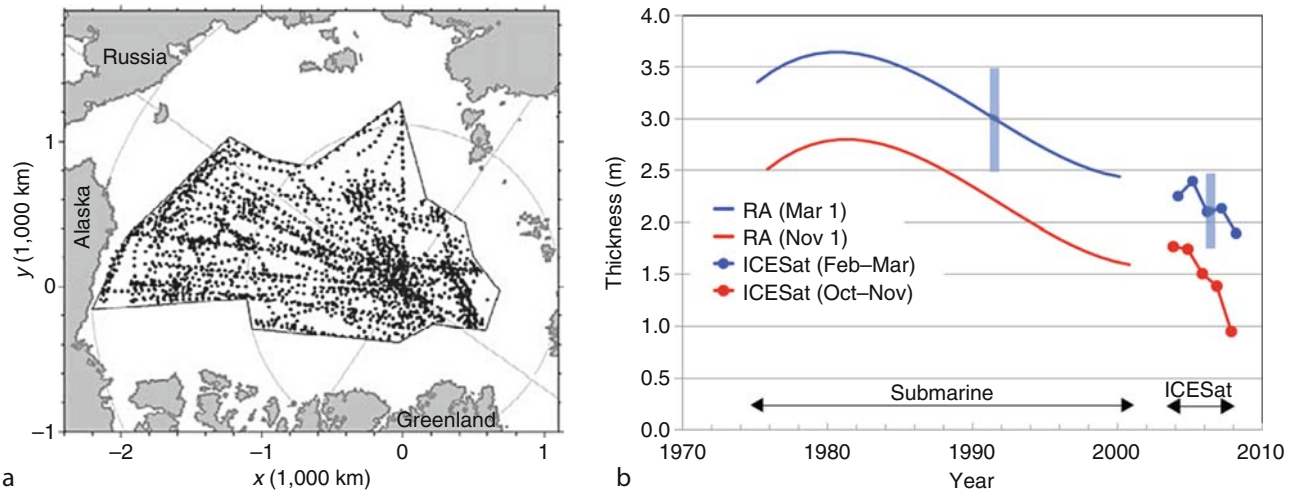
Recent radar altimeter records from the Envisat satellite for the regions south of 81.5° N show no evidence of short-term preconditioning through ice thinning between 2002 and 2007 but show that, after the record minimum ice extent in 2007, the average ice thickness was reduced, particularly in the Western Arctic (Giles et al., 2008).

Sea ice and global warming

The decline of the ice in the Arctic is likely directly linked to global warming caused by anthropogenic greenhouse gases. As in most of climate science, proof in the mathematical sense is not possible, but virtually all models of the global climate show a drastic reduction in late summer sea ice extent with increasing greenhouse gasses. Some important feedbacks to consider in understanding the reduction in Arctic sea ice include the ice-albedo feedback wherein reduced ice extent exposes more dark ocean waters (compared to the bright ice surface) to sunlight and the increased absorption of solar energy leads to increased ice melt, a positive feedback. A strong negative feedback is the greatly increased rate of ice growth in the winter for thin ice compared to thick ice. Another interesting positive feedback is seen in the average speed of the ice movement. As the ice thins, it becomes weaker and more mobile, deforming more rapidly. Then more ice is readily exported through Fram Strait, further reducing the volume of ice in the Arctic Ocean (Rampal et al., 2009). A negative feedback related to the deformation is found in the increased areas of open water caused by the increased deformation, areas that are then the locations of accelerated ice production.

Antarctica

Sea ice in the southern hemisphere differs from that in the north in several respects. It forms around the periphery of the Antarctic continent at latitudes much farther from the pole. Most of the ice forms and melts each year. Only the ice in the more southerly Weddell Sea and the Ross Sea survives the summer. It also is often covered with so much snow that the weight pushes the top surface of the ice below the water level and the top floods. During the winter, much of the ice is therefore growing on the top



Thinning of Arctic Sea Ice, Figure 2 (**a**) Data points from U.S. Navy cruises used by Rothrock et al. (2008) and the data release area (irregular polygon). (**b**) Interannual changes in winter (*blue*) and summer (*red*) mean ice thickness based on submarine data from the regression equation of Rothrock et al. (2008) and from ICESat laser altimeter data centered on the ICESat campaigns (Kwok et al., 2009). *Blue error bars* show residuals in the regression and quality of ICESat data. Figure from Kwok and Rothrock (2009).

while melting on the bottom, and in the summer most of the melt is from the bottom.

The winter ice extent in Antarctica is slowly increasing in spite of global warming at an annual mean rate of 0.97%/decade (Turner et al., 2009). This increase is linked to changes in the surface wind speeds in specific sectors of the Antarctic coastal regions, changes caused by the springtime loss of ozone in the stratosphere, the so-called ozone hole (Turner et al., 2009). Some areas, such as the Amundsen-Bellinghausen Sea are losing significant amounts of ice while others, such as the Ross Sea, are gaining ice. As the ozone hole dissipates in decades to come, the global warming impact on the Antarctic will likely be seen in a reduction of the sea ice extent.

Summary

The sharp decline in the Arctic mean ice thickness began about 1990, when there was a very significant shift in the wind patterns over the Arctic Ocean for several years linked to changes in the Arctic Oscillation. The wind patterns are no longer so unusual but the ice decline continues due to global warming and feedback mechanisms. The changes in the ice age are clearly observed in satellite measurements that distinguish multiyear ice from first-year ice (Maslanik et al., 2007), while the changes in the thickness are seen in new laser and radar satellite measurements of the ice thickness. Because the sea ice is floating in the ocean, melting of sea ice has negligible impact on sea level, as opposed to land-based ice sheets and glaciers that add mass to the ocean when they melt.

The ice responds strongly to the regional air temperatures and a runaway positive feedback (a tipping point) is not likely. The summer ice extent is likely to continue to decline in the next few decades and to be highly variable from year to year, while winter ice is likely to be extensive for many decades to come because of the thin-ice-rapid-growth feedback and the very large loss of thermal energy from the surface when there is no sunlight in the Arctic.

THINNING OF GLACIERS

Etienne Berthier
LEGOS/CNRS/UPS, Toulouse, France

Definition

Reduction of the glacier thickness

Introduction

A glacier in equilibrium with the climate is characterized by a given geometry. This geometry results from a balance between snow accumulation, ablation (mainly by melting), and the flow that redistributes the mass accumulated at high elevations toward the lower parts of the glacier. If external forcings (climate) or internal forcings (ice flow) change, the geometry of the ice body also evolves. Nowadays, most glaciers around the globe are responding to climate change by a reduction of their thickness. This *thinning* is the topic of the present article. We will describe how the thinning can be measured, what can cause a glacier to thin, and briefly review the thinning of glacierized areas around the globe.

How to measure the thinning of a glacier?

Ice elevation changes can be determined by comparing sequential measurements of the altitude of the glacier surface collected during field, air-borne, and space-borne surveys.

Field surveys provide very accurate elevation change measurements but they generally only cover a limited portion of a glacier. In the French Alps, for example, 4–5 transverse profiles are surveyed yearly on a few selected benchmark glaciers using differential GPS (Vincent et al., 2009). The high accuracy of these field surveys (typical $\pm$ 20–30 cm) allows studying the year-to-year fluctuations in ice thickness. They also provide a precious ground truth reference in order to validate/calibrate air- and space-borne surveys.

Differential digital elevation models (DEMs) derived from *aerial photographs* are considered the most reliable measurement of ice elevation changes over one or several decades (Thibert et al., 2008). This approach is limited by the relatively small coverage of the photographs (30–40 km^2) and is generally restricted to glaciers already monitored in the field. Airborne laser altimetry is also an efficient tool to estimate the volume change of glaciers (Echelmeyer et al., 1996). Its high accuracy in the accumulation area and the possibility to extract thickness changes along longitudinal profiles of large glaciers (Arendt et al., 2002) are the main advantages of this method.

Eventually, ice thinning can also be observed from satellite data by comparing sequential digital elevation models (Berthier et al., 2004), repeat laser profiling (Sauber et al., 2005), or using a combination of both techniques (Kääb, 2008). The challenge consists in measuring a small signal (generally a few meters of elevation changes) from a sensor located a few hundred kilometers above the Earth surface. This challenge is addressed either by having very precise individual elevation measurements (e.g., ICESat laser profiles) or by adjusting some less accurate DEMs on the stable ice-free regions surrounding the ice bodies and then averaging over a large number of pixels (Berthier et al., 2004).

What causes the changes in glacier elevation?

The primary cause of thickness changes are the fluctuations of the glacier surface mass balances. The topic of surface *mass balance* (the difference between accumulation and ablation) is discussed in a different section of this encyclopedia and, thus, is not examined in detail here. The current thinning of most glacier tongues is partly the glacier response to increase in surface ablation (itself a response to rising air temperature). However, other factors than surface mass balances also contribute to glacier thickness changes.

Ice flow variations can also lead to ice elevation changes. A clear illustration is given by the changes experienced by glaciers of the Antarctic Peninsula that drained into the former Larsen B ice shelf which disintegrated in March 2002. The loss of resistive stress due to shelf removal led to a strong acceleration of those glaciers and a rapid lowering (10s m/yr) of their surface (Scambos et al., 2004). The lowering was so fast that stranded ice remained on their margins (Figure 1).

The surge phenomenon illustrates how elevation changes can occur without some changes in the total glacier volume. The life cycle of a surging glacier is characterized by a quiescent phase when ice flow rates are small and mass is accumulated in the reservoir area

Thinning of Glaciers, Figure 1 Stranded ice on the margins of Crane glacier (Antarctic Peninsula). Crane glacier thinned so rapidly after the collapse of the Larsen B ice shelf that ice remained on its flanks. Stranded ice underlies the level of the glacier surface before thinning (© T. Scambos, February 11, 2006).

(Clarke, 1987). During the active phase, ice velocities increase by a factor of 10–100 (or more) leading to a rapid transfer of mass from the upper "reservoir" area to the lower "receiving" area. This active phase results in thinning of the reservoir area and thickening of the receiving area. Many glaciers in Svalbard, Iceland, and Southeast Alaska are surge-type so that, over a short time scale (years to decades), their elevation changes are not directly linked to climate fluctuations.

If part of the glacier is floating on the sea or on a lake, thinning can occur at its base through basal melting. Basal melting rates as high as 40 m/year have been reported for outlet glaciers of the Antarctic and Greenland ice sheets and are an important component of their mass balance (Rignot and Jacobs, 2002). For a grounded glacier, basal melting due to geothermal heat fluxes is generally small, in the order of a few mm/yr. These rates can be much larger if the glacier is located above a volcano. For example, volcanic eruptions and continuous geothermal activity at the bed of the Vatnajökull ice cap (Iceland) accounted for >5% of its overall melting during the late 1990s and early 2000s (Björnsson and Pálsson, 2008).

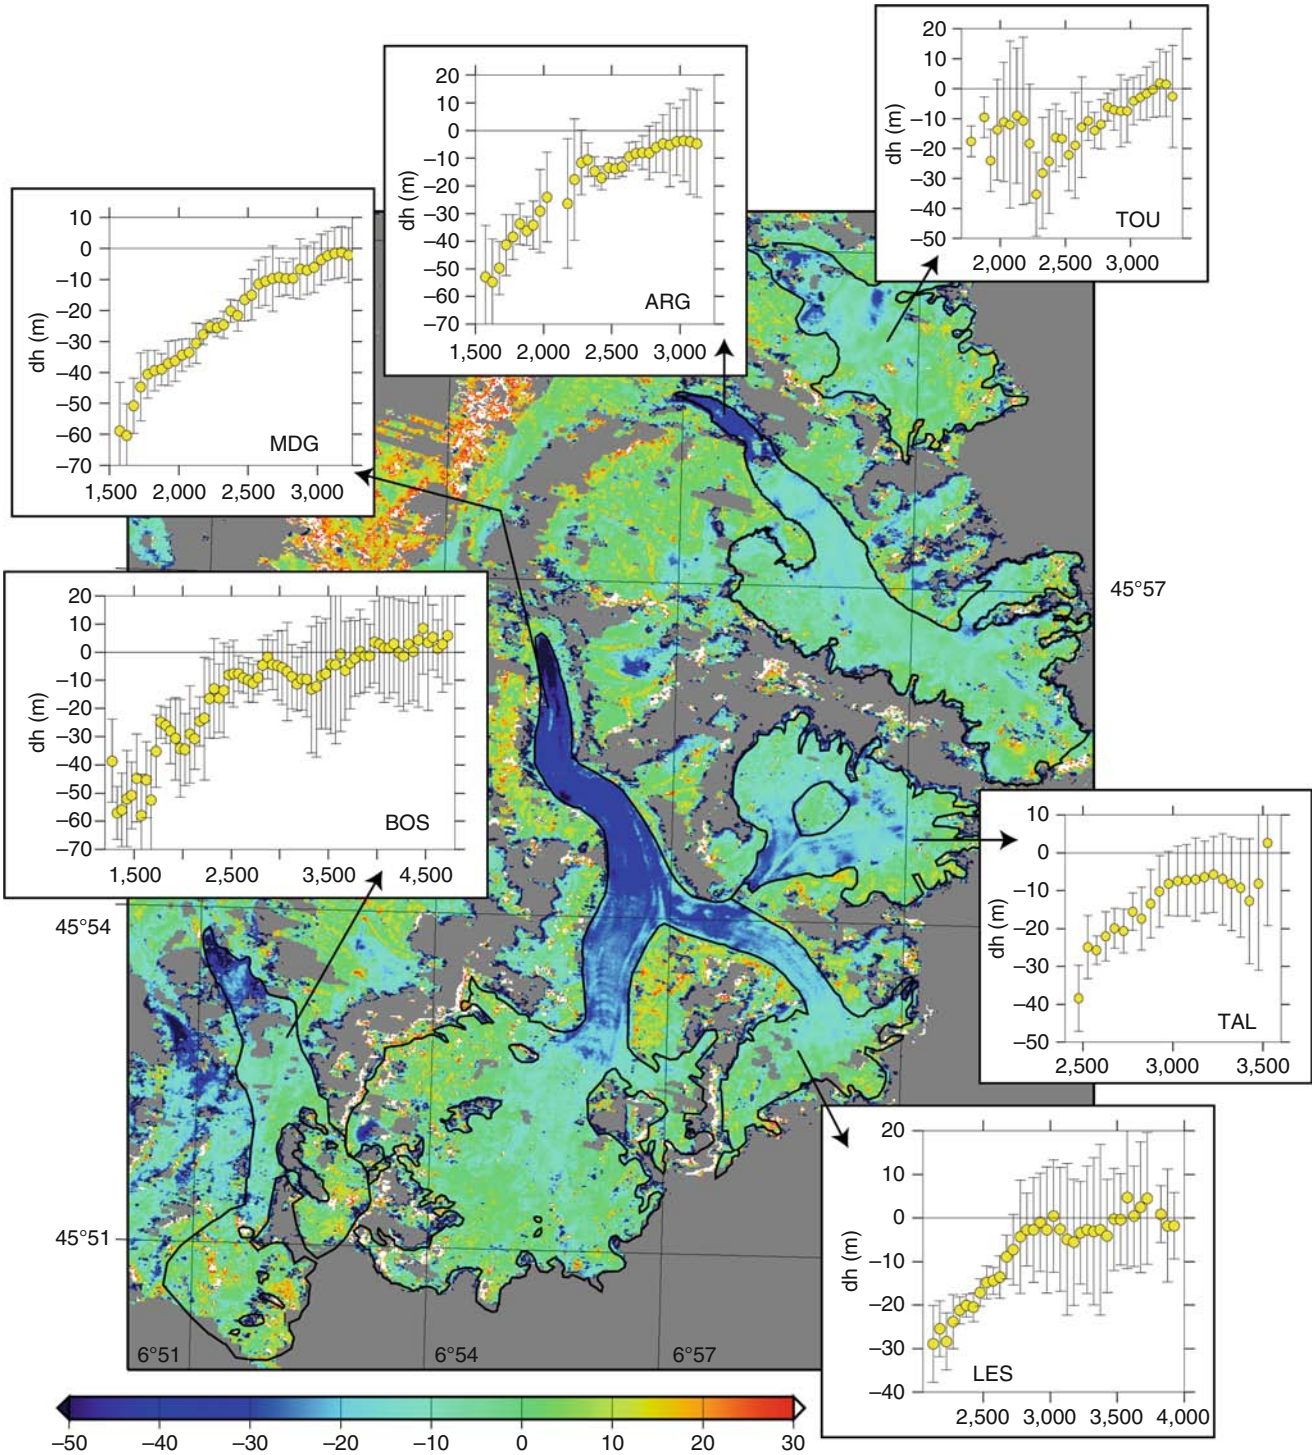
An elevation change is not necessarily associated with a change in mass or flow of the glacier. It can also be due to a change in the rate at which the snow falling on the surface is metamorphosed into firn (first) and then into ice. For example, if accumulation is maintained at the same level but the atmosphere above the glacier surface gets warmer, the snow metamorphism will be faster and a lowering of the glacier surface will occur. Such mechanisms are difficult to measure and model although they are crucial for a realistic assessment of the mass balance of the polar ice sheets (Helsen et al., 2008).

Recent thinning of glaciers

Most glaciers around the globe are now thinning at a rapid rate (Cogley, 2009) and, between 2003 and 2008, mountain glaciers and ice sheets were the main contributors (85%) to a sea-level rise of 2.5 mm/year (Cazenave et al., 2009). The rare regions where glaciers were in equilibrium or thickening in the 1990s (West of Norway, Iceland, and New Zealand) are now also thinning (on average) and losing mass (Björnsson and Pálsson, 2008; Chinn et al., 2005; Nesje et al., 2008). There is a striking similarity between the patterns of thinning in different regions. As observed in Alaska (Arendt et al., 2002), in Patagonia (Rignot et al., 2003), in the Alps (Berthier et al., 2006; Paul and Haeberli, 2008), and in many other mountain ranges, the thinning of glaciers is maximum at low elevation and limited in their accumulation areas (Figure 2). This is an expected thinning pattern during the retreat phase of mountain glaciers (Schwitter and Raymond, 1993).

Summary or conclusions

Together with their retreat, thinning of glaciers is their most striking response to global warming and explains why they are generally regarded as a symbol of the ongoing global warming. Yet, the number of glaciers whose elevation changes have been actually observed is still too limited. The number is currently growing thanks to some recent advances in our capabilities to measure glacier



Thinning of Glaciers, Figure 2 Elevation changes in the Mont-Blanc area (French Alps) between 1979 and 2003. Plots of elevation changes as a function of altitudes are given for, from North to South, *TOU* Tour glacier, *ARG* Argentière glacier, *TAL* Talèfre glacier, *MDG* Mer de Glace, *LES* Leschaux glaciers, *BOS* Bossons glacier.

elevation changes, in particular from satellite data (ASTER and SPOT stereo-images, ICESat laser profiles). This capability will even increase in the near future thanks to new satellite missions to be launched in 2010 (and beyond) such as CryoSat-2 (European Space Agency) and Tandem-X (DLR, German Aerospace Center).

TIBETAN PLATEAU

Tandong Yao, Yongqin Liu, Huabiao Zhao, Wusheng Yu
Laboratory of Tibetan Environment Changes and Land Surface Processes (TEL), Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing, China

Definition

The Tibetan Plateau lies between 25°N and 40°N, 74°E and 104°E. It constitutes the world's largest Plateau, covering an area of 2.5 million km^2 that extends from the Pamir Plateau in the west to the Hengduan Mountains in the east; and from the Kunlun Mountains and Qilian Mountains in the north to the Himalaya Mountains in the south. The Tibetan Plateau also includes the highest land mass, with an average elevation of over 4,500 m sometimes called "the roof of the world." It forms one of the major drivers of global climate, referred as the Earth's "third pole." It includes the headwater areas for a series of major Asian rivers, called the "water tower" of east-south Asia. It embraces a unique natural lab for the study of global climatic change and geodynamics, drawing the attention of increasingly more international researchers.

Mountains on the Tibetan plateau

The mountain systems of the Tibetan Plateau have been uplifting rapidly since the late Tertiary and now form the world's highest and largest high mountain region. Towering mountains cover the Tibetan Plateau. Most of the mountains exceed 5,500 m; over 100 mountains rise above 7,000 m. All of the world's 14 mountains higher than 8,000 m rise from the Tibetan Plateau, ten of them in the Himalayan Mountains, the other four in the Karakorum Mountains.

Eight mountain ranges strike east–west across the Plateau, from north to the south, the Aerhchin, Qilian, Eight mountain ranges strike east–west across the Plateau, from north to the south, the Aerhchin, Qilian, Kunlun, Karakorum, Tanggula, Gangdisi, Nyainqentanglha, and Himalayan Mountains. The Himalayan Mountains, meaning "abode of snow," include the planet's highest mountains. The Himalayas run east to west, from Mt. Namcha Barwa (7,756 m) to Nanga Parbat (8,126 m), continuing for about 2,500 km. The average altitude of the Himalayan Mountains exceeds 6,000 m and they include Mount Qomolangma (8,844 m), the world's highest peak. The Karakorum Mountains make up one of the greatest ranges of the world, including K2 (8,611 m), the second highest peak on earth. The Kunlun Mountains runs eastward from the Pamir Plateau, extending more than 2,500 km. The main ridge of the range varies between 6,000 and 6,500 m, including its highest mountain, Mt. Kunlun Goddess (7,167 m). The Tangula Mountains span about 700 km with their main ridge averaging more than 5,000 m, with (6621 m) its tallest peak. The Nyainqentanglha Mountains run 740 km across Tibet, from the Nimu County in the west to Ranwu County in the east. The range's highest peak, Mt. Nyainqentanglha, reaches 7,162 m. The Gangdisi Mountains parallel the Himalayas, extending about 1,100 km. The main peak, Mt. Kailas (6,638 m) owes its sacredness to Tibetan Buddhism and Hinduism. With its unique geographical location and graceful landscape, Kailas is considered the most holy of all mountains. Buddhist pilgrims believe that Mt. Kailas holds the sacred abode of the deity Chakrasamvara and his consort Dorje Phamo. Hindu pilgrims regard it as the throne of the great God Shiva. The 800 km long Qilian Mountains consist of a series of alternating northwest-trending ridges and valleys. Tuanjie Peak (5,808 m) is the highest peak of the range. The Aerhchin Mountains run roughly 1,000 km, forming the boundary of the Tarim Basin the Qaidam Basin. The highest peak, Shulamutage Peak, reaches 6,295 m. The north–south striking Hengduan Mountains lie on the southeastern Plateau and consist of a series of high parallel ranges and deep canyons oriented north to south.

Glaciers on the Tibetan plateau

The Tibetan Plateau encompasses the largest mid-low latitude part of the world currently covered by glaciers. Shi's (2005) Chinese glacier inventory has counted all the glaciers on the Tibetan Plateau. The inventory show that 36,102 existing glaciers on the Plateau, with a total area of 49,688 km^2 and a cumulative ice volume of 4,972 km^3, or a total water equivalent ice volume of 5.04×10^{12} m^3. This immense fresh water reservoir on the Tibetan Plateau could provide 6.16×10^{10} m^3 of water to river runoff (Yang, 1991).

The Kunlun, Nyainqentanglha, Himalayan, and Karakorum Mountains account for over half of the total number of glaciers and ice volume on the Tibetan Plateau (Shi, 2005, 2008). Most of glaciers in the Kunlun Mountains concentrate in the western section. The West Kunlun Mountains (75° 10′–80° 40′ E) contain 6,580 glaciers, with a total area of 10,844 km^2 and a volume of 1,175 km^3, accounting for 85%, 88%, and 92%, respectively, of these numbers for the entire Kunlun Mountains. More than 50% of the glacier covered area of the West Kunlun Mountains contains various valley glaciers. These include the Duofeng Glacier, the largest dendritic valley glacier, with a length of 31 km and an area of over 250 km^2. Many complex valley glaciers and dendritic valley glaciers exist on the northern slopes of the West Kunlun Mountains. However, the southern slopes accommodate numerous flat-topped and outlet glaciers with piedmont lobes. As the glaciers on the northern and southern slopes may originate on the same peak, a glacier composite may form an ice cap, e.g., the Guliya Ice Cap. The maximum length of the Guliya Ice Cap reaches 30.9 km from north to south, and includes a total area of 212 km^2. The average depth of the ice cap has been estimated at over 200 m, with the maximum in excess of 350 m, making it the highest, largest, and coldest ice cap in the mid-low latitudes. A 308.7 m deep ice core has been recovered from the ice cap.

The Nyainqentanglha Mountains contain 7,080 glaciers, with a total area of 10,700 km^2, with two-thirds of the galcier and five-sixths the area lying in the eastern section. The eastern section faces the approaching moist southwest monsoons, which enter the Plateau at the Grand Bend of the Yarlung Zangbo River. The terrain forces the air flow to rise, providing the region with the maximum precipitation and highest moisture on the Plateau, enhancing glacier development. Thirty-two glaciers exceed 10 km in length, with the Kyagqen Glacier largest, at 35.3 km in length and 207 km^2 in area.

Of the Mt. Qomolangma, glaciers cover 1,600 km^2. This zone contains 15 glaciers larger than 20 km^2, and 18 other glaciers larger than 10 km^2. The largest glacier on Qomolangma's northern slope is the Rongbuk Glacier, a dendritic valley glacier consisting of the Middle and West Rongbuk Glaciers, 22.4 km long and covering 85.4 km^2. The largest glacier on the southern slopes is the Ngozumpa Glacier, 23 km in length and 80.8 km^2 in area. A series of seracs lie between 5,300–5,700 m on the Rongbuk Glacier, within a horizontal distance of 6 km. These include embryonic, connected, and isolated seracs, ranging in height from a few meters to 50 m, forming a forest of neve penitentes, under conditions of strong solar radiation, a high angle of incidence, and a dry climate.

Mt. Xixiabangma forms another glaciation center in the Himalayan Mountains. The peaks and sides of the main ridges contain 438 glaciers, with a total glacier area of 1,173 km^2 and an ice volume of 122 km^3. The 20.2 km long Langtang Glacier (covering 58.57 km^2) forms the largest complex valley glacier on Xixiabangma's southern slope. The 14.3 km Daqu Glacier (covering 44 km^2 and holding 8.3 km^3 of ice), is the largest complex valley glacier on the northern slope. Another large valley glacier,

the Dasuopu Glacier (11.0 km long, covering 26.2 km^2, and containing 3.4 km^3 of ice) also sits on the northern slope.

Glaciers in the Karakorum Mountains cover 17,835 km^2, accounting for about 37% of the total mountain area. They cover mainly the western and southwestern portions of the mountains. The Karakorum Mountains within China contain five dendritic glaciers with an area greater than 100 km^2, namely, the Yengisogat, Yulin, Teram Kangri, Gasherbrum, and Kyagar Glaciers. Of these, the Yengisogat Glacier (42.0 km long, covering 380 km^2, and with an ice volume of 116 km^3) ranks as both the longest glacier in China and the one covering the largest area.

The glaciers on the Tibetan Plateau have been retreating continuously under the impact of climatic warming for several recent years. The decrease in glacial volume in the High Asian China falls between 587 km^3 during the past 40 years (Yao et al., 2004).

Lakes on the Tibetan plateau

The Tibetan Plateau includes a fairly high density of lakes, 1,091 of which exceed 1.0 km^2. Lakes cover a total area of more than 400,000 km^2 (Wang and Dou, 1998). Tectonics has controlled the placement of most of the large lakes on the Plateau, while numerous small lakes result from glacial processes. Depending on their sources, these lakes may also be categorized as glacier-fed or non-glacier-fed.

Remote sensing data from the Landsat TM show that 11 lakes on the Plateau exceed 13,300 km^2 (Lu, 2006). The big lakes on the Plateau include: (1) Qinghai Lake, the largest salt lake in China, with a surface elevation of 3,196 m, 67 km wide and 109 km long, covering 4,344 km^2 in 2001, and a maximum depth of 27 m as measured in 1981; (2) Nam Co, the largest holy lake in Tibet, with a surface elevation of 4,718 m, 50 km wide and 78.6 km long, and covering 1962 km^2; (3) Serling Co, a mysterious lake at 4,350 m, with a maximum width of 45.5 km and maximum length of 77.7 km, and a total area of 1,628 km^2; (4) Zhari Namco, a lake with rich fishing resources, at 4,613 m, 26.2 km wide and having a total area of 997 km^2; and (5) Tangra Yumco at 4,528 m, with a width of 19.4 km, length of 71.7 km, and 836 km^2 of total area.

Rivers on the Tibetan plateau

The Tibetan Plateau gives birth to many of the great rivers in Asia, i.e., the Yellow, Yangtze, Mekong, Salween, Ganges, Indus, and Brahmaputra rivers.

The 5,464 km long Yellow River originates in the southwest of the Yoigilangleb Basin on the northern slope of Mount Bayan Har. Water flows down from the Maqu Quguori Divide through Gyaring Lake and Ngoring Lake, before discharging finally into the Maqu and forming the Yellow River.

The Yangtze River ranks as the longest river in China. It has three recognized sources. Its main source, the Tuotuo River, lies in the glacial region of Mt. Geladandong in the Tanggula Mountains, serves as its southern source and the Qumar River as its northern source. These three sources merge into the Tongtian River and form the Jinsha Jiang, which winds over 6,300 km before eventually flowing into the East China Sea in the Pacific Ocean.

The Mekong River (4,500 km in total length) originates on the northern slope of the Tanggula Mountains. It flows down to the Zachu River, joins the Lancang River and merges into Burma to form the Mekong River. The river finally discharges into the South China Sea after passing Laos, Thailand, Cambodia, and Vietnam.

The Salween River (2,690 km long) originates near Dengka Peak to the east of Tanggula Pass. Afterward, it merges into the Nujiang River and becomes the well-known Salween River once it enters Burma, and finally discharges into the Indian Ocean.

Four international rivers originate from Mt. Kailas in the Gangdisi Mountains, named, respectively, after four auspicious animals: the horse, the peacock, the lion, and the elephant. The Maquan River (meaning "Horse Fountain") runs on its eastern side, traveling through the Yarlung Zangbo, the Brahmaputra, and the Ganges rivers before discharging into the Bay of Bengal. On the south, the Kongque River (meaning "Peacock Fountain") flows to the west, running through the Indus River Plain before discharging into the Arabian Sea. The Shiquan River (meaning "Lion Fountain") lies on the north, and joins other rivers to also join the surging Indus River and travels through the Indus River Plain to pour into the Arabian Sea (Xu, 1992).

Ice cores from the Tibetan plateau

Ice core studies have contributed considerably to global change research. These studies have provided not only the information about the past temperature changes, but also about the past precipitation, greenhouse gas concentrations, volcanic activity, desert development, atmospheric circulation intensity, solar activity, biogeochemical cycles, and other worldwide events. Ice core studies on the Tibetan Plateau have made substantial progress over the past 2 decades and have attracted much attention from international geoscientists. Many shallow and deep ice cores have been extracted from the Qilian Mountains, West Kunlun Mountains, Tanggula Range, the Himalayas, and other regions.

The drilling of ice cores on the Tibetan Plateau began on the Dunde Ice Cap in the Qilian Mountains. In 1984, the Byrd Polar Research Center and the Lanzhou Institute of Glaciology and Geocryology (Chinese Academy of Sciences), conducted a cooperative glaciological research program to retrieve and study the Dunde ice cores. Four shallow cores (10.2, 16, 32, and 34.5 m long) and three ice cores to bedrock (139.8, 136.6, and 138.4 m long) were recovered from 1984 to 1987 (Yao and Xie, 1991). Analyses of these ice cores provided a detailed record of climatic and environmental changes in the region since the late Pleistocene (Thompson et al., 1989).

The Guliya ice core was then drilled and yielded the longest record from the middle and low latitudes. The 308.6 m long core was recovered from Guliya Ice Cap in the West Kunlun Mountains in 1991. The ice at the bottom of the core dates from about 760 ka BP. Climatic and environmental changes on several different time scales since the Last Interglacial Stage have been reconstructed from the Guliya ice core (Thompson et al., 1997; Yao et al., 1997, 2001).

The Dasuopu ice core comes from the highest elevation (7,100 m) and was drilled in the Dasuopu Glacier on Mt. Xixabangma, in the middle of the Himalayas. In 1997, three deep ice cores were recovered, with lengths of 160, 150, and 164 m. Analyses of these deep ice cores reveal the evolution of the Indian Monsoon (with high resolution and good quality), the history of the impact of human activities on the environment, and the characteristics of climate change in the middle of the Himalayas (Thompson et al., 2000).

TIDEWATER GLACIERS

Andreas Vieli
Department of Geography, Durham University, Durham, UK

Definitions

Calving. Refers in context of glaciers to the mechanism of breaking off of ice blocks from a vertical ice cliff.

Calving rate. The rate of ice loss by calving measured in along flow distance per time unit.

Introduction

Tidewater glaciers are glaciers that terminate in the sea and discharge icebergs to the ocean through the mechanism of calving (Calving Glaciers; VanderVeen, 1996, 2002; Benn et al., 2007). This mechanism of ablation is highly efficient and accounts for 70% of the annual mass transfer from the world's glaciers and ice sheets to the ocean. Tidewater glaciers currently only occur in latitudes higher than 45° and can be found in Alaska, the Canadian Arctic, Greenland, Svalbard, Novaya Zemlya, the Antarctic Peninsula, and to a small extent in Patagonia. The vertical ice cliff at the terminus of a tidewater glacier is usually grounded in temperate regions (e.g., Alaska), but in polar regions they are often floating and form small ice shelves that are laterally confined in fjords (Ice Shelf). Tidewater glaciers that discharge ice from ice caps or ice sheets (Ice Sheet) into coastal fjords are referred to as tidewater outlet glaciers (Outlet Glacier).

Tidewater glaciers are different to land-based valley glaciers (Glacier) in many ways. For tidewater glaciers, the dominant mechanism of ablation is through iceberg calving and surface ablation plays only a minor role in the overall mass balance (Glacier Mass Balance). Such glaciers are characterized by fast flow near their terminus of up to a few kilometers per year and the flow is dominated by basal motion rather than internal ice deformation (Glacier Motion/Ice Velocity and Glacier Sliding). This increased flow toward the glacier terminus causes strong along-flow extension and explains the observed intense crevassing of the glacier surface toward the terminus (Crevasses). Further, along-flow acceleration is caused by enhanced basal motion due to reduced resistance from the glacier bed as the surface approaches the level of flotation toward the terminus (Benn et al., 2007).

In contrast to land-based glaciers or ice sheet margins, fluctuations in terminal positions of tidewater glaciers are not necessarily directly related to changes in climate (Climate Change and Glaciers and Dynamics of Glaciers). For example, the terminus position of Columbia Glacier in Alaska (Figure 1; Alaskan Glaciers) was stable until 1980 located at a shallow morainal bank but then a rapid unstable retreat into deeper water set in, with average retreat rates of almost 2 km/year (VanderVeen, 1996). Over the last two centuries, many other tidewater glaciers in Alaska seem to have gone through such phases of rapid retreat through fjord overdeepenings and restabilization in more shallow water upstream.

Tidewater glacier cycle

This highly nonlinear behavior was first explained by the empirical observation that calving rates are roughly linearly proportional to water depth at the terminus (VanderVeen, 2002; Meier and Post, 1987). Typically, tidewater glaciers terminate at a shallow morainal bank or bedrock sill within the fjord. When the terminus starts to retreat, the water depth increases due to the reverse bed slope and further enhances calving and thereby accelerates the retreat until the fjord gets shallower again. This retreat seems irreversible in that it would require an unrealistic high shift to a more positive surface mass balance for the terminus to readvance over the fjord overdeepening. Many such glaciers erode and deliver a large amount of basal sediment at the terminus. Consequently, they can build up and plow a shallow morainal bank in front of them. This reduces water depth at the terminus and thereby calving rates and eases readvance (Nick et al., 2007), but requires high sedimentation rates and time, typically several decades or centuries. Hubbard and Taku Glacier in Alaska are examples of such an advance mechanism; the latter built up a terminal moraine that almost completely protected the terminus from the marine water and allowed it to readvance 7 km through a 100-m deep fjord over the last 120 years (Motyka and Beget, 1996).

This cyclic behavior of rapid retreat through overdeepenings in a fjord and slow readvance through the build up of a morainal bank is referred to as the "tidewater glacier cycle" (Meier and Post, 1987).

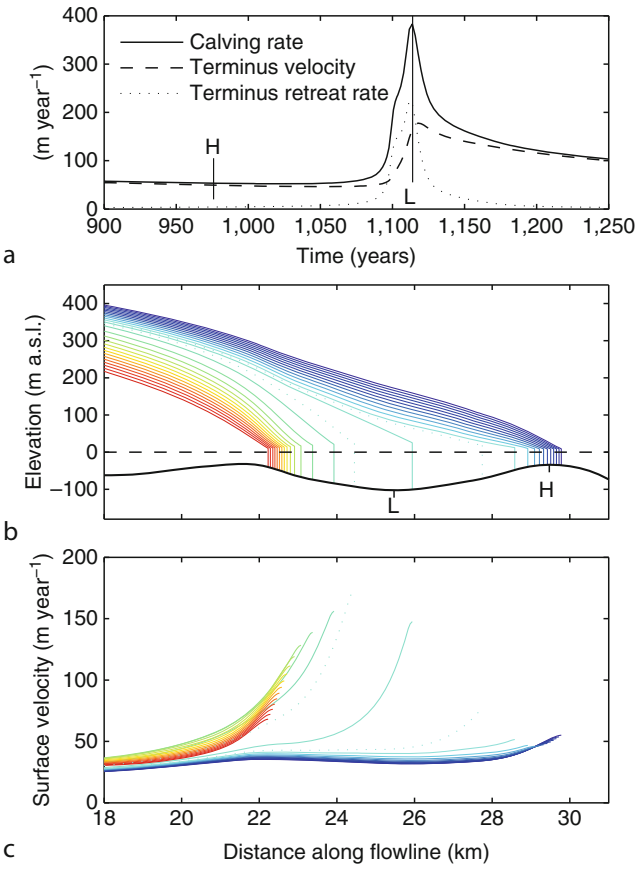
Tidewater glacier dynamics

During the rapid retreat of Columbia Glacier, the flow velocities at the terminus increased almost as much as the calving rates from 2 to 10 km/year. This increase in ice flux leads to a drawdown of the glacier surface. Under the assumption that the ice calves off due to buoyancy forces when the surface approaches the flotation level, this surface lowering leads to a further retreat of the terminus (VanderVeen, 1996, 2002).

Based on this concept a "buoyancy-induced calving model" has been proposed to explain the dynamical behavior of tidewater glaciers (VanderVeen, 1996, 2002).

Tidewater Glaciers, Figure 1 Columbia Glacier in Alaska in 1969 with its stable terminus at a shallow morainal shoal. (Photo: Unknown, 1969.)

The rates of retreat and calving are then a direct result of the flow dynamics and controlled by the rate of thinning of the surface at the terminus. This concept has been successfully tested using a numerical model (Vieli et al., 2001). Results from such a modeling experiment are shown in Figure 2 and illustrate how tidewater glaciers dynamically behave. Initially, the terminus is stable at a topographic high. At time zero of the model experiment, the Equilibrium-Line Altitude (ELA) is raised by 50 m. This shift to a more negative surface mass balance causes the glacier to thin and slowly retreat and eventually, it retreats over the basal high into slightly deeper water. This leads to an increase in flow speed and therefore an increase in ice flux at the terminus that provokes a thinning and further retreat into deeper water and leads to an unstable retreat-thinning feedback. Note the strong increase in flow at the terminus and the resulting peak in calving rates when reaching deeper water (Figure 2a and c). Eventually, the terminus retreats behind the basal low and reaches shallower water that decreases the calving rates, slows down the retreat, decelerates the flow, and stabilizes the terminus again. The main driver of this unstable retreat is a flux instability in the case of a reversed bed slope as similarly proposed on theoretical considerations for explaining the marine ice sheet instability (Schoof, 2007; Marine Ice Sheet).



Tidewater Glaciers, Figure 2 Calculated response of a small tidewater glacier to a rise in ELA at time 0. The modeling results are shown from 900 years onward. (**a**) Modeled calving rate (*solid line*), terminus velocity (*dashed line*), and retreat rate (*dotted line*) against model time. Modeled profiles of glacier surface (**b**) and surface velocity (**c**) are shown at 20-year intervals (10 years for *dotted lines*). The lines are color-coded for time and go from dark blue through green and yellow to red. In (**b**), the *solid line* shows bed elevation and the *dashed line* sea level.

This instability can be further enhanced by a positive feedback between subglacial motion and water pressure at the glacier bed. As the surface approaches flotation, the basal water pressure approaches the hydrostatic pressure of the overlying ice and thereby reduces the frictional forces at the glacier bed (Pfeffer, 2007). Variations in glacier width may also affect the stability of a tidewater glacier terminus, with terminus positions being more stable where the glacier channel narrows in the upstream direction.

Glaciers that terminate in freshwater such as a lake behave dynamically very similar to tidewater glaciers, although their calving rates are an order of magnitude lower for the same terminal water depth (Calving Glaciers; Benn et al., 2007).

Tidewater glaciers with a floating tongue

Although the above mechanism has been derived for tidewater glaciers with a grounded terminus, in theory the same dynamical effect occurs for tidewater glaciers with a floating tongue by simply replacing the calving terminus by the grounding line, which defines the point at which the glacier terminus starts to float due to buoyancy forces. This is only true if the floating tongue itself does not provide a significant resistance from lateral friction at the valley walls ("backstress") to the grounded ice upstream. Many outlet glaciers of the Greenland Ice Sheet have floating ice tongues that provide such backstress and act to stabilize the grounding line.

After 3-year phase of strong acceleration, thinning, and retreat related to a basal overdeeping, Helheim Glacier, a major tidewater outlet glacier in East Greenland, started to form a temporary floating ice tongue that slowed the glacier down (Howat et al., 2007) and allowed the terminus to readvance over a basal depression and thereby stabilize its ice tongue. This process reversed the dramatic retreat within a year and on far shorter timescales than considered in the tidewater glacier cycle. A further example illustrating the stabilizing effect of a floating tongue is from Jakobshavn Isbrae, another major tidewater outlet glacier of the Greenland ice sheet. Its recent doubling of flow speed to 13 km/year seems synchronous with the retreat and partial break up of a floating tongue in front of it (Joughin et al., 2004).

Tidewater outlet glaciers

Tidewater outlet glaciers such as Helheim Glacier often terminate in deep ocean fjords and their dynamical behavior appears similar to the rapid and unstable changes of valley tidewater glaciers discussed above (Nick et al., 2009). In Greenland, many such tidewater outlet glaciers are currently undergoing rapid retreat in combination with

a dramatic increase of flow and surface drawdown that both seem to be triggered from the terminus and propagate rapidly inland (Howat et al., 2007; Joughin et al., 2008). These dynamic changes seem to occur synchronously (Rignot and Kanagaratnam, 2006; Howat et al., 2008), suggesting that a common external forcing has acted as a trigger, for example, a regional warming. Indeed, these changes fall into some of the warmest years on record and indications of significantly warmer ocean waters reaching the calving termini have also been found (Holland et al., 2008). Such synchronous behavior and tight link between dynamic changes and climate or ocean are in contrast to the tidewater glacier cycle discussed above.

The recent observations and numerical modeling studies indicate that tidewater outlet glaciers can be extremely sensitive to short-term perturbations at their ocean termini and they react with strong dynamic changes that propagate rapidly inland (Nick et al., 2009). This high dynamic sensitivity and rapid adjustment are a result of the high flow rates and imply that the recently observed dramatic changes in Greenland are likely to reflect short-term fluctuations in climate or ocean conditions and should not necessarily be extrapolated to the future (Howat et al., 2008).

The observed seasonal variations in flow and terminus position of tidewater glaciers, with or without a floating tongue, further support their high sensitivity to short-term changes in climate. The termini of Jakobshavn Isbrae and Columbia Glacier both undergo seasonal cycles of advance and retreat in the order of kilometers per year. Although the short-term variations in tidewater glacier dynamics seem to be related to climate or ocean changes the actual linking mechanisms are not clear but a few potential mechanisms are briefly discussed below.

Triggering mechanisms

Enhanced surface melt in summer may lead to enhanced crevassing through the process of hydrofracturing and thereby weaken the glacier terminus and increase calving (Sohn et al., 1998). Warmer ocean water may increase subaqueous melt at the terminus and provoke more intense calving, or thin the floating tongue and thereby reduce its backstress onto the grounded ice. The onset of acceleration of Jakobshavn Isbrae coincides with the arrival of warmer subsurface ocean water (Holland et al., 2008). For grounded tidewater Glacier LeConte in Alaska, subaqueous melt rates at the calving terminus of 12 m/day have been estimated and demonstrate the potential of ocean melt in influencing calving dynamics (Motyka et al., 2003). Winter Sea Ice that freezes together with icebergs within the fjord ("Sikussak") may provide some backstress onto the calving front and thereby suppress calving. A reduction of winter sea ice duration may therefore increase the annual calving rate (Joughin et al., 2008).

Conclusions

The dynamics of tidewater glaciers is strongly affected by the process of calving and the geometry of the fjord they flow into and is characterized by rapid unstable retreats through basal overdeepenings. Their changes in terminus positions often appear unrelated to changes in climate; however, recent observations indicate that at least on shorter timescales of seasons to a few years tidewater glaciers seem dynamically highly sensitive to fluctuations in climate or ocean conditions. The linking process, however, is still poorly understood and currently subject of intensive research.

Given the high dynamic sensitivity of tidewater glaciers, their potential for rapid changes and their vital role in ice sheet drainage (Ice Sheet Mass Balance), a better understanding of their dynamical behavior, the process of calving and the linking processes to climate are crucial in improving our ability to predict the contribution of glaciers and ice sheets to future sea level (Sea-Level).

TIEN SHAN GLACIERS

Vladimir Aizen
College of Science, University of Idaho, Moscow, ID, USA

Synonyms

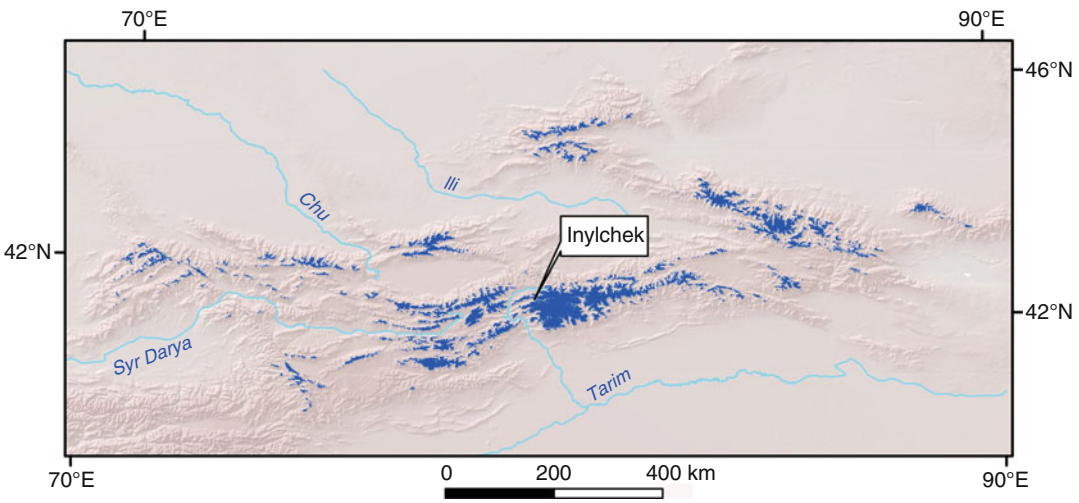
Alpine glaciers; Glaciers of central Asia; Glaciers of Kyrgyzstan, China, Kazakhstan, Uzbekistan; Glaciers of mid-latitudes; Tien Shan Glaciers

Definition

The Alpine glaciers of the mid-latitudes that exist in Tien Shan high mountains in continental climate.

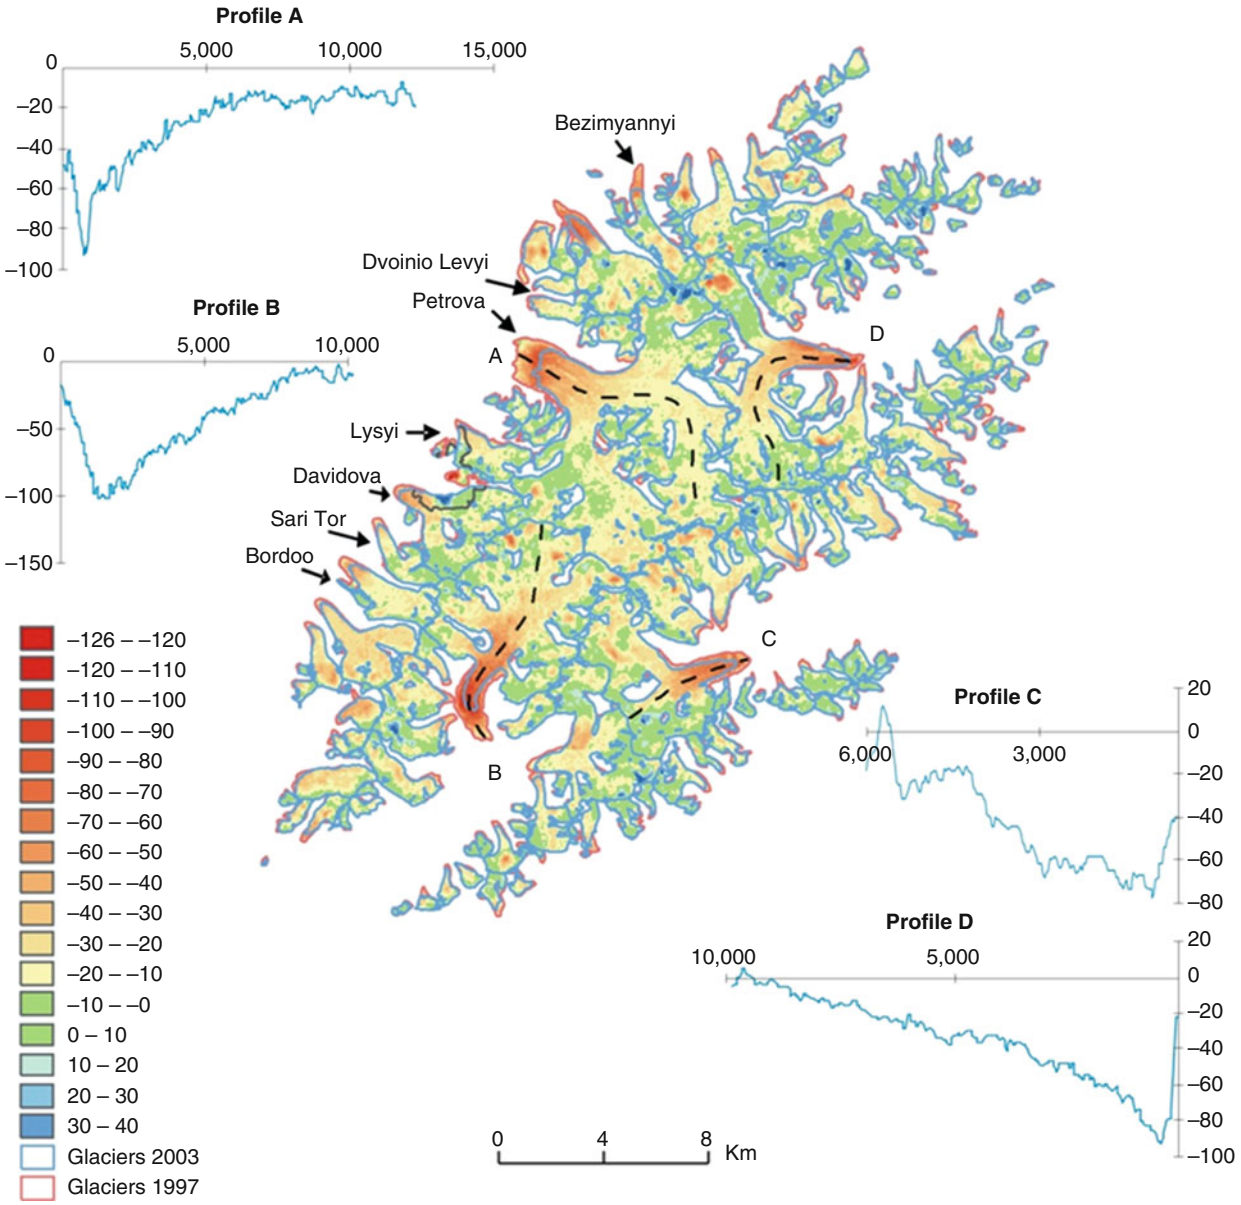
Tien Shan is one of the largest mountain systems in Asia stretching 2,000 km from west to east between 39–46°N and 69–95°E. Glaciers of Tien Shan (Figure 1) spread in altitudinal belt between 2,800 m a.s.l. and 7,400 m a.s.l. and inters one of the major sources of water in central Asia endorheic basins feeding the Aralo-Caspian, Balkhash, Issik Kul, and Tarim hydrographic systems. The glaciers of Tien Shan are supplying water for approximately 50 million populations of Kyrgyzstan, Uzbekistan, Kazakhstan, northern Tajikistan, and Xinjiang supporting the low lands agriculture, urban, and industrial areas. The latest investigations over the whole Tien Shan mountains based on remote sensing data numbers 7,590 glaciers with total area of 13,271.45 and 1,840 km^3 volume of ice (Aizen et al., 2008, 2009). There are different types of glaciers in Tien Shan, from large valley and dendrite glaciers, prevalent in central Tien Shan, to small lobes, niche glaciers in all Tien Shan alpine areas. Large valley glaciers form 82% of the Tien Shan total glacierized area. The South Inylchek (59.5 km long) is the largest Tien Shan glacier located in central Tien Shan, Khan-Tengri glacierized massif that covers 4,320 km^2. The Turkestan type of glaciers nourished by snow avalanches and mass of ice falling from hanging glaciers, are the prevailing glaciers in central Tien Shan, the Khan-Tengri glacierized massif. The mass of the rock falling on the glacier's surface with snow and ice is burying the tongue of the Turkestanian type of glaciers under thick moraine and commonly make glacier ice dead (Kotlyakov, 1984). The flat ice cap glaciers are typical of the Inner Tien Shan high elevated area.

The main factor controlling the glacier regime in Tien Shan is the impact of air temperature that affects the type of precipitation, the duration, and the intensity of snow



Tien Shan Glaciers, Figure 1 Glaciers of the Tien Shan Mountains.

and ice melt throughout altitudinal belts. The Tien Shan glaciers represent all though glacier ice formation zones, from cold recrystallization at altitudes over 6,000 m to warm infiltration-recrystallization and infiltration-congelation (Aizen et al., 1997). The modern increase of air temperature, which is observed in the Tien Shan's alpine areas, extends the period and intensity of melt not only in the glacier ablation area but also in the upper accumulation areas of the glaciers, which impact on acceleration of glacier recession in Tine Shan particularly from the mid 1970s. The Tien Shan glaciers lost 8.5% of their total area since the 1970s. However, different Tien Shan regions have different rates of glacier recession for the same period. The largest absolute, as well as relative glacier area loss occurred in the northern Tien Shan (−361 km^2, 14.3%), where the annual and seasonal sums of precipitation decreased at elevations above 3,000 m (18.6 mm), and the summer air temperatures increased by 0.44°C. Similar large absolute recession occurred in the inner and central Tien Shan (287 and 244 km^2) (Figure 2) where annual precipitation decreased on −35 mm and summer air temperatures increased on 0.71°C. However, the relative glacier area loss is 10% and 5%, respectively, due to large total glacierized area in inner and central Tien Shan. The least



Tien Shan Glaciers, Figure 2 Akshiirak glacierized massif in inner Tien Shan region. Changes in glacier area and surface elevation between 1977 and 2003 (Aizen et al., 2006).

absolute glacier recession occurred in the western Tien Shan (45 km^2), where summer air temperatures increased only by 0.23°C and annual precipitation decreased on 13.4 mm. The eastern Tien Shan lost 196 km^2 of the total glacier area (12%) (Liu et al., 1998; Aizen et al., 2009). The retreat of the Tien Shan glaciers was accompanied by equilibrium line altitude (ELA) with an uplift of 23 m from 4,012 m a.s.l. in 1973 to 4,035 m a.s.l. in 2003. On average, air temperatures in Tien Shan increased on 0.8°C with 7% precipitation decrease at the ELA (Aizen et al., 2008, 2006). Tien Shan glaciers exist in arid continental climate only because of spring-summer or summer maximum precipitation, which increase albedo in periods of glacier melt. Therefore, even a small decrease of precipitation along with increase of air temperature causes acceleration in Tien Shan glacier recession.

Synonyms

Boulder clay

Definition

Till. A sediment that has been transported and deposited by or from glacier ice, with little or no sorting by water.
Tillite. A lithified till from a pre-Quaternary glaciation.

Introduction

The term till is older than the glacial theory and has been first used by Scottish country folk to describe coarse, obdurate land, the soil developed on the stony clay that covers much of northern Britain (Flint, 1971). Despite its widespread occurrence in all areas covered by glaciers and ice sheets making it one of the most common sediment in the Northern Hemisphere, its origin and the interpretation of structural and textural characteristics are highly debated. Till is more variable than any other sediment known under a single name (Dreimanis, 1988) and its properties mirror the great complexity of processes involved in erosion, transport, and deposition of geological material by glaciers. For over a century researchers have tried, with variable success, to define diagnostic criteria of different till types and formulate a definition of till that would account for most of its characteristics. One problem is the gap between our understanding of glacial processes based on the study of environments glaciated at present, and the interpretation of the geological product of these processes, that is, a till, formed in the past. This is to a large extent caused by the inaccessibility of glacier beds and, consequently, the perplexing lack of direct observations of till formation. Therefore, reconstructions of till origin often lack reference to modern analogues verified by observation. The till definition given above (after Dreimanis and Lundqvist (1984)) is therefore a broad, descriptive formulation purposely avoiding any specific reference to till properties or the mechanisms of formation.

Till characteristics and classifications

Tills are typically diamicton consisting of a wide range of grain sizes from clay to boulders mixed together in various proportions depending on the rock types overridden by a glacier, transport modes, and the process in which glacial material is released from ice to become sediment. They contain both far-travelled and local components reflecting the flow path of a glacier, and their occurrence unequivocally marks the extent of past glaciers in Earth's history. On a continental scale, tills occur as meter to tens of meters thick sheets often separated by other glacial materials such as clay, silt, sand, and gravel leading to a pronouncedly stratified appearance of glacial sequences consisting of diamictons interbedded with sorted sediments. Besides being essential indicators of past glaciations, tills are important aquitards that influence groundwater flow in the upper lithosphere and they constitute a substrate for diverse engineering activities. The hydrogeological and geotechnical parameters of tills vary according to their lithological composition, texture, structure, and degree of compaction.

Numerous genetic classifications of tills have been proposed, typically based on their environment of formation (subglacial or supraglacial) or the relation to ice movement (formed by active or stagnant ice) (Dreimanis, 1988; Benn and Evans, 1998; Menzies, 2002). As research progresses, the till classification is being simplified merging the various local till types reported in the literature into fewer, more general classes (Evans et al., 2006). It is now

recognized that tills (1) often are hybrids derived from superposition of different processes that operated at a certain place in space during a glaciation (Larsen et al., 2004; Piotrowski et al., 2006), and (2) are typically parts of a glacial continuum characterized by overlapping properties and poorly defined boundaries (Evans, 2007) rendering rigid and complicated classifications unverifiable and unnecessary. The most important glacial processes leading to till formation are lodgement, deformation, melt-out, and flowage.

Lodgement till

This till type is deposited by plastering of glacial debris from the base of a moving glacier onto the substratum by pressure melting and/or other mechanical processes (Dreimanis, 1988). Lodgement occurs at the ice/bed interface (IBI) below active, warm-based glaciers particle by particle or in packages, whenever frictional forces between the debris and the bed overcome adhesion forces keeping the debris in the ice. This does not happen instantaneously and the debris is first dragged along the bed. Boulders dragged over the bedrock generate striations and percussion marks whereas finer-grained material may polish the bedrock. When lodgement occurs on a soft bed, boulders carve characteristic plowing marks in the bed before being liberated from the ice (Clark and Hansel, 1989; Jørgensen and Piotrowski, 2003; Thomason and Iverson, 2008).

Since lodgement tills are deposited from a base of a sliding glacier (or an ice sheet), their various structural elements have consistent orientation caused by the regionally uniform ice movement direction. This refers in particular to the till fabric whereby elongated stones are typically aligned parallel with the ice flow direction, which is the position of least resistance to the flow. Lodgement tills host syndepositional glaciodynamic structures such as slickensides, ribs, wedges (Ehlers and Stephan, 1979), and erosion tails behind boulders (Piotrowski and Kraus, 1997). Frequently, boulders' bottom surfaces bear signature of mechanical attrition imprinted during plowing, and their tops are flattened by abrasion after they have been lodged and the debris-laden ice was moving over them. Striations on the flat upper surfaces of the boulders are oriented parallel to the elongated stones found in the surrounding till matrix. Bullet-shaped boulders occur, with their blunt ends pointing up-glacier (Krüger, 1984). The base of a lodgement till is erosive, reflecting ice movement along the bed before till accretion commenced. Shear planes and subhorizontal fractures (Boulton, 1970; Benn, 1994) may also occur in lodgement tills but they may equally well be found in any other, postdepositionally mobilized tills and therefore their presence cannot be considered diagnostic for any particular process of till formation. Due to abrasion accompanying lodgement, these tills tend to have bimodal grain-size distribution with a distinct peak in the silt fraction caused by grain comminution (Haldorsen, 1981). Unless interrupted by other processes such as basal decoupling and sediment sorting by meltwater, accretion of lodgement tills by gradual release of basal debris together with lateral motion of the ice sole leads to their macroscopically structureless appearance. If porewater drainage from an accreting lodgement till is possible (e.g., through subglacial channels or into a permeable bed below), these tills are overconsolidated by the weight of the overlying ice. However, efficient drainage may be impeded under the ice and the pressurized porewater often prevents consolidation (Piotrowski and Kraus, 1997).

For decades it was assumed that lodgement tills are major components of flat to gently undulating ground moraines covering large areas of previously glaciated continents and are thus the volumetrically most important till type. However, it now appears that the typical volume of material transported englacially may be insufficient for the formation of thick till sequences by pure lodgement alone. Also, clay fraction which sometimes accounts for over 20–30% of these tills is difficult to attribute to lodgement because of the high mobility of this soft, low-strength material. Alternatively, some combination of lodgement and mobilization of the preexisting subglacial material may be considered (see below).

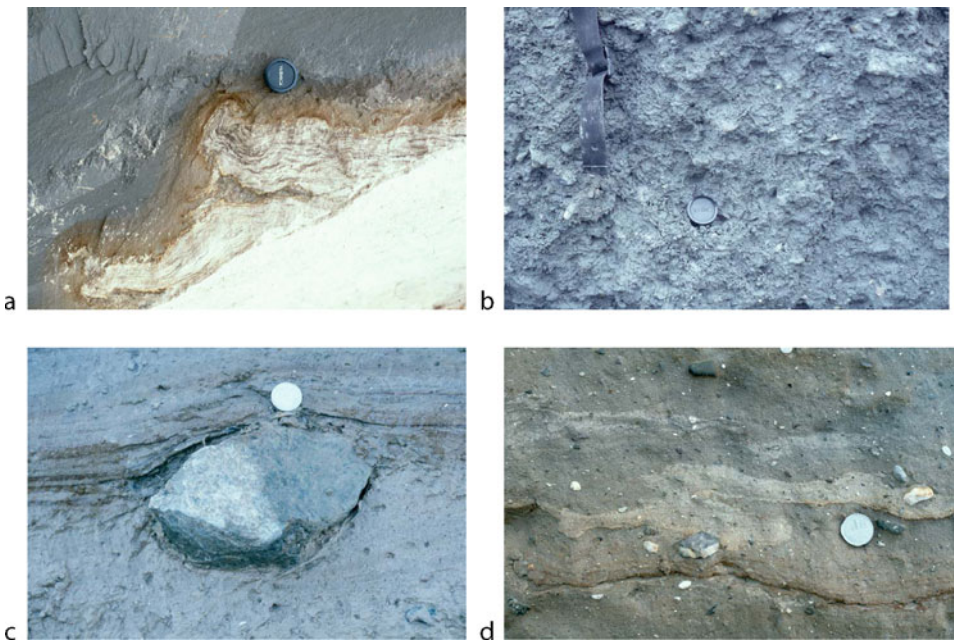
Deformation till and glaciotectonite

Named and described from the geological record by (Elson, 1961), deformation till can be regarded as weak rock or unconsolidated sediment that has been subglacially mobilized from its in situ position, the primary structures deformed or destroyed, and some foreign material admixed (cf. Elson, 1988). This type of till is produced beneath the glacier in the zone called deforming bed, mobile layer, or subglacial traction carpet where soft, dilated sediment, weakened by elevated porewater pressure cannot withstand stresses applied to it by the overriding glacier and starts to deform. Depending on local conditions controlling the sediment strength and ice-bed coupling, the zone of deformation may be in the range of centimeters (Engelhardt and Kamb, 1998) to several meters thick (Boulton, 1996), or it may be absent altogether. Because of the rheologically complex nature of diamictons subjected to stress, there are no universally agreed-upon criteria to distinguish deformation tills that experienced large strain from those that have not (Paterson, 1994). This is particularly true for macroscopically massive tills. The problem of the identification of deformation tills has generated some controversy as to how widespread deforming beds were under past ice sheets (Piotrowski et al., 2001). However, some proxies, as summed up below, help constrain the deformation process and identify its product. It is worth emphasizing that the genesis of deformation tills has consequences reaching far beyond glacial sedimentology alone; it also bears on our understanding of continental-scale debris redistribution by ice sheets and the processes controlling ice sheet stability, movement mechanism, and the

generation of certain landforms such as drumlins and megascale glacial lineations.

It is agreed that progressive deformation leads to sediment mixing and homogenization by mechanically predictable (Weertman, 1968) grain diffusion and advection. Therefore, deformation tills that experienced pervasive strain may be expected to have macroscopically massive appearance while revealing a large spectrum of microstructures when viewed under a microscope (van der Meer, 1993; Menzies, 2000; Hiemstra and Rijsdijk, 2003). If strain was lower, heterogeneities such as pods, lenses and stringers of sorted sediments bounded by smudged contacts with the surrounding till matrix (Hooyer and Iverson, 2000a) may occur. Thin intra-till stringers of sorted sediments produced by tectonism through mobilization and detachment from the bed, partial mixing with till matrix, and finally thinning and attenuation during advection within the deforming bed may be difficult to distinguish from the inclusions of sorted sediments formed by in situ sedimentation in water. Yet, careful examination is highly recommended since the unequivocal identification of tectonic versus sedimentary process may be crucial for the reconstruction of the genesis of the entire sequence of a bedded till. Deformation tills that experienced lower strains will be characterized by well-preserved tectonic layering with flat, overturned folds and rooted structures (Figure 1a). Given the uneven distribution of strain in the vertical profile of a deforming bed with the highest degree of deformation close to the ice sole (Boulton and Hindmarsh, 1987), basal contacts of deformation tills may be expected to be gradational from the undisturbed substratum (Piotrowski et al., 2006). Stress-induced intergranular collisions lead to particle comminution and thus grain-size modification (Boulton et al., 1974), they imprint wear pattern on grain surfaces (Benn, 1994), and generate specific micromorphological features such as in situ crushed quartz grains (Larsen et al., 2006b). Under such conditions, fragile material has low preservation potential and is typically absent in deformation tills, although nearly intact shells have been reported from fine-grained diamictons generated by subglacial deformation (Boulton et al., 1996; Hicock and Dreimanis, 1992).

Fabric signature of deformation tills has been interpreted differently, depending on the rheological model applied to the deformation. Earlier studies suggested that tills behave as viscous materials whereby clasts rotate freely within the matrix (Jeffery-type rotation model) leading to weak fabric strength. Since it was established that tills are more likely to be plastic materials, March-type rotation models have been applied to explain till fabric development (Benn, 1995; Hooyer and Iverson, 2002) whereby elongated particles quickly rotate into a quasi-stable, strain-parallel position and remain there



Till, Figure 1 (**a**) Deformation till overlying outwash sand. Note sand mobilization and incipient mixing with till matrix caused by basal shear stress. Stohl cliff, northern Germany. irrespective of further advection of till around them. This type of rotation has been confirmed in laboratory experiments (Hooyer and Iverson, 2000b; Hooyer and Iverson, 2002) that demonstrated a rapid evolution of fabrics in a pervasively deforming till, its strong final clustering and up-ice dip of elongated particles (Thomason and Iverson, 2009). These findings, together with strain-rate dependent evolution of microshears (Thomason and Iverson, 2006), can help estimate strain in a till of unknown history (Larsen et al., 2006a) and possibly distinguish it from other till types.

Deformation tills may or may not be overconsolidated. During pervasive deformation, a coarse-grained till is dilated due to grain rotations pulling the sediment skeleton apart whereby pressurized water fills in the enlarged pore spaces and prevents till compaction by the weight of the overlying ice. If porewater drains after the deformation ceases, the till may collapse to a denser state. The thicknesses of deformation tills can be expected to increase toward the ice margin (Evans and Hiemstra, 2005) where the subglacial advection of glacial debris terminates. Deformation tills consist primarily of local material with limited admixture of far-travelled components (Kjær et al., 2003) and occur at the bottom of a till sequence deposited during one glacial cycle.

A rock or sediment that has been deformed by subglacial shearing but retains some of the structural characteristics of the parent material and does not contain any admixture of foreign, ice-transported debris is called glaciotectonite (cf. Benn and Evans, 1998). This term includes comminution till, a dense fine-grained diamict formed by abrasion and crushing of bedrock underneath the ice (Elson, 1988). Ideally, an upward transition from undeformed bed to glaciotectonite and finally deformation till can be expected.

Subglacial traction till

Generated in the same environment (subglacial), under similar conditions (active, warm-based ice), and from similar parent material (any kind of bedrock and sediment overridden by a glacier), deformation and lodgement tills bear numerous common features and often are indistinguishable. Lodgement and deformation frequently coexist. For example, clasts plowing the bed at an early stage of lodgement may deform the bed to a depth of several clast diameters (Tulaczyk, 1999). This can imprint deformation signatures now distributed through the entire till thickness because of the time-transgressive accretion of till accompanied by plowing by clasts progressively emerging from the ice sole. Debris making up the lodgement till should, strictly speaking, remain immobile immediately after it was released from the ice which is difficult to envisage given the very low strength of a fresh till. It is therefore reasonable to consider lodgement and deformation tills as closely related and largely overlapping members of a subglacial continuum, and merge them into one common till type called subglacial traction till (STT) as suggested by Evans et al. (2006) (Figure 1b). The term STT would also include diamicts formed by creep or flowage into cavities on the lee sides of roches moutonnées (lee-side tills of Hillefors (1973)), and sorted sediments locally formed at the IBI due to ice-bed decoupling and washing partly referred to as "subglacial sliding bed deposits" (Evans, 2007).

Processes generating tills under active glaciers and ice sheets depend on the coupling of ice with its bed (e.g., Fischer and Clarke, 2001; Piotrowski et al., 2004), strength of the subglacial sediment, hydrological and thermal conditions and, as such, they vary in time and space which yields a mosaic of features whose interpretation often is contentious. Among several lines of modern research, on-site studies under modern glaciers (e.g., Iverson et al., 1995; Hart et al., 2009) and laboratory experiments (e.g., Iverson et al., 2008) and seem particularly promising in better constraining the origin of active-ice-till properties.

Melt-out till

Melt-out till is an ablation deposit formed by slow, in situ melting of ice. It consists of sediment released by the melting of stagnant or slowly moving debris-rich glacier ice and it is deposited without subsequent transport or deformation (Benn and Evans, 1998). Therefore, melt-out tills are typically formed at a late stage of glaciation when inactive ice melts down and the load it carried is gradually lowered onto the bed. These tills often occur on top of active ice tills and may constitute the bulk of sediment found in ice-disintegration landforms. When ice wastage occurs under cold and dry conditions, sublimation may replace melting and give rise to a specific till type known as sublimation till (Shaw, 1988). Melt-out tills can be generated by ablation at the top or at the bottom of a glacier, but the preservation potential of the latter is higher (Paul and Eyles, 1990). Formation of melt-out tills has been monitored in a modern environment (Lawson, 1981) but the significance of melt-out tills in the sedimentary record of past glaciations is contentious because the volume of englacial debris needed for the production of thick melt-out tills seems larger than it is typically observed in modern ice sheets.

Since the process of passive release of debris from the ice is clearly different from the processes involved in the formation of active-ice till facies, melt-out tills should be comparatively easy to identify. They are characterized by the preservation of original structures inherited from englacial transport, contain clasts of unlithified fragile material and abundant unabraded stones. Melt-out tills have a high proportion of far-travelled material including large, intact rafts of soft bedrock, in some cases transported for hundreds of kilometers. Elongated stones in melt-out tills tend to have high strength of clustering and they are aligned parallel to the ice flow direction as during the preceding englacial transport. The strong fabric can be reduced by stone collisions if ice has high debris

content. Dip angles of elongated stones are smaller than during the englacial transport due to subsequent ice removal causing wholesale volume reduction (Menzies, 2002). Melt-out tills can have undulating bases with little evidence of erosion. Sometimes, melt-out tills are found on top of upward-convex outwash sediments deposited in subglacial cavities that have been subsequently draped by the morainic material released from the ice sole.

Formation of melt-out tills is intimately associated with meltwater, and the diamictic matrix of the till may be occasionally intercalated with layers of sorted sediments such as sand and silt containing subglacial dropstones of various sizes. The contacts between these layers and the till matrix are often gradational which indicates transitions between phases of passive melting of material from the ice base in shallow subglacial cavities under stagnant-water conditions, and episodes of water flow through these cavities leading to lateral transport and sediment sorting. Such shifts in deposition are sometimes recorded as successions of current ripples preserved below the diamictons formed during subsequent melt-out phases (Piotrowski, 1994). An important feature of some melt-out tills are cm-thick, subhorizontal layers of sand that either drape stones in the till matrix (Figure 1c), or are downwarped underneath them. This results from volume reduction during ice melting and can be considered diagnostic for melt-out tills (Shaw, 1979). The drape structures above the stones are symmetrical, that is, lack lateral folding that is characteristic for tills generated by active ice. The layers of sand themselves are formed due to sorting of englacial debris where layers of relatively clean ice melt and release water. Basal decoupling and turbulent flow of meltwater along the IBI may lead to the formation of scour marks underneath boulders embedded in basal ice (Munro-Stasiuk, 2000). Given the ubiquitous presence of water preventing matrix compaction, melt-out tills are unlikely to be overconsolidated.

Despite the well-constrained process of in situ loss of ice from a melting debris-rich glacier, the recognition of past melt-out tills is often controversial with the same properties being attributed either to melting or to deformation (Evans, 2007).

Flow till

For many researchers not a true till but rather an ice-slope colluvium, flow till can be regarded as glacial debris gravitationally redeposited in direct contact with glacier ice (cf. Dreimanis, 1988). Its formation comprises (1) release of morainic material from the ice surface due to melting, (2) gravity-driven flowage along the sloping ice surface, and (3) deposition at the ice margin (Lawson, 1979). The dynamics of the flowage depend primarily on the ice slope angle, water saturation of the material, and the air temperature. Formed during a late stage of ice disintegration, flow tills commonly occur at the top of a till succession generated by a single glaciation and they are found in hummocky ice-disintegration landscapes, kames, and end moraines. They have limited aerial extent and variable thickness.

Flow tills are loosely packed (unless overridden during ice re-advance), coarse-grained diamictons with fine fraction depleted due to meltwater washing on the ice surface. If the washing is intense, flow tills may contain irregular pockets and lenses of sorted sediments, often deformed and partly mixed together with diamictic matrix during the flowage (Figure 1d). Gravitational folds and normal faults triggered by melting of the surrounding ice such as those reported from kames and end moraines are common. Flow tills may have locally strong but regionally inconsistent fabrics with stone orientation governed by the local configuration of the ice slope and the area where the flow stopped.

Conclusions

Considering a small number of features unique to a given till type and the genetic continuity between most types of tills, only a complex study of multiple proxies can help decipher the origin of a certain till. Unfortunately, many of these proxies are open to subjective interpretation by the individual researcher, which leads to disagreement that frequently cannot be resolved using rigorous scientific approach. Recent years have witnessed (1) a rapid development of analytical techniques such as analogue experiments in large ring-shear devices to test the behavior of tills under conditions mimicking those beneath glaciers; (2) advances in studies of till micromorphology to learn more about the small-scale structural diversity of macroscopically massive tills; (3) sophisticated on-site investigations of the ice/bed interface using probes and other devices inserted into the subglacial bed to monitor the behavior of till in its natural environment; and (4) enhanced development of numerical models to simulate till rheology in the context of continental-scale ice sheet dynamics. These fields are also the areas where research will likely be focussed in the near future.

Definition

Topographic normalization of satellite imagery represents the removal/reduction of multi-scale topographic effects in satellite imagery. Surface spectral reflectance should be representative of land-surface compositional and land-cover structural variations.

Introduction

Earth scientists studying the Earth's cryosphere are increasingly making use of multispectral satellite imagery for assessing land-surface composition and properties, thematic mapping, and change detection (Bishop et al., 2004; Bishop and Shroder, 2004). The availability of new imagery and information extraction technology (i.e., algorithms and pattern recognition approaches), however, does not directly translate into obtaining accurate surface information, as image spectral variability is governed by numerous environmental factors. Consequently, the information content in imagery varies depending upon atmospheric, topographic, surface composition, land-cover structure, and sensor characteristics that collectively determine the nature of the radiation transfer (RT) cascade at any particular location in time. These complexities often dictate the need for image preprocessing and radiometric calibration to convert calibrated digital numbers (DNs) to absolute units of at-sensor spectral radiance, and ultimately to surface spectral reflectance parameters, as many Earth science applications are primarily concerned with surface characterization.

It is widely known that topography plays a significant role in the RT cascade (Holben and Justice, 1981; Bishop and Colby, 2002). Complex topography, which includes extreme relief, steep slopes, and variations in slope azimuth (cardinal direction of slope), directly influence the amount of radiation that reaches the surface (surface irradiance). Altitude variations partially determine the magnitude of atmospheric attenuation. Other multi-scale topographic parameters, in relation to solar geometry, also cause variations in surface irradiance (e.g., shadows). The topography also governs microclimate and surface processes that control surface composition and land-cover structure. Collectively, the topography and surface composition and structure govern surface reflectance, such that the magnitude of surface reflectance varies in all directions (anisotropic reflectance). Surface reflectance is characterized by the bidirectional reflectance distribution function (BRDF). Furthermore, the topography in relation to the sensor's viewing geometry determines the BRDF sampling location, such that the magnitude of reflectance only from this BRDF location will directly propagate into the sensors field-of-view. Atmospheric attenuation and sensor characteristics then determine the magnitude of at-sensor radiance.

Clearly, the RT cascade is inherently complex, and RT interactions between the atmosphere, topography, and the surface must be taken into consideration. The influence of topography on the RT cascade dictates that satellite imagery acquired over complex terrain will exhibit spectral variability that is not representative of surface biophysical conditions. Consequently, satellite imagery frequently exhibits the *topographic effect*, which includes the presence of cast shadows, and spectral variation caused by differential illumination. It is also important to note that the influence of topography on spectral variability is not always visually detectable in imagery, as a particular topographic parameter may have varying degrees of impact on the magnitude of irradiance and reflectance. Therefore, radiometric calibration of satellite imagery requires anisotropic reflectance correction (ARC) to ensure that image reflectance variations are representative of surface-matter composition and structure, rather than indicative of atmospheric, irradiance, and topographic-induced BRDF pattern variations.

Researchers have attempted to remove the topographic effects in satellite imagery using a variety of

methodological approaches. This is generally referred to in the literature as *topographic normalization.* It should be noted, however, that topographic normalization techniques focus on removing/reducing the topographic effect in imagery, although they may not address numerous RT components influenced by topography. Consequently, topographic normalization does not represent comprehensive ARC. To our knowledge, an operational ARC model has yet to be developed to address the inherent complexities of topography and anisotropic reflectance. Therefore, we review the problem of ARC, provide simple guidelines for radiometric calibration, review various topographic normalization approaches, and assess the issues and feasibility of removing topographic effects from satellite multispectral imagery.

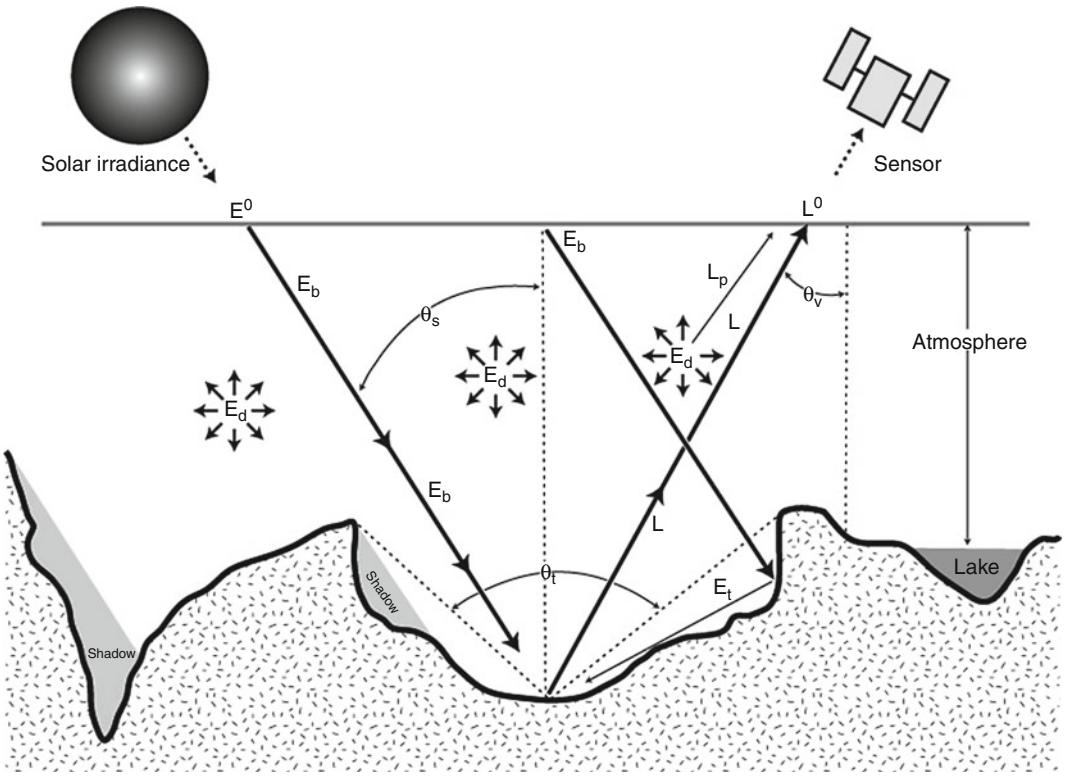
Background

Addressing the complex problem of anisotropic reflectance requires an understanding of radiation transfer processes, matter–energy interactions, and RT cascade components. Topography plays a significant role, as it has a multi-scale influence on the RT cascade. Topographic effects, however, have not been accurately characterized or systematically evaluated (Smith et al., 1980; Teillet et al., 1982; Proy et al., 1989; Bishop and Colby, 2002).

Radiation transfer

The passive reflection model of remote sensing is based upon the RT cascade from the Sun to the sensor (Figure 1). Solar irradiance variations occur at several timescales related to solar rotation, magnetic field variations, and sunspot activity. Earth's orbital variations influence the magnitude of irradiance that reaches the top of the Earth's atmosphere (exo-atmospheric irradiance, E^0) at a multitude of temporal scales. The orbital parameters of eccentricity (shape of the elliptical orbit around the Sun), obliquity (tilt of the Earth on its axis), and longitude of perihelion govern solar geometry and the distance between the Earth and the Sun. Consequently, solar and orbital parameters cause variations in the magnitude of E^0 on diurnal, annual, and longer timescales.

The exo-atmospheric irradiance is attenuated by the atmosphere, as numerous processes such as scattering, absorption, and refraction govern the magnitude of attenuation/transmission. This is controlled by atmospheric composition and the temperature/pressure vertical structure. The integrated influence of atmospheric attenuation is related to the optical depth of the atmosphere that is a function of solar geometry and landscape hypsometry (i.e., altitude distribution). Solar geometry, atmospheric, and terrain conditions are coupled to generate other sources of irradiance. Therefore, the topography strongly governs the amount of energy reaching the Earth's surface.



Topographic Normalization of Multispectral Satellite Imagery, Figure 1 Conceptual diagram of the primary radiation transfer components and multi-scale topographic effects.

Surface irradiance

The total spectral irradiance at the Earth's surface (E) is a composite of three irradiance components that are wavelength (λ) dependent such that

$$E(\lambda) = E_b(\lambda) + E_d(\lambda) + E_t(\lambda), \quad (1)$$

where E_b is the direct-beam irradiance component, E_d is the diffuse-skylight irradiance component, and E_t is the adjacent-terrain irradiance component.

The atmosphere attenuates the direct irradiance primarily by gaseous absorption and molecular and aerosol scattering (Chavez, 1996). Therefore, the downward atmospheric transmission ($\tau^{\downarrow}$) is a function of the total optical depth of the atmosphere. In many mountain ranges, extreme relief dictates significant changes in $\tau^{\downarrow}$ over relatively short horizontal distances.

The direct irradiance is also a function of solar and terrain geometry. Local topographic conditions are represented by the incidence angle of illumination (i), such that

$$\begin{aligned}\cos\ i = &\cos\ \theta_s\ \cos(\beta_t) \\ &+ \sin\ \theta_s\ \sin\ \beta_t\ \cos(\phi_t - \phi_s),\end{aligned} \quad (2)$$

where θ_s is the solar zenith angle, ϕ_s is the solar azimuth angle, β_t is the slope angle of the terrain, and ϕ_t is the slope-aspect angle of the terrain.

The value of cos i can be ≤ 0.0, indicating no direct irradiance due to the orientation of the topography. The regional scale topographic relief is not accounted for by Equation 2, and the altitude distribution in the direction of ϕ_s must be considered to determine if a pixel is in shadow (S). Satellite imagery acquired in rugged terrain with relatively high, solar zenith angles and/or steep slopes exhibit cast shadows (Figure 2). The local topography and cast shadows increase the global spectral variance in satellite images, with a decrease in spectral variance associated with shadowed areas. These multi-scale topographic effects are incorporated into E_b as

$$E_b(\lambda) = E^0(\lambda)\tau^{\downarrow}(\lambda)\ \cos\ i\ S. \quad (3)$$

This component can be highly variable over complex mountain terrain.

Atmospheric scattering will produce a hemispherical source of irradiance (E_d, Figure 1). This source is composed of a direct-downward skylight component and a secondary diffuse component caused by multiple interactions between the ground surface and the atmosphere (Iqbal, 1983; Proy et al., 1989). Diffuse-skylight irradiance is influenced by hemispherical shielding of the topography, as a significant part of the hemisphere can be masked by the mesoscale relief. Consequently, only a solid angle of the sky will contribute to E_d, and this angle (θ_t) will change as a function of pixel location and direction. In general, the solid angle will increase with altitude. In mountain environments exhibiting extreme relief and deep valleys, topographic shielding of the solar diffuse irradiance can be significant (Proy et al., 1989). Mesoscale topographic shielding plays less of a role in terrain exhibiting low to moderate relief.

Topographic Normalization of Multispectral Satellite Imagery, Figure 2 ASTER false-color composite (bands 3, 2, 1) depicting the Bualtar Glacier within the Hispar Mustagh region of the Karakoram Himalaya, Pakistan. This subscene exhibits extreme relief and a multitude of surface-cover types. Multi-scale topographic effects include cast shadows, local topographic effects, hemispherical shielding of the topography, and adjacent-terrain influences. Spectral variation caused by the topography is problematic for estimating surface properties and for thematic mapping applications.

The irradiance components E_b and E_d interact with the terrain to generate an adjacent-terrain irradiance component (E_t, Figure 1). This source of irradiance can be highly variable depending upon terrain geometry and surface composition and structure. Furthermore, the hemispherical integration of these factors, dictates the complexity of accounting for this component in mountain environments. Therefore, topographic normalization approaches do not usually account for E_t. Nevertheless, Proy et al. (1989) attempted a first-order approximation to this irradiance component assuming Lambertian reflectance (magnitude of reflectance is equal in all directions).

The contribution of E_t to the total surface irradiance in alpine environments is not accurately known, although it is generally thought to be highly variable, and significant where highly reflective rocks/sediment, vegetation, and ice/snow are prominent.

Surface reflectance

The magnitude of the reflected energy at the surface is determined by the conservation of energy, such that

$$\rho(\lambda) + \alpha(\lambda) + \tau(\lambda) = 1.0, \tag{4}$$

where, ρ, α, and τ represent reflectance, absorption, and transmission, respectively. For opaque objects ($\tau = 0.0$), α is equivalent to the emissivity (ε) of the object, which describes how well the object radiates energy. The reflected surface radiance (L) can be described as

$$L(\lambda) = \rho(\lambda)\left(\frac{\mathrm{E}(\lambda)}{\pi}\right). \tag{5}$$

Equation 5 represents isotropic reflectance (Lambertian). This assumption, however, is not valid in alpine environments due to the topography and biophysical characteristics of alpine landscapes (Smith et al., 1980; Kimes and Kirchner, 1981; Hugli and Frei, 1983; Hall et al., 1988; Dozier, 1989; Aniya et al., 1996; Greuell and de Ruyter de Wildt, 1999).

Given spatiotemporal variations in solar geometry, topography, surface composition, and land-cover structure, surface reflectance in alpine environments is highly anisotropic. It is necessary to characterize the BRDF, which describes the magnitude of reflectance for all combinations of input–output angles. For example, Greuell and de Ruyter de Wildt (1999) measured numerous BRDFs for melting glacier ice in Switzerland. They found that all BRDFs exhibited similar patterns and that the amount of anisotropy increased with an increase in wavelength, with increasing solar zenith angle, and decreasing albedo. Unfortunately, the BRDF is very difficult to accurately measure, especially on inclined surfaces, and more research is required to understand the influences associated with topography, surface-matter mixtures, and land-cover structure. This will require the development and evaluation of RT BRDF models.

The at-sensor radiance (L^0, Figure 1) does not represent the magnitude of L, as it is attenuated by atmospheric effects governed by sensor viewing geometry and topography. Consequently, spectral variations in satellite imagery are differentially influenced by atmospheric effects, topography, and BRDF geometry variations, which are not directly related to surface-matter composition. ARC is required to address these complexities, while topographic normalization usually focuses on reducing multiscale topographic effects related to surface irradiance. The complexity of the problem requires a special emphasis be given to radiometric calibration of satellite data before it can be utilized reliably for environmental information extraction.

The at-sensor radiance values require modification to account for the influence of the atmosphere. Numerous atmospheric-correction models for images have been developed for remote-sensing applications, and they enable the estimation of surface radiance, such that

$$L(\lambda) = \frac{\left(L^0(\lambda) - L_p(\lambda)\right)}{\tau^{\uparrow}(\lambda,\ \theta_v)}, \tag{6}$$

where L_p represents the collective additive path-radiance component caused by the scattering of the direct-beam component into the sensor field-of-view, $\tau^{\uparrow}$ is the beam transmittance of surface reflectance through the atmosphere in the upward direction, and θ_v is the view angle of the sensor. The surface radiance must then be modified to account for topographic effects and BRDF geometry variations.

Topographic normalization

Research into topographic normalization and ARC has been ongoing for 30 years. To date, a comprehensive operational model designed to meet the needs of Earth scientists has yet to emerge. In general, scientists have taken a variety of approaches to reduce spectral variability caused by the topography. The primary approaches include the following.

Spectral feature extraction

Spectral feature extraction methods usually involve linear transformations of the original data to produce *spectral features* that enhance spectral variation related to surface conditions. Techniques such as spectral band ratioing, principal components analysis, and other methods have been shown to reduce the influence of local topographic effects (i.e., cos i and S) in satellite images (Holben and Justice, 1981; Kowalik et al., 1983; Yool et al., 1986; Walsh et al., 1990; Colby, 1991; Conese et al., 1993b; Horsch, 2003). Although such spectral features are relatively easy to generate, research has shown that local topographic effects are still present in the transformed images (Holben and Justice, 1981; Kowalik et al., 1983; Colby, 1991). The limitations of this approach are in the empirical nature of the results, such that they are scene dependent. Furthermore, there are radiometric and technical issues that must be considered.

It is important to account for atmospheric effects such as the additive path-radiance term before ratioing (Kowalik et al., 1983). This dictates that DN values must be converted to radiance and that atmospheric-correction procedures account for optical-depth variations, which are a function of altitude. In addition, information may be lost in areas where cast shadows are present, depending upon solar geometry.

One might also expect that ratioing using visible bands may not be effective due to the influence of the atmosphere. Ekstrand (1996) found this to be the case and indicated that the blue and green spectral bands of Landsat Thematic Mapper Data should not be used in ratios to

remove the topographic effect. Therefore, depending upon topographic conditions and time of image acquisition, spectral feature extraction may or may not be useful for biophysical remote sensing or thematic mapping.

Empirical approaches

Given these difficulties, empirical equations can be used to characterize the relationships between reflectance and topography within a particular scene. Normalizing equations can be generated by sampling cover types and using cos i and regression analysis (Meyer et al., 1983; Civco, 1989; Naugle and Lashlee, 1992; Ekstrand, 1996; Allen, 2000; Riano et al., 2003; Nichol et al., 2006; Wu et al., 2008).

For example, Civco (1989) used a two-stage normalization procedure that included a linear transformation based on an illumination model, and compared samples from northern and southern slopes to known areas of deciduous forest to derive an empirical wavelength-dependent calibration coefficient. In other studies, a statistical-empirical approach reportedly outperformed semi-empirical modeling (Vikhamar et al., 2004; Wu et al., 2008). It has been noted, however, that in steep and highly variable terrain, or when using imagery acquired with high solar zenith angles, empirical corrections may be less reliable (Franklin, 1991), or may not be effective at all wavelengths (Civco, 1989; Naugle and Lashlee, 1992). Empirical functions by their nature are difficult to use, as their complexity must vary to account for variations in topographic conditions (Allen, 2000).

Semi-empirical modeling

The most common approach to topographic normalization is semi-empirical modeling of the influence of topography on spectral response. Although numerous topographic parameters play a role, the parameter, cos i, is considered to be the most significant and proportional to the direct irradiance. It is used in the most common algorithms as described below.

Cosine correction

Topographic effects can be reduced in imagery by accounting for the nature of surface reflectance (Lambertian or non-Lambertian) and the local topographic conditions (Colby, 1991; Ekstrand, 1996; Colby and Keating, 1998). Semi-empirical approaches make use of a digital elevation model (DEM) to account for the local illumination conditions for each pixel, and may assume isotropic upward radiance. Given the Lambertian assumption, the cosine-law correction can be used as follows:

$$L_n(\lambda) = L(\lambda)\left[\frac{\cos\,\theta_s}{\cos\,i}\right], \tag{7}$$

where L_n represents the normalized radiance.

Research indicates that this approach may produce reasonable results for terrain where slope angles and solar zenith angles are relatively low (Smith et al., 1980), although numerous investigators have found that this approach does not work well in more complex topography, as overcorrection occurs (Figure 3), producing an inverse topographic effect (Civco, 1989; Bishop and Colby, 2002). This result can be potentially attributed to not accounting for the diffuse-skylight and adjacent-terrain irradiance components, which can significantly affect E and L (Proy et al., 1989; Trotter, 1998).

C-correction

Teillet et al. (1982) developed a semi-empirical function which is based upon linear regression such that

$$L(\lambda) = \beta \cos i + a, \tag{8}$$

where β is the slope coefficient and a is the Y-intercept of the linear relationship between L and cos i. The correction

Topographic Normalization of Multispectral Satellite Imagery, Figure 3 False-color composite of normalized spectral radiance using the cosine-correction model. The influence of topography has not been removed, and extreme radiance values are generated (overcorrection) because the model does not account for irradiance from the diffuse-skylight and adjacent-terrain irradiance components.

parameter c is used to modify the cosine law as an additive term such that

$$L_n(\lambda) = L(\lambda)\left[\frac{\cos\ \theta_s + c}{\cos\ i + c}\right], \quad (9)$$

where $c = a/\beta$, and is thought to be related to the effects of indirect illumination, presumably from the diffuse-skylight irradiance and the adjacent-terrain irradiance components. It is important to note that c is not a specific physical irradiance component, because the regression analysis may also include spectral variability from atmospheric, land cover, and other multi-scale topographic effects. It does not appear to work very well in complex topography as documented in Figure 4.

Minnaert correction

The Minnaert-correction procedure has been used by a variety of investigators to reduce the topographic effect in imagery (Smith et al., 1980; Justice et al., 1981; Teillet et al., 1982; Colby, 1991; Bishop et al., 1998; Colby and Keating, 1998; Hale and Rock, 2003). The correction procedure makes use of the Minnaert coefficient k, such that

$$L_n(\lambda) = \frac{(L(\lambda)\ \cos\ e)}{(\cos^k\ i \cos^k e)}, \quad (10)$$

where e is the existence angle ($e = \beta_t$ for nadir viewing). As shown here, k represents a globally derived dimensionless coefficient that is wavelength dependent and ranges from 0.0 to 1.0. It is calculated using least-squares regression on the variables x and y, where $x = \log(\cos i \cos e)$ and $y = \log(L \cos e)$. The slope of the regression equation represents k. The correction procedure defaults to the Lambertian assumption when $k = 1.0$.

Although this procedure reduces the topographic effect in imagery (Figure 5), the use of one globally derived k value may not accurately characterize the variability of anisotropic reflectance caused by topography and land cover in complex environments (Bishop and Colby, 2002). Several investigators have found the use of one fixed k value to be inadequate and that a unique k value may be needed for each land-cover class in order to produce statistically significant k values (Estes, 1983; Ekstrand, 1996; Bishop and Colby, 2002).

Topographic Normalization of Multispectral Satellite Imagery, Figure 4 False-color composite of normalized spectral radiance using the C-correction model. This model attempts to account for additional topographic variation globally, and produces better results than with the cosine-correction model. The topographic effects have been reduced, however, local topographic variation is clearly present. This demonstrates that statistical characterization via regression analysis cannot adequately account for topographic effects in complicated terrain. The values of *c* for ASTER VNIR spectral bands are 1.761870, 1.546854, and 1.502178, respectively.

Radiative transfer modeling

Radiation transfer processes can be mathematically characterized to account for photon flux, atmospheric and irradiance components, as well as the BRDF of surface area and volumetric mixtures of surface materials. A number of studies have recognized the importance of accounting for atmosphere-topographic coupling and the diffuse-skylight and adjacent-terrain irradiance components (Dozier, 1980; Kimes and Kirchner, 1981; Proy et al., 1989; Conese et al., 1993a; Duguay, 1993). For such modeling efforts researchers have either developed radiation transfer models (e.g., Dozier, 1980; Proy et al., 1989), or have utilized existing models such as MOTRAN (Berk et al., 1989), 6 S (Vermote et al., 1997) ATCOR (Richter, 1997, 1998), and/or GIS-based solar radiation models (Dubayah and Rich, 1995).

The difficulty in developing and applying a comprehensive physically based RT model for ARC has been noted, as a treatment of all the RT components has not been considered feasible (Hugli and Frei, 1983; Woodham and Gray, 1987; Yang and Vidal, 1990; Duguay and LeDrew, 1992). Therefore, numerous simplifying assumptions are frequently applied, including the small-angle approximation (constant solar geometry), isotropic diffuse-skylight, Lambertian reflectance, and exclusion

Topographic Normalization of Multispectral Satellite Imagery, Figure 5 False-color composite of normalized spectral radiance using the Minnaert-correction model and a global Minnaert coefficient. This model accounts for the exitance angle and anisotropic reflectance. Normalization results appear to be better than the C-correction model in some places, although the C-correction model produces better results in other places. It is clear that the topographic effect has not been effectively removed, as variation in topographic and land-cover conditions cannot be characterized by one Minnaert coefficient, and the topographic effect is evident in the imagery. Explicit modeling of multi-scale topographic effects and radiation transfer modeling are required. The values of *k* for ASTER VNIR spectral band are 0.214693, 0.233699, and 0.241097, respectively.

of E_t. In addition, atmospheric variables are not usually available at the time of image acquisition, and these include temperature, pressure, aerosol, water vapor, ozone, and carbon dioxide vertical profiles. Furthermore, complex surface area and volumetric mixtures of snow, ice, and mineral debris govern the anisotropic nature of the BRDF that governs E_t, and L in the direction of the sensor. Although statistical models of various RT components exist, they do not account for photon fluxes (first principles) given specific atmospheric and surface compositional mixtures.

A physically based operational ARC model requires a BRDF model based upon radiation transport theory. To our knowledge, a fully coupled ARC model that includes atmospheric, topographic, and surface RT BRDF modeling of complex mixtures in alpine environments, has yet to be developed and tested. Additional research is needed in order to better understand the relationship between the surface BRDF and topographic boundary conditions.

Issues and concerns

The complexity of the ARC problem has resulted in the dominance of empirical and semi-empirical approaches to topographic normalization. A multitude of assumptions have been utilized to address many difficult issues related to parameterization schemes and computation (Hugli and Frei, 1983). In general, the issues focus on addressing the anisotropic nature of the RT cascade, and include primary and secondary influences of topography with respect to atmospheric effects, irradiance, and surface reflectance. Furthermore, it is imperative to recognize that the numerous approaches to topographic normalization have not been systematically evaluated in terms of radiometric accuracy.

This raises concerns related to quality of data, standardization of computational methods, and approaches for evaluating normalized imagery.

Data quality

Accurate quantitative characterization of the atmosphere, topography, and surface-cover characteristics are required to determining the utility of a particular topographic normalization technique. For example, accurate geomorphometric parameters (i.e., slope angle and slope-azimuth angle) are required for each pixel, although numerous issues associated with DEM generation need to be taken into consideration. These parameters include DEM resolution, DEM source data, spatial interpolation algorithms, and geomorphometry algorithms (Justice et al., 1981; Teillet et al., 1982; Conese et al., 1993a; Pons and Sole-Sugrafies, 1994; Colby and Keating, 1998; Wu et al., 2008). Similarly, the degree of generalization associated with data collection, as governed by sensor spatial (point-spread function), spectral (spectral-response function), and radiometric characteristics may determine the influence of topography on at-sensor spectral response, and the degree to which a particular technique may reduce topographic effects. Furthermore, geometric preprocessing of satellite imagery may also influence spectral variance.

Standardization

Unfortunately, there are inconsistencies in the computation/estimation of semi-empirical model parameters. For example, a number of techniques have been used to derive the Minnaert coefficient *k*. In addition, different parameterization schemes are utilized. Consequently, investigators must choose from a wide variety of techniques that

have been published, without any assurances as to which approach is best suited for a particular area and topographic complexity.

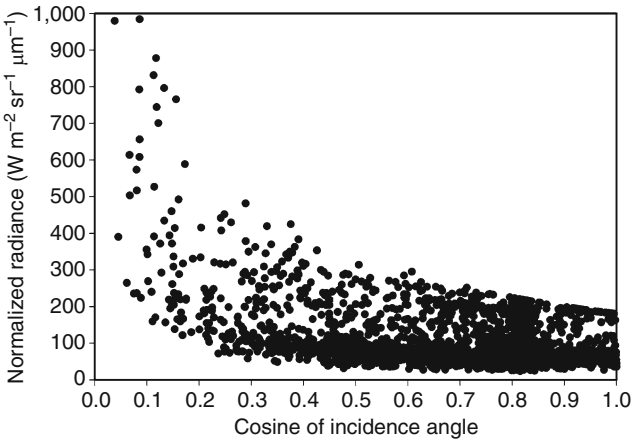
Given significant variations in landscape complexity, study area characteristics are not systematically reported to enable effective evaluation of methodological approaches. An approach may work in a particular geographic area, but may have little value in another region due to unique terrain and land-cover conditions. Investigators typically assume that their study area represents complex topography, although when compared to a standard, it is clear that there is a wide range of topographic conditions that determine whether an approach will work, as documented by others and our examples of normalized imagery. Consequently, some degree of standardization seems warranted given variations in parameterization schemes and landscape complexity. It is plausible that selected approaches/methods may be appropriate under limited conditions, although this aspect of topographic normalization has not been thoroughly investigated.

Finally, standard diagnostics to determine the ability of a method/approach to actually reduce spectral variability due to multi-scale topographic effects is sorely needed. Current diagnostic methods do not effectively address the spatial variability in spectral reflectance caused by variations in spatial, spectral, and radiometric resolution. Furthermore, data characteristics/quality and landscape complexity determine the degree to which topographic effects will manifest as spectral variation given sensor characteristics.

Image diagnostics

Normalized imagery should exhibit a global reduction in spectral variation caused by multi-scale topographic effects, and local increases in spectral variability within shadowed areas caused by land-cover variation. Unfortunately, the definition of what constitutes acceptable normalization varies by application and/or study area. The most common approach is to examine the visual appearance of imagery to determine if global spectral variation has been reduced. Very few investigators have evaluated local increases in spectral variance. Bishop and Colby (2002) have noted that topographic normalization procedures can alter the spatially dependent variance structure of satellite imagery, such that normalization may result in variance compression (loss of information) that may be visually interpreted as a reduction of topographic effects. It is extremely difficult to objectively assess the scale-dependent spectral variance in imagery via human interpretation. Furthermore, variance compression is the extreme opposite of overcorrection, as discussed in the cosine-correction section.

Another common approach has been to examine the relationship between normalized radiance and cos *i* (Figure 6). This approach enables the identification of statistical trends (linear or nonlinear) that may reveal overcorrection associated with lower cos *i* values. It is assumed that the lack of a statistical trend ($r^2 = 0.0$) is representative of good normalization and removal of topographic effects. This statistical characterization, however, does not necessarily account for topographic variation related to other multi-scale topographic effects that potentially influence atmospheric transmission, cast shadows, hemispherical shielding, and adjacent terrain and viewing geometry, as cos *i* only accounts for local topography. It is plausible that existing topographic effects are masked by compositional and land-cover spectral variation that can vary significantly in mountain environments. To address this would require an examination of spectral variation with altitude and the shielding coefficient, for example, although the nature of the specific relationships might also be masked by surface spectral variability.



Topographic Normalization of Multispectral Satellite Imagery, Figure 6 Relationship between normalized radiance (cosine correction of ASTER near-infrared band (0.78–0.86 μm) and the cosine of the incidence angle). The cosine-correction procedure generates a nonlinear increase in normalized radiance with decreasing values of cos *i*. This is commonly referred to as overcorrection that is indicative of a topographic bias.

Statistical approaches have also been traditionally used to assess the global reduction in spectral variance. Examples include basic descriptive statistics, analysis of variance, correlation analysis, and more recently, semivariograms. These are used to demonstrate a change in spectral variance, although, with the exception of variogram analysis, these methods do not account for the spatially dependent variance structure. More importantly, however, they do not account for radiometric accuracy.

Finally, many investigators have evaluated topographic normalization techniques based upon the use of pattern recognition and classification accuracies. The assumption is that improved classification accuracies are indicative of effective normalization. This thematic mapping perspective is far removed from the notion of effective normalization of imagery to reduce topographic effects. Fundamentally, the removal of topographic effects represents a radiometric calibration issue, where the focus is

on the magnitude of surface reflectance given the BRDF. Normalization methods alter the magnitude and the spatial variability of spectral reflectance, although it is not known if the magnitude and the spatial variability are consistent with surface-matter property variation.

Thematic mapping using normalized imagery does not adequately address the issue of topographic effects and BRDF variations. Such an approach makes use of spectral variability and statistical separability in *n*-dimensional space, irrespective of changes in surface composition/properties.

Brute-force supervised and unsupervised classification algorithms produce thematic maps, but the classification results are also dependent upon decision rules. Consequently, classification accuracies generated from normalized imagery do not permit direct evaluation of surface reflectance and its spatial variability in terms of radiometric accuracy.

Accuracy assessment

Ultimately, it is important to better understand the anisotropic nature of the surface BRDF in mountain environments. Surface BRDF measurements are required to account for variations related to wavelength, surface composition and structure, solar geometry, and topography. Although difficult to obtain, such measurements need to be compared to radiometrically calibrated imagery (normalized imagery) to ascertain the primary and secondary topographic effects on sensor spectral response. It is also necessary to determine how well various normalization approaches generate radiometrically accurate surface reflectance values.

Without field and scale-dependent assessment of normalized imagery, it is difficult to determine the inherent advantages and disadvantages associated with various methodological approaches. Such field-based and spatial validations have yet to be established. The development and evaluation of RT BRDF models that can address the heterogeneous mixtures of surface materials typically found in mountain environments can greatly assist in better evaluating topographic normalization approaches and the production of validated surface reflectance information products.

Summary and conclusions

Understanding the complex nature of anisotropic reflection and the RT cascade in mountain environments is difficult. Multi-scale topographic effects govern numerous primary and secondary RT components. Consequently, satellite imagery contains scale-dependent spectral variation that is commonly referred to as topographic effects. The removal of spectral variation caused by topography is required to assess surface biophysical conditions and permit accurate thematic mapping. Investigators have utilized a variety of topographic normalization procedures and RT models to accomplish this, with varying degrees of success. To date, an operational model to address the difficulties of ARC has yet to emerge, given the full range of the Earth's topographic complexity.

A simplistic spatial perspective dominates most approaches, with an emphasis on direct irradiance. The nature of the problem dictates the understanding of a multitude of RT parameters in order for operational ARC of satellite imagery to be routinely conducted. This will require an explicit evaluation of time, location, matter–energy interactions, and sensor characteristics. For example, what is the influence of changing orbital parameters on irradiance and solar geometry over specific time periods, and when do these parameters need to be accurately modeled? Given the spatiotemporal variability of solar geometry, when should we not use the small-angle approximation? How does topographic complexity in relation to geographic location influence the utility of topographic normalization methods? What is the error associated with using the Lambertian assumption or statistical models of the BRDF on irradiance and reflection? To what degree does the topography influence the anisotropic nature of the BRDF? Furthermore, to what degree do sensor system characteristics determine the utility of topographic normalization methods? Many of these and other questions have not been definitively answered.

This makes it extremely difficult to determine the implications of using various topographic normalization techniques for a multitude of practical mapping applications in the Earth's cryosphere. The image ratioing method is most frequently used and is very useful for basic glacier ice and snow mapping. Very little research, however, has specifically focused on the many issues that have been previously addressed, in terms of the accuracy and validity of results needed for various alpine research and environmental concerns (e.g., water resources, mountain hazards, climate change). Clearly, more research is warranted.

TRANSFORMATIONS OF SNOW AT THE EARTH'S SURFACE AND ITS CLIMATIC AND ENVIRONMENTAL CONSEQUENCES

Laboratoire de Glaciologie et Géophysique de l'Environnement, CNRS, Saint Martin d'Hères, France

Definition

Snow crystals: Snow crystals are ice crystals formed in the atmosphere by the condensation of water vapor or the freezing of water droplets (i.e., riming).
Snow: Snow can refer either to snow crystals in the atmosphere or to snow on the ground. Here snow means snow on the ground, and the discussion is limited to seasonal snow.
Transformations of snow: Because snow has a high surface-to-volume ratio, it is thermodynamically unstable and undergoes transformations at the Earth's surface. These transformations include densification, sublimation, and changes in physical properties of snow such as specific surface area, albedo and thermal conductivity. Physical changes in snow are regrouped under the term snow metamorphism. Transformations of snow also involve changes in the chemical composition of snow, ice, and glaciers.

Introduction

When the first snow falls on the ground in autumn, it immediately creates an enormous change in the energy balance of the surface: the albedo in the visible spectral range changes from about 0.25 to about 0.95. This produces a forcing at the surface that can exceed 100 W m^{-2}, resulting in a change in the temperature of the air near the surface of several degrees at least. Another effect of this new snow is that it thermally insulates the ground from the cold autumn air, limiting its cooling (Zhang, 2005). If the first snow fall is late in season, the ground will cool more than usual, favoring the preservation of permafrost. These two examples illustrate how snow can affect climate and the environment. Other examples can be found in Armstrong and Brun (2008).

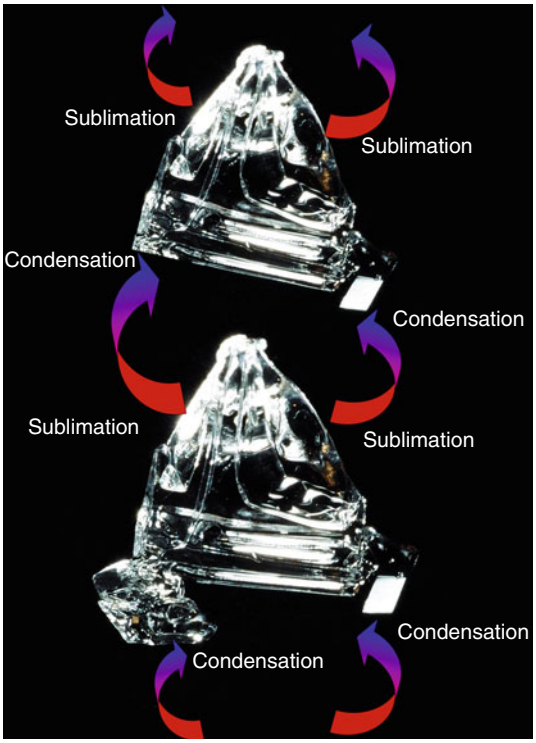
After deposition to the surface, snow undergoes physical changes called metamorphism, which generates numerous types of snow crystals whose classification has been updated by Fierz et al. (2009). In the absence of liquid water, that is, if the snow remains below 0°C, snow metamorphism is caused by the transfer of water vapor between grains (Colbeck, 1982), and results in changes in snow grains sizes, shapes, and bond strength. The physical properties of snow such as albedo and thermal conductivity are affected by metamorphism, and since metamorphism is determined by climatic variables such as temperature, wind speed, and the amount of precipitation, there are some feedback loops between the transformations of snow and climate. This entry examines some of the changes undergone by snow physical properties during metamorphism and discusses a few of the relevant implications for climate and the environment.

Transformations of snow at the Earth's surface

After snow falls on the ground, a temperature gradient ∇T establishes itself between the cold atmosphere (e.g., −10°C) and the ground (e.g., 0°C), producing a gradient in the partial pressure of water vapor, ∇P_{H_2O}. This gradient, in turn, causes water vapor fluxes from the base to the top of the snowpack. At the macroscopic scale, what takes place is the transfer of water vapor from the top of a crystal to the base of the overlying crystal, typically 1 mm further up (Figure 1). If the temperature gradient is greater than 20°C m^{-1}, layers of large hollow depth hoar crystals form, which have very little mechanical strength (Colbeck, 1982). If on the contrary the temperature gradient is less than a few degrees per meter, then water vapor transfer is determined mostly by the Kelvin effect, according to Equation 1

$$P_{H_2O}(r) = P_0 e^{2\gamma V_m / rRT} \quad (1)$$

where $P_{H_2O}(r)$ is the water vapor partial pressure over an ice surface of curvature r, P_0 is the water vapor partial pressure over a flat surface, γ is the ice surface tension (104 mJ m^{-2}), V_m is the molar volume of ice (1.96×10^{-5} m^3 mol^{-1}), R is the gas constant, and T is the temperature in Kelvin. Shapes with a small positive radius of curvature sublimate, and the water vapor produced condenses preferentially in concave spots such as contact points between grains. In this case, cohesive snow layers of small rounded grains form (Colbeck, 1980). These two distinct dry metamorphic regimes have been discussed at length since Sommerfeld and LaChapelle (1970), who called them TG (for temperature gradient) and ET (for equi-temperature) metamorphisms. Water vapor fluxes are much more important under the TG than under the ET regime. For example, if ∇T is such that a change in temperature from −10°C to −15°C over a vertical distance of 25 cm is observed, the resulting water vapor pressure gradient will be ∇P_{H_2O} = 400 Pa m^{-1}. In comparison, under isothermal conditions, ∇P_{H_2O} can be calculated using Equation 1 for the case of a faceted crystal 400 μm in size, and whose edges have



Transformations of Snow at the Earth's Surface and its Climatic and Environmental Consequences, Figure 1 Water vapor transfer between depth hoar crystals during TG metamorphism.

a radius of curvature r = 10 μm. A value ∇P_{H_2O}= 15 Pa m^{-1} is found at −15°C, much lower than under the above TG conditions.

Melting of the snow can also take place. In this case, liquid water accumulates in concaves spots, which increases the mechanical strength of the snow upon refreezing. Grains also grow with each melt-freeze cycle (Colbeck, 1982), so that melt-freeze layers are the hardest layers in a snowpack.

Wind is also involved in metamorphism. Some snow grains become airborne in windy conditions, and they partially sublimate, thus becoming smaller and more rounded. Eventually, grains accumulate in wind-sheltered spots, such as the lee of sastrugi (i.e., snow dunes caused by winds, whose height is often 5–30 cm), and sinter, forming hard layers of small rounded grains called windpacks. The hardness and density of windpacks depend on the speed of the wind event that formed them. Densities of about 500 kg m^{-3} are observed in the Arctic for wind speeds around 30 m s^{-1}.

It has been observed that the growth of depth hoar was considerably hindered in high density snow (Marbouty, 1980). Even though high density depth hoar can form in the Arctic under extreme temperature gradients, such depth hoar has few large grains and many small grains can still be observed. Recent models of snow grain size evolution (Flanner and Zender, 2006) have confirmed that grain growth was slower in high density snow, with the growth rate being close to 0 for a density of 480 kg m^{-3}. It is therefore not sufficient to consider air temperature and ∇T in the snowpack to predict the evolution of snow grain size and morphology. Wind speed, because it largely determines snow density, is also an essential variable.

Climate and changes in snow physical properties

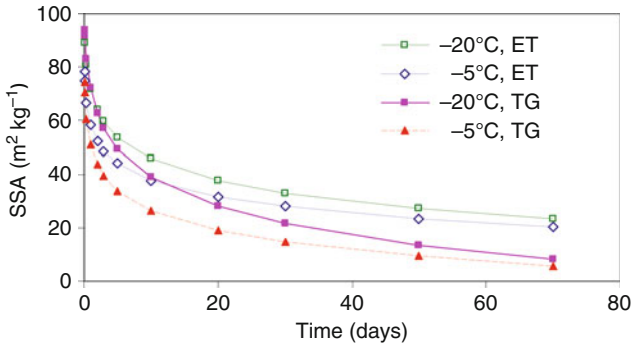
Snow metamorphism is determined by variables such as the temperature of the air, wind speed, and insolation, i.e., climate. Here we review examples of how climatic conditions can affect climate-relevant variables such as specific surface area, albedo, and thermal conductivity. In the following section, we detail examples that integrate some of these physical changes.

Specific surface area and albedo

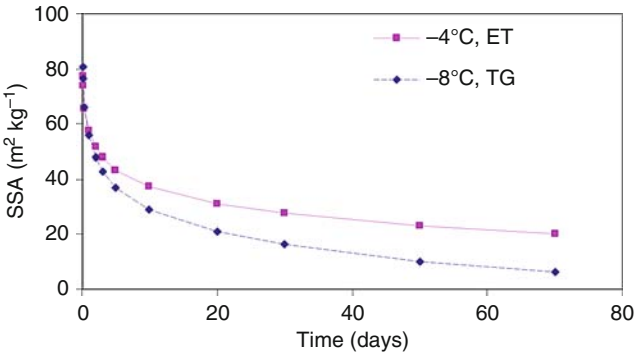
The specific surface area (SSA) of snow is the surface area per unit mass. It can easily be related to intuitive grain size: if snow grains are assumed to be spheres, then SSA = $6/\rho_{ice}\, d$, where d is the sphere diameter and ρ_{ice} is the density of pure ice (917 kg m^{-3} at 0°C), as detailed in Physical Properties of Snow. Measured values of snow SSA range from 1.9 m^2 kg^{-1} for a melt-freeze crust to 155.8 m^2 kg^{-1} for fresh dendritic snow (Domine et al., 2007a), which translates into d = 3.4 mm and d = 42 μm, respectively.

SSA in part determines snow albedo. In the visible range, albedo is little affected by grain size (see Figure 3 of Physical Properties of Snow), because ice absorbs visible light very weakly, and scattering of light onto the many surfaces provided by the snow crystals will eventually lead to light escaping the snow, with little influence of grain size (see also *Optical Remote Sensing of Alpine Glaciers*). The main variable affecting albedo in the visible is the concentration of light-absorbing impurities such as mineral dust and soot (Warren, 1982). In the near infrared, on the contrary, ice is a moderate to strong absorber of light, so that an infrared photon propagating through solid ice would be absorbed after a few millimeters. In snow, the chance that an infrared photon will be reflected before it is absorbed will be increased by the number of scattering events at the surface of snow crystals, so that snow with smaller grains, that is, with high SSA, will increase the probability that light is reflected before it is absorbed. Snow SSA therefore affects snow albedo in the infrared, while absorbing impurities are responsible for most of the albedo variations in the visible range.

The SSA of fresh snow is often in the range of 50–156 m^2 kg^{-1}. In most cases, the natural evolution of snow is to reduce its surface energy, and SSA therefore almost always decreases with time (Taillandier et al., 2007), even though increases have been observed (Domine et al., 2009). Equations of the form SSA = B − A ln(t + Δt), where t is time and A, B, and Δt are temperature-dependent coefficients, have been proposed by



Transformations of Snow at the Earth's Surface and its Climatic and Environmental Consequences, Figure 2 Effect of temperature and of the metamorphic regime on the rate of decrease of snow SSA. Initial SSA values are 100 $m^2\ kg^{-1}$, and the rates of decrease are according to the equations of Taillandier et al. (2007).



Transformations of Snow at the Earth's Surface and its Climatic and Environmental Consequences, Figure 3 Effect of a simultaneous increase in temperature and total amount of precipitation, producing a change in metamorphic regime from TG to ET, on the rate of decrease of snow SSA. After 10 h time, the SSA of the snow under the warmer conditions is greater than that in colder conditions, indicating a negative climate-snow albedo feedback. Initial SSA values are 100 $m^2\ kg^{-1}$, and the rates of decrease are according to the equations of Taillandier et al. (2007).

Taillandier et al. (2007) to describe the rate of SSA decrease of seasonal snow, as a function of the snow temperature averaged over the time period considered and of the metamorphic regime, TG or ET. Figure 2 shows the decrease of snow SSA according to those equations, for four sets of conditions. As expected, higher temperatures lead to a faster rate of decrease, because P_{H_2O} is greater and therefore metamorphism is faster. The decrease is also faster under TG that under ET conditions, because the greater ∇P_{H_2O} values accelerate metamorphism.

Figure 2 illustrates a positive snow–climate feedback. Warmer temperatures lead to faster snow aging and SSA decrease, that is, a faster albedo decrease and therefore a faster surface warming. The magnitude of this snow aging forcing can be quite large. Radiative transfer calculations using methods detailed in Stamnes et al. (1988) show that decreasing snow SSA from 32.8 to 16.4 $m^2\ kg^{-1}$ would decrease surface reflectance by ~3%, producing a 22 $W\ m^{-2}$ forcing at the tropopause at local noon, 65°N, at the summer solstice. The yearly average forcing under clear sky conditions is about 5 $W\ m^{-2}$, a value comparable to that caused by CO_2 doubling.

Feedbacks between snow SSA and climate can also be negative. A warmer climate will decrease the ∇T in the snowpack and may increase the amount of precipitation, further contributing to a decrease in ∇T. A change in metamorphic regime, from TG to ET, may therefore accompany the temperature increase, and Figure 3 shows that this can lead to a slower rate of decrease in snow SSA. In this case, warming will lead to an albedo increase, and a negative feedback loop then exists. Of course, this is only one aspect of all the processes that can take place, as warming will inevitably be accompanied by a change in the frequency of snowfalls, and therefore in the frequency of presence of fresh snow of high SSA on the surface, of changes in wind storms and wind speeds, etc., so that considerations of temperatures alone do not suffice to quantify snow–climate interactions.

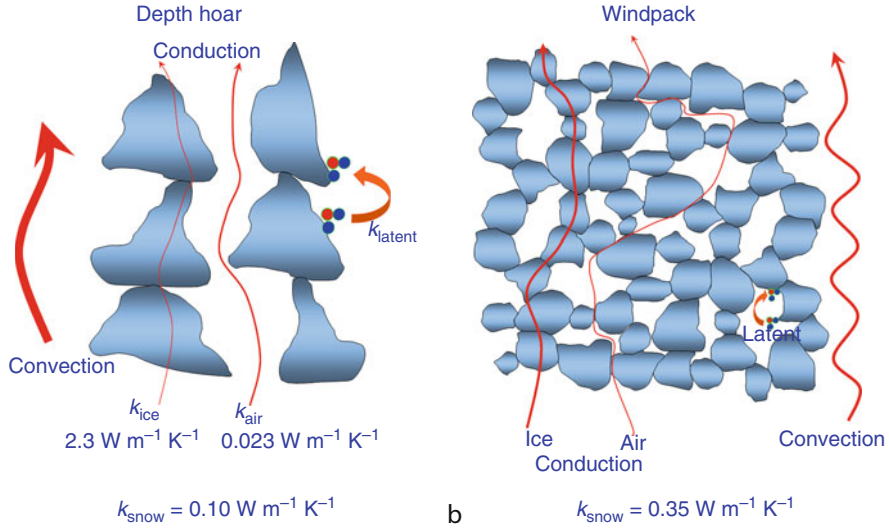
Thermal conductivity

The thermal conductivity of snow k_{snow} relates the heat flux q through the snow to ∇T in the snowpack.

$$q = -k_{snow}\nabla T \tag{2}$$

Heat conduction through ice involves several processes described in Figure 4, including conduction through the snow crystals and through interstitial air. Given that $k_{ice} >> k_{air}$, conduction through the network of interconnected snow grains is often the main heat transfer process in snow (Sturm et al., 1997). Intuitively, one therefore expects the hardest snows to have the greatest thermal conductivity values, even though today no experimental study has related thermal conductivity to mechanical properties, that is, to how snow reacts to an applied force (see *Ram Resistance*). However, Sturm et al. (1997) have shown that there was a strong positive correlation between snow density and thermal conductivity. In seasonal snow, the lowest values are encountered for freshly fallen snow and for depth hoar, with values as low as 0.025 $Wm^{-1}\ K^{-1}$, and the highest values, up to 0.65 $Wm^{-1}\ K^{-1}$, have been measured in windpacks and melt-freeze layers.

Figure 4 illustrates the fact that k_{snow} depends on snow structure. The metamorphic history of the snow, and therefore climate, then determines k_{snow}. Sturm and Johnson (1992) have monitored the evolution of k_{snow} in the taiga snowpack in central Alaska. There, thin snowpacks, cold temperatures, and low wind speeds combine to produce temperature gradients that reach 200 $K\ m^{-1}$ and average about 40 $K\ m^{-1}$. The snowpack therefore transforms almost entirely into depth hoar of low density, typically 200 $kg\ m^{-3}$. Most k_{snow} values that they measured were in the range 0.04–0.09 $W\ m^{-1}\ K^{-1}$, and they observed alternating stages where k_{snow} increased and decreased

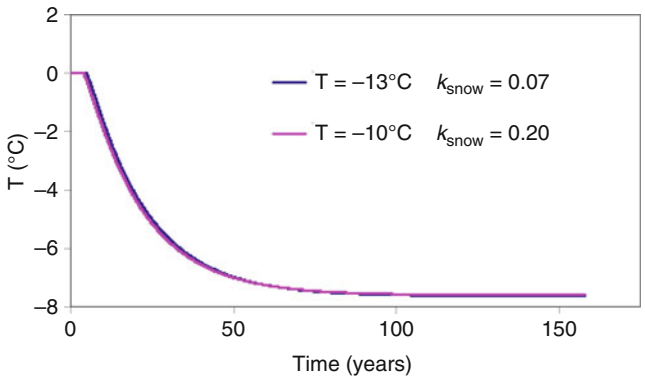


Transformations of Snow at the Earth's Surface and its Climatic and Environmental Consequences, Figure 4 Main processes involved in heat transfer though (**a**) depth hoar and (**b**) windpacked snow. Heat conduction in snow is the result of mainly four processes: (1) heat conduction through the network of interconnected ice crystals; (2) heat conduction through interstitial air; (3) latent heat transfer caused by the sublimation-condensation cycles induced by metamorphism; and (4) air flow through snow, in the form of either convection caused by high temperature gradient in the snow or advection caused by wind blowing over a rough snow surface. Air flow is often not important, latent heat transfer is significant only in depth hoar and the thermal conductivity of ice, k_{ice} = 2.3 W m^{-1} K^{-1} at −10°C is much greater than that of k_{air} = 0.023 W m^{-1} K^{-1} at −10°C. As a result, heat flow in snow mostly results from conduction through the interconnected network of snow crystals, and the thermal conductivity of windpacks is usually much greater than that of depth hoar.

over time. In contrast, Schneebeli and Sokratov (2004) performed experiments where they monitored the evolution of k_{snow} in a small snow chamber for about 10 days. They studied mostly snow samples of moderate to high densities (268–514 kg m^{-3}) that were subjected to ∇T values in the range 25–100 K m^{-1} and observed that k_{snow} increased during metamorphism, because of the growth of intergranular bonds, that facilitated heat conduction.

At present, there is clearly insufficient data to allow a full understanding and prediction of the effect of climatic variables on the value of k_{snow}. However, since depth hoar has the lowest k_{snow} values, while snow formed of small rounded grains and windpacks have moderate to high values, it appears likely that colder temperatures that generate larger temperature gradients will lead to lower k_{snow} values. All other things being equal, warming will then probably lead to increase in k_{snow} values. This will be further enhanced by the more frequent occurrence of melt-freeze layers that have high k_{snow} values.

An obvious consequence is that snow will shield the ground from the effect of cold air less efficiently. Figure 5 illustrates that an increase in temperature of 3°C, if it results in an increase in k_{snow} from 0.07 W m^{-1} K^{-1} (typical of depth hoar) to 0.20 W m^{-1} K^{-1} (typical of small rounded grains), will produce no change in permafrost temperature. As far as ground temperature is concerned, snow in this case therefore produces a negative feedback on warming, that is, the effect of snow is to reduce the effect of warming.



Transformations of Snow at the Earth's Surface and its Climatic and Environmental Consequences, Figure 5 Combined effect of a warming of 3°C and of a change in snow thermal conductivity on permafrost temperature at a depth of 18 m, where seasonal variations are negligible. In the cold scenario, the air temperature shows annual sinusoidal variations of amplitude 40°C with a mean of −13°C. The snowpack lasts from November 1st to June 1st with a maximum height of 60 cm in March, and k_{snow} = 0.07 W m^{-1} K^{-1}. The ground has 25% water content and the mean geothermal flux is 0.06 W m^{-2}. Calculations start in January 2000, with the unfrozen ground at 0°C, and the temperature at 18 m depth takes 80 years to stabilize. The cold scenario has the same characteristics, except that the mean temperature is −10°C and k_{snow} = 0.20 W m^{-1} K^{-1}. The change in k_{snow} therefore compensates a warming of +3°C.

Increases in temperature are however almost always accompanied by other changes, such as changes in wind speed and amount of precipitation, which also cause changes in vegetation. Higher vegetation shelters snow from the effects of wind, hindering the formation of windpacks, which have small grains and a high thermal conductivity, and favoring the formation of depth hoar, which has large grains and a low thermal conductivity, so that warming, when associated with changes in wind speed, can lead to a decrease in k_{snow}. An example of these complex changes is the warming-induced transformation of arctic tundra into boreal forest, also called taiga. This example is detailed in the next section.

Examples of snow–climate interactions

The transformation of tundra to taiga

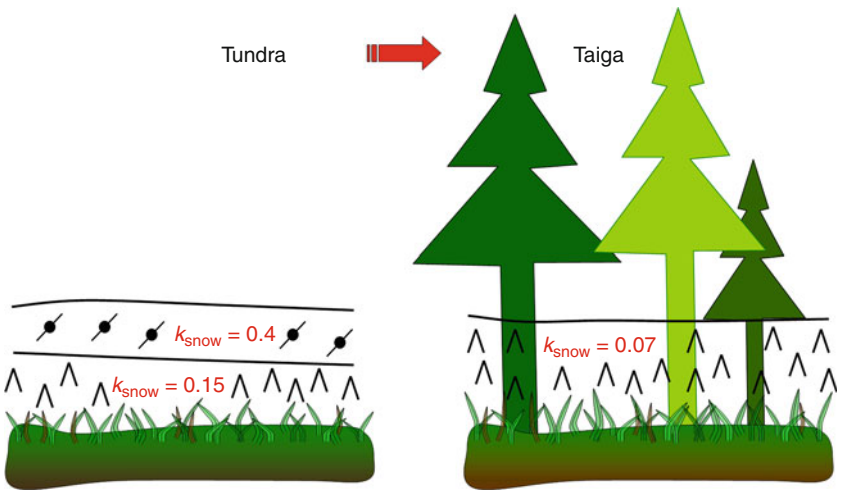
Warming can facilitate vegetation growth, and the increased presence of shrubs on the Arctic tundra, as well as the transformation of tundra into taiga, have recently been observed (Chapin et al., 2005; Tape et al., 2006). Vegetation in turn shelters snow from wind action, limits its densification, and therefore facilitates depth hoar formation. As a result, the structure of the snowpacks is greatly modified, as shown in a simplified manner in Figure 6. The tundra snowpack is in general comprised of a basal depth hoar layer surmounted by a windpack, as detailed in Physical Properties of Snow. Tundra depth hoar forms from windpacks deposited in autumn that undergo partial sublimation because of the thermal contrast between the warm ground and the rapidly cooling atmosphere. The resulting density decrease allows the growth of depth hoar, but tundra depth hoar often remains fairly hard so that its thermal conductivity is usually moderate, typically k_{snow} = 0.15 W m^{-1} K^{-1}. Subsequent windpacks formed in the winter are much less affected by sublimation because the ground has cooled and the temperature gradient is not sufficient anymore to cause significant sublimation and density decrease. They often do not transform into depth hoar and their thermal conductivity is usually high, typically k_{snow} = 0.40 W m^{-1} K^{-1}. The snowpack thickness is about 40 cm.

In contrast, the taiga snowpack is not subjected to densification by wind. Densification by compaction is in part compensated by vigorous water vapor transfer from the warm base to the colder top of the snowpack (Sturm and Benson, 1997) so that most of the snowpack remains of moderate density, typically 200 kg m^{-3}. Conditions are optimal for the growth of large loosely bonded depth hoar crystals that have a low thermal conductivity, typically k_{snow} = 0.07 W m^{-1} K^{-1}. The changes in snowpack properties can be quantified by calculating the thermal resistance R_T of both snowpacks:

$$R_T = \sum_{i}^{\text{layers}} h_i / k_{\text{snow},i} \tag{3}$$

where h_i is the thickness of layer i. For the tundra, R_T = 1.8 m^2 K W^{-1} while for the taiga, R_T = 7.1 m^2 K W^{-1}, that is, the insulating power of the snowpack is increased almost fourfold. Calculations similar to those shown in Figure 5 show that in that case a warming of 3°C, from a mean temperature of −13°C in the tundra to −10°C in the taiga will eventually result in a permafrost warming of 10°C at a depth of 18 m. It is then clear that in this case, snow will positively feedback on ground temperature.

Other effects will come into play, further strengthening this feedback. Precipitated snow crystals evolve slower on the tundra than on the taiga because of the lower temperature gradient near the surface, so that the SSA of surface snow is about 40 m^2 kg^{-1} on the tundra



Transformations of Snow at the Earth's Surface and its Climatic and Environmental Consequences, Figure 6 Simplified view of the impact of a vegetation change from tundra to taiga on the snowpack thermal properties. A depth hoar layer of moderate thermal conductivity and a windpack of high thermal conductivity are replaced by a depth hoar layer of low conductivity. The thermal resistance of the snowpack is increased from 1.8 to 7.1 m^2 K W^{-1}.

(Dominé et al., 2002) versus about 30 $m^2\ kg^{-1}$ on the taiga (Taillandier et al., 2006). Taiga snow will therefore often have a lower albedo than tundra snow, enhancing warming. Of course, the presence of vegetation will have an even greater effect on the albedo of the surface, and all these effects will combine and contribute to the observed enhanced warming of boreal regions (Chapin et al., 2005).

Modification of snow on sea ice

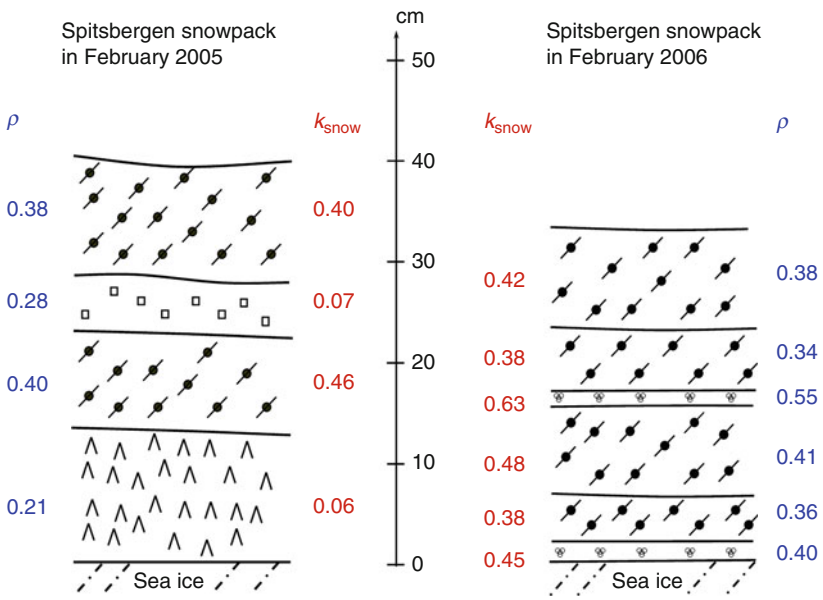
The rapid decrease in Arctic sea ice coverage (Comiso and Nishio, 2008) suggests that strong positive feedbacks operate, such as enhanced export of ice through the Fram strait due to easier icepack deformation and migration allowed by a decreased thickness (Rampal et al., 2009). However, other feedbacks involving snow are also likely to take place, as suggested by the observations of Domine et al. (2007b), who studied sea ice thickness and measured snowpack physical properties on the Eastern coast of Spitsbergen for two consecutive years. In 2005, the weather was normal while in 2006, the average winter temperature was almost 6°C warmer. Despite this unusual warmth, sea ice was thicker in 2006, and Figure 7 shows that this was mostly due to the fact that the snow layers had higher k_{snow} values.

The lower R_T value in 2006 (0.7 versus 3.3 $m^2\ K\ W^{-1}$ in 2005) of course led to enhanced ocean cooling, and the thickness of landfast ice (i.e., sea ice that is attached to land and is therefore not drifting) was a bit thicker than in 2005. Domine et al. (2007b) performed simple calculations to explain observations, and these confirmed that changes in snow thermal conductivity could indeed explain thicker ice in 2006. In this case, snow exerted a powerful negative feedback on sea ice growth, as warming alone obviously would lead to the expectation of thinner ice.

Other possible feedbacks

Other physical snow climate feedbacks exist, but have been insufficiently studied or have not received attention. For example, metamorphism affects snow permeability, that is, the ability of snow to allow the flow of air when subjected to a pressure gradient, such as that caused by wind over a rough snow surface. Air flow in the snow transports heat (Albert and Hardy, 1995; Albert and Schultz, 2002). Warmer temperatures, by reducing depth hoar formation and increasing the occurrence of melt-freeze crusts of low permeability, are likely to reduce heat transfer by air flow through snow. Warming-induced changes in snowpack permeability are then expected to reduce ground cooling in the winter and to slow down snowpack melt in the spring.

Chemical processes in snow and Ice can also feedback on climate. For example, vigorous TG metamorphism generate sublimation-condensation cycles that release species dissolved in the ice crystals lattice to the atmosphere. Such species include formaldehyde, HCHO, an oxidant precursor that can enhance aerosol formation. Experiments in Alaska have indeed shown that HCHO concentrations in the natural taiga snowpack decreased as depth hoar formation proceeded, while concentrations were stable when depth hoar formation was suppressed (Domine et al., 2007b). This was achieved by allowing



Transformations of Snow at the Earth's Surface and its Climatic and Environmental Consequences, Figure 7 Comparison of the thermal properties and densities of the snowpack on sea ice near Spitsbergen in 2005 (normal winter) and 2006 (warm winter). k_{snow} is the thermal conductivity and ρ is the snow density. In 2005, layers of depth hoar and faceted crystals with moderate k_{snow} values were present, while in 2006, they were absent while melt freeze crusts of high k_{snow} values were present. Windpacks were present during both years. In 2005, $R_T = 3.3\ m^2\ K\ W^{-1}$ while $R_T = 0.7\ m^2\ K\ W^{-1}$ in 2006.

the natural snowpack to form on tables, under which air circulation prevented the establishment of any significant temperature gradient.

Climate-induced changes in snowpack physical properties such as albedo and light penetration (Domine et al., 2008) will also affect the rate of snowpack photochemical reactions (Grannas et al., 2007), therefore modifying the chemical composition of snow, ice, and glaciers, the amount of reactive species released to the atmosphere, the oxidative capacity of the atmosphere and therefore climate through chemistry-climate interactions such as aerosol formation (Ming and Ramaswamy, 2009).

Some snow and vegetation interactions were mentioned earlier. In particular, vegetation impacts snowpack structure by limiting snow blowing and densification. In return, snow and snow–climate interactions impact vegetation by determining the length of the growing season (Jonas et al., 2008) and nutrient cycling such as nitrogen mineralization through influences on soil temperature (Chapin et al., 2005). However, all these complex interactions are only starting to be explored.

Summary

The transformations of seasonal snow at the Earth's surface lead to dramatic changes in snowpack physical properties, including climate-relevant variables such as SSA, albedo, thermal conductivity, and permeability. Physical properties in turn affect chemical processes in the snow, and therefore determine the modification of snow chemical composition. Both snow physical properties and chemical composition impact climate. Examples detailed here illustrate that changes in the thermal conductivity of snow can have locally dramatic effects on ground temperature and sea ice growth. Other studies also show that modulation of surface-atmosphere heat exchanges also affect atmospheric temperature at a global scale (Cook et al., 2008) so that it is becoming clear that snow–climate feedbacks must not be forgotten when attempting to predict future climate change, especially in polar regions. Many of these feedbacks have barely started to be explored, such as those caused by changes in permeability and also feedbacks between snow physics, snow chemistry, and climate. It is anticipated that the near future will lead to a much improved understanding of those fields.

TRANSIENT SNOWLINE

Markus Konz
ETH Zürich, Institut für Umweltingenieurwissenschaften, Hydrologie und Wasserwirtschaft, Zürich, Switzerland

The term snowline is an umbrella term for different interpretations of the boundary between a snow-covered surface and a snow-free surface with different temporal and spatial focus.

The "transient" snowline determines the boundary at any given time on the ground as well as on the surface of a glacier (Ostrem, 1974). In most regions the transient snowline depicts a seasonal dynamics. It shows a seasonal alternation of altitude with minima at positions near sea level in winter at some locations, and maxima at high altitudes in mountainous environments in summer. The final height of the transient snowline at the end of the melting season is subject to climatic variability and thus varies from year to year.

The snowline can be measured using automatic cameras, aerial photographs, or satellite images, for example, Landsat TM images. Its position is a useful constraint to calibrate hydrological models in alpine environments due to its integral character of precipitation input and melt. In this sense the transient snowline is a highly valuable variable, because it can be determined by remote sensing techniques and does not require ground measurements. This enables assessments of hydrological variables in remote areas.

The average elevation of the transient snowline is called the "climatic" snowline. This parameter is used to classify regions by means of climatic conditions.

Commonly, the boundary between the accumulation zone and the ablation zone on glaciers is expressed by the "annual" snowline (Flint, 1971). It is measured at the end of the melting season. The region below the annual snowline delimits the part of a glacier where melting occurred during the previous season, and it is often referred to as equilibrium line or firn line. Per definition, it is also the line where the glacier mass balance is zero or accumulation is equal to ablation.

The term "orographic" snowline is used for regions outside glaciers where the annual snowline continues on the ground. Both, the annual and the orographic snowlines are controlled by local topography and orientation. A more regional, larger-scale view on the orographic snowline helps to understand the distribution of alpine glaciers. In this context, the term "regional" snowline is used to describe a large area or band varying in width, which represents regional temperature and precipitation conditions (Flint, 1971). It expresses the critical summit elevation, which is necessary for a glacier to arise on a mountain, therefore it is also known as the glaciation level.

TREE-RING INDICATORS OF GLACIER FLUCTUATIONS

Dan J. Smith, Lynn Koehler
Tree-Ring Laboratory, Department of Geography, University of Victoria, Victoria, BC, Canada

Definition

Glacier response to climate change is commonly benchmarked by dating trees overrun and killed during glacial advances (Figures 1 and 2), or by dating trees found growing on moraines formed as glaciers retreat from advanced positions. These traditional dendroglaciologic applications employ dendrochronologic methods to reconstruct past glacier activity. Evolving methodologies, including the construction of proxy glacier mass balance histories from tree rings, are expanding the avenues of glaciological research by using tree-ring indicators to examine the pre-instrumental response of glaciers to changing climates.

Dendroglaciology

Dendroglaciology describes the application of tree-ring dating principles to assign ages to glacial sediments and landforms (Schweingruber, 1988; Luckman, 1998; Smith and Lewis, 2007). Lawrence (1946) pioneered early efforts and numerous researchers subsequently used the total number of annual rings within first-colonizing trees inhabiting deglaciated terrain as a minimum estimate of surface age (McCarthy and Luckman, 1993; Osborn et al., 2007; Koch, 2009). Surveys of the age of the oldest trees colonizing recently deposited moraines provide the chronological control necessary to develop detailed Little Ice Age glacial histories (Heusser, 1956; Smith et al., 1995; Luckman, 2000; Allen and Smith, 2007).

In many settings, retreating glaciers regularly expose the remains of forests buried or killed by past advances (Figures 1 and 2). Dendroglaciology allows for dating the glacier activity recorded by these woody deposits (Luckman, 1993, 1998). This approach to event dating rests foremost on the assumption that trees in the higher latitudes form annual growth rings; and, secondly that the annual tree ring-width vary in response to limiting factors (i.e., temperature and/or precipitation climate) to create distinctive time series (Fritts, 1976).

Tree-ring cross-dates of living and glacially killed trees provide an opportunity to precisely date glacial forefield histories by

- Resolving the year of death of glacially overridden trees by cross-dating, a process that involves comparing ring-width patterns, between living and glacially reworked trees (Osborn et al., 2001; Reyes et al., 2006; Jackson et al., 2008; Barclay et al., 2009a, b).
- Establishing the calendar year of glacial advance into ice-marginal forests, through the selection of trees exhibiting callous tissue, corrasion scars, or reaction wood, which demonstrate abnormal cell development in response to encroaching glacier snouts (Luckman, 1988; Wiles et al., 1996).
- Applying radiometric dating to the perimeter wood of subfossilized samples, when ring-widths fail to cross-date with a master chronology, or when the preservation of wood is poor (Glasser et al., 2002; Wood and Smith, 2004; Allen and Smith, 2007; Barclay et al., 2009a, b).

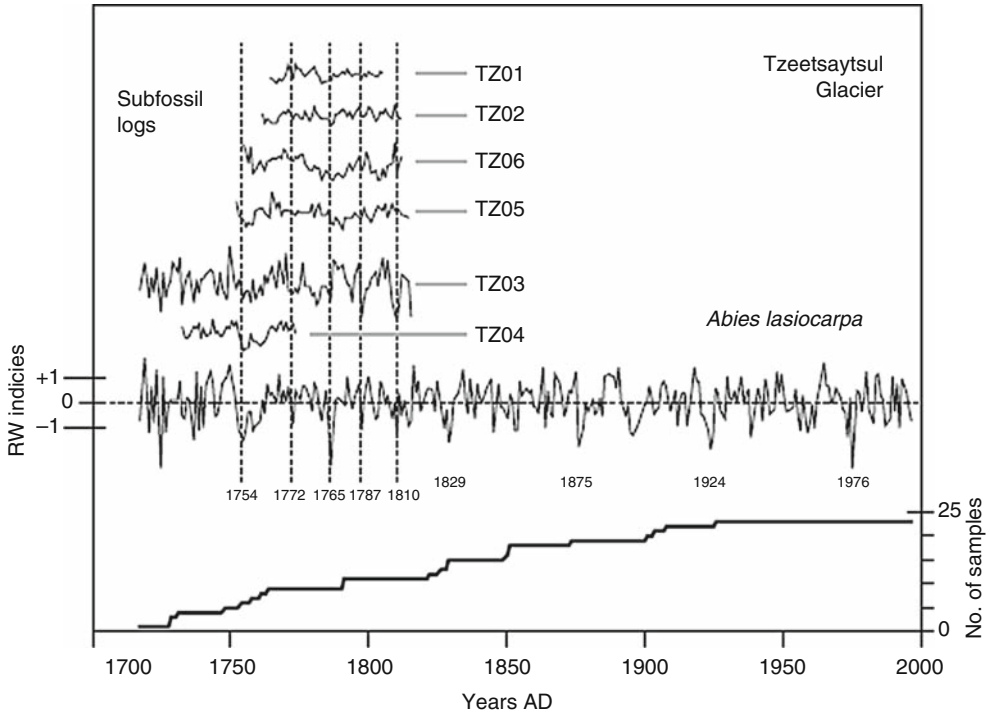
Tree-Ring Indicators of Glacier Fluctuations, Figure 1 The construction of a Little Ice Age lateral moraine in the British Columbia Coast Mountains killed and buried this 232-year-old subalpine fir tree in 1733 AD.

Tree-Ring Indicators of Glacier Fluctuations, Figure 2 Standing snag located adjacent to the distal slope of Little Ice Age lateral moraine in the British Columbia Coast Mountains. The tree died in 1738 AD, following the deposition of the moraine. Note in the background the growth of subalpine fir trees on the stabilized moraine surface. Counts of the number of annual rings in the oldest cohort of living trees provide a minimum date for surface stabilization following the most recent advance of glacial ice.

Tree-Ring Indicators of Glacier Fluctuations, Figure 3 Excavation of subfossil trees killed and buried in till by an advancing glacier in the British Columbia Coast Mountains. Cross-dates of the annual ring patterns within the trees to a living tree-ring chronology indicate the subfossil boles and branches were entombed in 1815.

- Relating the ring-width patterns of ice marginal trees to glacier-climate fluctuations and moraine building episodes (Bray and Struik, 1963; Matthews, 1977; Pederson et al., 2004; Pelfini et al., 2005; Nesje et al., 2008).

The global recession of glaciers over the last century has led to the exposure of an abundance of cross-datable material (Figure 3). These subfossil remains have successfully been interpreted using dendroglaciology to detail ice front fluctuations (Smith and Desloges, 2000). The annual ring-width patterns of the subfossil wood is measured and compared to the radial growth trends of living tree–ring chronologies (Figure 4). Where the growth trends match over time and cross-date, the perimeter date of the subfossil samples is interpreted to indicate when the glacier was advancing and killing the trees.



Tree-Ring Indicators of Glacier Fluctuations, Figure 4 Summary of dendroglaciological studies used to date subfossil wood shown in Figure 3. The upper portion of the figure illustrates the duration of cross-dated subfossil samples. While the youngest portion of each record indicates the pith date of the sample, the oldest portion does not necessarily represent the absolute age of the sampled wood due to surface abrasion. The middle portion of the figure illustrates the annual growth trends found in living trees growing in the forest adjacent to the glacier. Dates refer to common pointer years in the chronology and within the subfossil samples. The lower portion of the graph shows the sample depth of the living chronology (from Smith and Desloges, 2000).

Although dendroglaciology benefits from simplicity and low cost, several limitations are worth noting. The success of dendroglaciological research depends upon an abundant supply of wood and subsequent preservation within actively eroding proglacial environments (Allen and Smith, 2007; Koch, 2009). Dendroglaciologic interpretations are also restricted in their temporal range. For example, the success of cross-dating depends upon the longevity of local trees, which often fail to exceed 300–400 years in many subalpine locations (Schweingruber, 1988). Nonetheless, millennial length chronologies are being compiled from subfossil wood that has been preserved in glacial and glaciofluvial sediments that allow for absolute dating of glacier fluctuations over extended time periods (Scuderi, 1987; Barclay et al., 1999, 2009a).

Limitations to dendroglaciological dating arise because: (a) intercepting the pith when coring a tree is rare, especially for large diameter trees (Villalba and Veblen, 1997); (b) extracting cores from the root ball is challenging (McCarthy et al., 1991; Winchester and Harrison, 2000); (c) tree-ring series sometimes contain missing and/or false ring boundaries, resulting in incorrect age determinations; and, most importantly (d) opportunities for determining locally relevant ecesis intervals, the time it takes for seedlings to establish, are often limited by the lack of reliable control surfaces and/or inconsistent colonization rates due to microclimatic effects (Sigafoos and Hendricks, 1969; Villalba et al., 1990; McCarthy and Luckman, 1993; Koch, 2009).

Dendroclimatic mass balance reconstruction

Dendroclimatic investigations focused on climate-sensitive tree species found in glaciated settings offer the opportunity to acquire insights into glacial mass balance changes at decade-to-century timescales. A growing number of studies have demonstrated that a strong relationship exists between the annual ring-width variations of some tree species and glacier ice front fluctuations (Bräuning, 2006; Yang et al., 2008; Borgaonkar et al., 2009). The underlying relationship to climate variability has allowed for the hindcasting of mass balance fluctuations.

Changes in glacier volume reflect the sensitivity of glaciers to changes in climate. Conventional mass balance surveys provide a way to evaluate the long-term impact of climate variability on changes in glacier volume, area, and length (Calmanti et al., 2007). Most mass balance records are sparse and of short duration. Following recognition that the annual radial growth variations of trees are

often significantly correlated to local glacier activity (LaMarche and Fritts, 1971; Yang et al., 2008; Borgaonkar et al., 2009), attention has been directed to developing extended proxy glacier activity records from tree rings.

When examined in detail, mass balance measurements reveal that the winter and summer seasons are marked by peak accumulation and peak ablation phases (Bitz and Battisti, 1999). The same seasonal climates that govern these glaciological relationships influence the growth of tree rings. Climate conditions that promote above-average radial growth (wide rings) are the same conditions that favor glacier ablation (negative mass balance) and retreat (Bray and Struik, 1963; Bräuning, 2006). Conversely, the conditions that result in a shortened growing season and below-average radial growth trees (narrow rings) lead to accumulation, positive mass balance conditions, and glacier advance (Watson and Luckman, 2004; Larocque and Smith, 2005; Calmanti et al., 2007). Recognition of the inverse climatic relationship between tree-ring growth and glacier mass balances indicates it is possible to estimate past mass balance variations from tree-ring data (Leonelli et al., 2008).

A number of different methodological approaches and tree species have been used to explore the potential for reconstructing local and regional mass balance records (Lewis and Smith, 2004; Watson and Luckman, 2004; Larocque and Smith, 2005; Calmanti et al., 2007; Linderholm et al., 2007; Leonelli et al., 2008). Despite their inherent uncertainties, most tree-ring-derived mass balance models appear to provide a good approximation of summer (B_s) and net (B_n) mass balance conditions. Less certain is their ability to fully represent glacier winter balance (B_w) (Linderholm et al., 2007).

As noted by Leonelli et al. (2008), limitations to reconstructing glacier mass balance histories from tree ring chronologies arise because their annual variations are affected by distinct biological and physical processes and because diverse climatic factors may influence them during different periods of the year. It is also likely that the mass balance response of contemporary glaciers to climate is distinct from that of larger Little Ice Age glaciers (i.e., Nesje et al., 2008). If this is the case, mass balance models based upon assumed present-day causal relationships to climate by glaciers and tree growth may bias the reconstructions.

Summary

Dendroglaciological research methodologies provide the evidence necessary to precisely date the glacier activity. Annual ring counts of trees colonizing recently deglaciated terrain provides a spatial record of the glacial retreat patterns, as well as the means to establish chronologies of recent lateral and terminal moraine stabilization.

Dendroglaciologic evidence exposed by retreating glaciers provides an opportunity to develop Holocene glacial records. Since Holocene ice fronts periodically extended below tree line in many regions, advancing and retreating glaciers repeatedly overrode and buried forests beneath till deposits. Cross-dating and radiometric dating of these subfossil deposits provides an opportunity to delineate ice front positions over several millennia.

Tree-growth patterns have been used to reconstruct glacier behavior and mass balance with encouraging results. The extension of current glacier mass balance measurements to several centuries enables a more precise assessment of the impact of past climates on glacial systems.

TRIBUTARY GLACIERS

Hester Jiskoot
Department of Geography, University of Lethbridge, Lethbridge, AB, Canada

Synonyms

Confluent glaciers; Merging glaciers; Side glaciers; Tributary ice streams

Definition

A tributary glacier merges into a larger glacier, called trunk glacier, and often contributes mass to this trunk glacier from its separate accumulation basin. When two merging glaciers are of equal size, they are referred to as confluent glaciers rather than tributaries.

In case several tributary glaciers flow into a trunk glacier and some of these tributaries are themselves trunks to higher level tributaries, a glacier system becomes dendritic. At each junction of a tributary and a trunk glacier, the flow regime of one or both glaciers will be affected to some extent by the tributary-trunk interaction. Some of this interaction can have a long-term effect on

ice flow dynamics as well as mass balance, which can be particularly important in ice stream behavior. Where tributary and trunk glaciers join, they are often separated by a medial moraine. This medial moraine debris usually forms a straight line extending toward the trunk glacier terminus, but can also manifest a bulging moraine loop or an elongated teardrop-shaped or sheared-off moraine loop in the case of a glacier surge.

Glacier retreat can cause tributary glaciers to separate from their trunks, resulting in fragmentation of the glacier system into smaller glacier units. This process can lead to the formation of ice-dammed lakes in the gap between the two detached glaciers. If glacier fragmentation occurs where tributary glacier valley floors are at higher elevations than the deeper eroded trunk glacier valleys, hanging valleys will remain.

URBAN SNOW

Lars Bengtsson, Annette Semádeni-Davies
Department of Water Resources Engineering,
Lund University, Lund, Sweden

Definition

Urban snow is simply the snow in urban environments. Snow conditions in settlements and cities are different from those in the country side. Snow is removed by man. Activities within the city influence both the snow characteristics and its distribution, which are usually heterogeneous. The melt occurs at different rates at different places within the city, and at higher rates than in the country side.

Introduction

Settlements may become isolated after extreme snowfalls. River floods caused by melt or by ice jams can inundate towns. Still, it is non-extreme events which usually impact on urban hydrology throughout the winter and into the summer. The presence of snow is inevitable in northern cities. The snow conditions in an urban environment are different from those in the country side. For example, snow falling in the city is often wet, while it is dry in the rural environment. When the snow falls in a built environment, its distribution is influenced by the wind conditions between the buildings. The fallen snow is often removed from many surfaces and piled up at other surfaces or transported out of the city. The snow that remains in the city is affected by how people move over the snow and by dust or other impurities falling onto the snow. The snow is compacted and includes impurities giving it a high density and low albedo. The snow cover is highly heterogeneous.

Melt occurs earlier in the city than outside the city and proceeds at a higher rate than outside the city. It is usually warmer in the city but the enhanced melt is more due to changed radiation conditions. Compacted snow and snow surface with impurities have lower albedo than clean dry fresh snow, and therefore absorbs more solar radiation. Buildings emit longwave radiation. The melt occurs at different rate at different parts of the city depending on exposure to the sun and different snow characteristics. When the snow melts, runoff occurs from surfaces being permeable in summer time. The frozen ground is inundated, preventing water from flowing the shortest possible route to the conduit system, which may lead to flooding. Retention facilities are flooded and may not function as intended when there is a storm. The melt water that infiltrates leaks into the sewage system as the water table rises.

Melt intensities are low (10–20 mm/day) as compared to rain storms (20–40 mm/day for 1 year return period), but the melt continues for several days so the total runoff generated is generally larger. Also the peak flow may be comparable since the contributing area may be larger than for storms when frozen grassed and graveled surfaces contribute to urban runoff, Bengtsson and Westerström (1992). During rain events, when snow is still present in the city, there is runoff from permanently impervious surfaces as well as from snow-covered surfaces on hardly packed frozen ground. Thorolfsson and Brandt (1996) have show an example from Trondheim, Norway, when a rain event with a 15-year return period resulted in a one-in-30-year runoff event.

The water quality of urban snow is poor due to deicing chemicals, regular atmospheric fallout, airborne residue from heating fuels, friction material, oil, exhaust from motor vehicles, animal excrement, and debris from road surfaces and tires. Winter-long accumulation and storage within the snowpack means that melt runoff has a higher pollutant load than rain events. Much of the annual runoff

Vijay P. Singh, Pratap Singh & Umesh K. Haritashya (eds.), *Encyclopedia of Snow, Ice and Glaciers*, DOI 10.1007/978-90-481-2642-2,

load of some pollutants is transported via meltwater (Viklander, 1997). Soluble pollutants are eluted early in the melt period, while particles can be filtered by the soil and remain on the surface after melt or can be mechanically transported by the meltwater runoff. Water quality depends largely on location, population density, and traffic (e.g., Hautala et al., 1985).

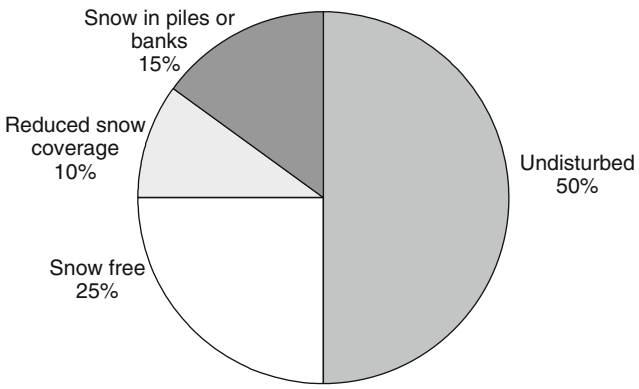
The concept of snow water equivalents (SWE) must be used with care for urban environments, since snow in towns is unevenly distributed with varying properties. Snow is almost completely removed from impervious surface to clear roads for traffic, to avoid the buildup of pollutants in the snowpack, and to decrease the risk of spring flooding. Snow accumulates in sheltered areas, whereas the snowpack is thin or nonexistent in exposed areas, especially on south-facing slopes and on roofs. Plowed snow can be stored in close proximity to the area cleared or it can be removed to sites outside the urban area. Private front gardens can have increased snow depths as snow is shoveled from drives and footpaths. Scales in snow hydrology have been discussed by Woo (1998), Blöschl (1999), and Bengtsson and Singh (2000).

Suburban piles of plowed snow tend to be on permeable surfaces such as parks, private gardens, vacant lots, and roadside verges, as shown in Figure 1, whereas they are found on asphalt in the inner city. Snow density and coverage in urban environments are related to land use intensity (e.g., Bengtsson and Westerström, 1992; Buttle and Xu, 1988). Undisturbed snow in Luleå, Sweden, has similar properties to nearby rural snow (density 200–300 kg m^{-3}). Plowed snow in piles and banks has a wide range of density, 250–700 kg m^{-3}, depending on location (Semadeni-Davies 1999).

Urban melt

The energy required for melt is determined from the energy balance for a snowpack:

$$Q_M = Q^* + Q_H + Q_E + Q_P + Q_G - \frac{dE}{dt}$$

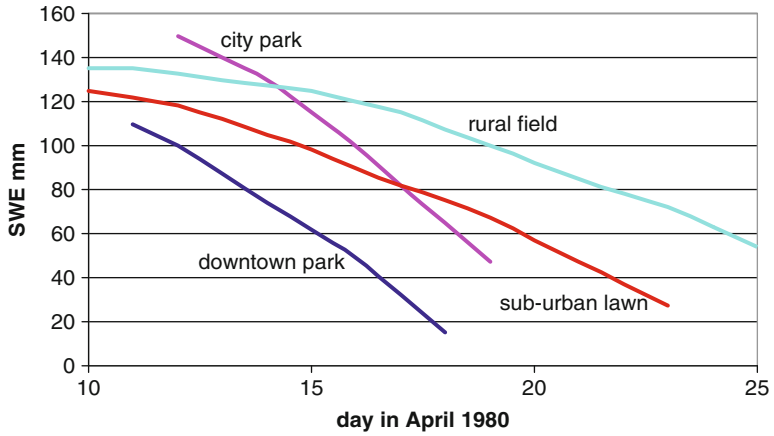


Urban Snow, Figure 1 Areal breakdown of snow cover in a residential suburb, Luleå (1979–1980) (Unpublished from first author).

where Q_M is heat flux density available for melt, Q^* is net radiation flux density, Q_H is turbulent sensible heat flux density, Q_E is turbulent latent heat flux density, Q_P is the advected heat flux from rain, Q_G is the conductive heat flux density to or from the ground, and dE/dt is the change per unit area in the internal energy held in the snow. The heat associated with rain is small as is the heat exchange with the ground. The change of the internal energy can be quite large since it is associated with refreezing of liquid water in the snowpack. The turbulent sensible and latent fluxes (in the order of 10 Wm^{-2}) can be in either direction. The sensible heat flux is related to the wind speed and the temperature difference between the atmosphere and the snow surface. The latent heat flux, sublimation, or condensation depends on the wind speed, the stability of the air, and the vapor pressure difference between the air and the snow surface. The energy balance is dominated by the radiative fluxes. In general, during daytime when melt occurs, sensible heat is an energy gain, while latent heat is an energy loss (Bengtsson, 1980; Male and Granger, 1981). The latent heat of vaporization is 7.5 times greater than the latent heat of fusion, so, even when Q_E is large, the volume of water loss to melt is low. Where there are bare patches or nearby building, which may be heated by the sun, the advection can contribute to increased sensible heat flux (see below).

The snow characteristics and the environment are different in the city than outside the city. Buildings alter the radiation balance. Moisture, aerodynamic, and thermal properties are different. Snow characteristics, distribution, and melt conditions in urban environments are related to land use and snow-handling practices. Snow accumulation and melt conditions form a mosaic over the city. The imperviousness in urban areas is augmented during spring as soils become frozen, saturated, and partly or fully impermeable. The energy balance changes over short distances with snowpack location and land use. Where there is little advection, melt is mostly driven by solar radiation, so the rate of melt depends largely on snow albedo and snow location with respect to the sun. Hence, the energy balance also varies temporally. Like the terrain effects of alpine topography, the surfaces of the "canyon" configuration of buildings interspersed with roads – with its reduced sky view, increased surface area, and multiple reflections – can serve to enhance the energy balance by trapping radiation in some places while others are shaded (Xu and Buttle, 1987; Verseghy and Munro, 1989a, b; Semadeni-Davies and Bengtsson, 1998). The urban surroundings as a whole reflect less shortwave radiation than rural areas partly due to the lower albedo of materials such as wood, brick, and asphalt, and partly due to the building geometry. The melt proceeds at different rate depending much on the degree of urbanization, as is shown with example from Luleå, Sweden, in Figure 2 (Bengtsson and Westerström, 1992).

Urbanization, by altering the land surface, affects radiative, aerodynamic, moisture, and thermal characteristics of the atmosphere. A well-known example is the heat



Urban Snow, Figure 2 Reduction of snow water equivalent at four different sites in Luleå, Sweden.

island effect which is related to building materials and artificial heat sources such as fuel combustion. Changes to the radiation balance in urban areas have been addressed by Xu and Buttle (1987), Todhunter et al. (1992), and Semadeni-Davies and Bengtsson (1998) for snowy conditions. They all show that the surfaces of the "canyon" configuration of buildings interspersed with roads can serve to enhance the energy balance by trapping both long- and shortwave radiation, while at the same time reducing shortwave radiation through shading. The maximum effect occurs during sunny days when shortwave radiation is mostly direct beam.

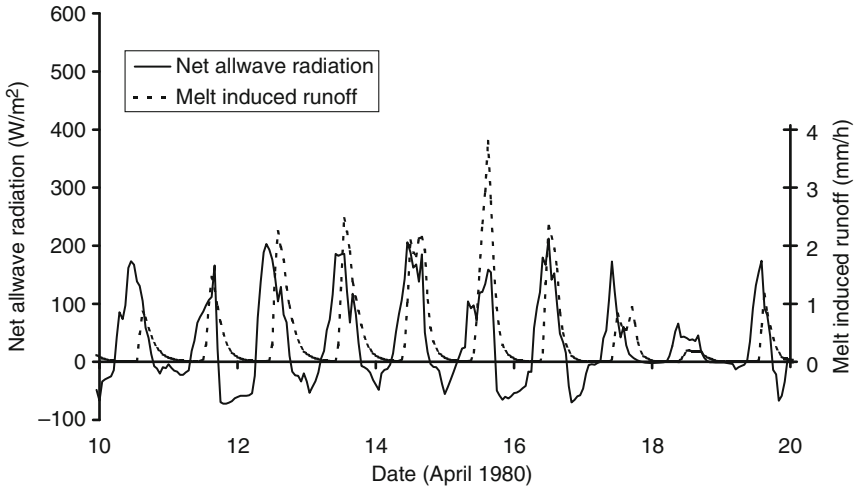
The albedo of urban snow itself is less than rural areas. A reduction from 70% to 40% means that the absorption of solar radiation is doubled. Compaction and the incorporation of gravel, exhaust fumes, debris, litter, and so forth lowers the albedo. In rural areas, albedo ranges from 0.8 for fresh dry snow to 0.6 at the onset of melt and 0.4 for old wet snow (US Army Corps of Engineers, 1956). Undisturbed urban snow has albedo values in this range, but albedo can be as low as 0.1–0.2 near roads (Bengtsson and Westerström, 1992; Semadeni-Davies, 1999).

The atmospheric longwave radiation is higher in a city than in the country side due to increased cloud cover, warmer air temperatures, and aerosols (Rouse et al., 1973). Shortwave radiation is absorbed by buildings and reemitted as longwave radiation. Urban snowpacks receive more longwave radiation than rural snowpacks. Bengtsson and Westerström (1992) measured the average enhancement integrated over 10 m from south-facing buildings to be about 100 W/m^2. In Canada, Xu and Buttle (1987) measured the net radiation in the vicinity of two houses; 8 m away from the buildings the net all-wave radiation could be between 67% and 435% greater than that in open areas. Hence, the location of snow with respect to buildings plays a part in energy availability. Semadeni-Davies et al. (2001) described the radiation balance for Luleå in detail.

Latent and sensible heat fluxes over urban snowpacks are difficult to estimate. Kirnbauer et al. (1994) point out that in complex terrain, notions of stability and roughness length become meaningless so common boundary layer theory cannot be used. Jetting and mixing along city streets (canyons) could cause localized increases in the turbulent fluxes. Advection from warm snow-free surfaces increases energy availability to the snowpack. Research in Arctic tundra with heterogeneous snow coverage showed that advection downwind from snow-free patches can be significant (Liston, 1995; Neumann and Marsh, 1998).

Piles or banks of plowed snow are features of the urban winter landscape located near roads or access ways. The snow is compacted and icy with low albedo. Gravel along with litter, oil, road debris, and exhaust particles is incorporated and airborne pollutants are deposited on the surface. The bulk energy balance of a melting snow pile is discussed and modeled by Sundin et al. (1999). The pile shape greatly influences melt due to high surface exposure per unit area. Gravel particles can cause localized points of melt by absorbing shortwave radiation. While gravel may initially enhance melt, it is possible that as thaw progresses, an insulating crust forms on the snow surface which slows the melt rate. Despite an increase in melt rate, the volume of snow held within piles means that they remain long after other snow is melted.

Snowmelt follows a diurnal pattern relating to energy availability, as seen in Figure 3 from measurements in Luleå by Bengtsson (1983). Since shortwave radiation dominates the energy balance, most melt occurs from shortly after sunrise until sunset with a clear peak at the hours around noon. In a homogeneous snowpack, it takes several hours for the meltwater to move from the surface to the bottom of the pack. However, especially in urban snow preferential flowpaths soon develops, and the required time to move through a ½ m snow cover is not more than an hour or so (Bengtsson, 1982a; Marsh



Urban Snow, Figure 3 Runoff measured from an impervious surface showing the diurnal melt phase and how melt runoff lags behind positive net radiation (Luleå, April 1980).

and Woo, 1984). Thus, there is not much delay between surface melt and runoff.

Meltwater reaching permeable surfaces can either infiltrate or flow overland depending on soil structure, moisture, and thermal status. The effective hydraulic permeability in spring is a function of the unfrozen and frozen water content, the fraction being related to the temperature of the soil (Gray and Prowse, 1993). Kane and Stein (1983) pointed out the influence of the moisture content prior to ablation on the storage capacity of the frozen soil and thus on the infiltration capacity and production of overland flow. The role of macro-pore flow is essential. Overland flow of meltwater is rare in forests, where the soil cover is thick and permeable with macro-pores. Espeby (1990) notes the effect of macro-pores on meltwater movement through frozen glacial deposits, stating that infiltration can be rapid. There is a rapid hydraulic coupling of groundwater recharge in upland areas and downhill groundwater discharge and consequent stream response (Thorne et al., 1998).

At the other end of the spectrum, meltwater from snow overlying a compacted urban soil can flow overland (Westerström, 1984; Bengtsson and Westerström, 1992). In comparison to rainfall-induced runoff generation, there is a progressive increase in the area contributing to overland flow during spring. Daytime meltwater infiltration can be followed by cold nights so that the soil infiltration capacity can be lowered by both saturation and freezing. Melt water either freezes in the soil or saturates the soil above an impervious frozen layer. Freezing caused normally permeable gravel and grass surfaces in Luleå to become virtually impervious while infiltration in a nearby forest was relatively unaffected (Engelmark, 1984). Observations from three 200 m^2 snow-covered plots with different surfaces – asphalt, gravel, and grass – showed that at the end of the melt period, overland flow from all three plots was similar. Observations in Norway (Thorolfsson and Brandt, 1996) and Canada (Buttle and Xu, 1988) also show that overland flow is great following melt, despite the fact that asphalted surfaces are snow-free.

Meltwater flows overland via the minor natural drainage system pathways in the city. These are natural irregularities on the ground and often lead onto asphalt surfaces and, in turn, toward inlets into the major drainage conduit system. However, in spring, flow in the storm- and wastewater pipes is often more than can be attributed to overland flow; water also enters indirectly as sewer infiltration (inwards leakage) through pipe cracks and joints. While water reaching pipes directly accounts for quick-flow peaks, sewer infiltration can be equated to the slow or base-flow component of hydrograph. This water may take days or weeks to enter the wastewater system (e.g., Annette Semádeni-Davies, 1998; Hernebring et al., 1997). It influences the water balance of a town for months as shown by Semádeni-Davies and Bengtsson (1999).

Ponds, wetlands, and streams fringed with riparian vegetation offer a natural technique for handling stormwater. However, these systems may function differently during spring than during summer. Marsalek (1991) gives example of detention ponds during thaw. Ponds can remain ice-covered forcing meltwater to flow either over or beneath the ice. In either case, both the storage capacity and ability of suspended solids to settle are lowered.

Snow models

Snowmelt models are used to estimate stormwater runoff. There are three different types of models: temperature index models relating melt solely to air temperature, energy balance models treating the snowpack as a single layer, and energy balance models considering different snow layers and having routines for the water transport through the snowpack. The commonly used temperature index models for rural areas are crude in temporal as

well as spatial resolution. They perform best for large (100 km^2) homogeneous river basins, where time resolution of 1 day or more is sufficient. While energy balance computations at point scale are successful, the transfer of the energy balance models from the point scale to basin scale has not been very successful (Kirnbauer et al., 1994). The simple temperature index method is better able to model average conditions (e.g., Kuchment and Gelfan, 1996). It is, however, not possible to use a temperature index method, also known as degree-day method, to compute melt over short periods, since solar radiation contributes very much to the melting and the solar radiation vary much over the day, as shown in Figure 3.

Temperature indices or the degree-day approach relate melt to the average daily ambient air temperature, simply as $M = C\ (T_a - T_s)$, where the daily melt, M, is in mm day^{-1}, C is the melt-rate factor (mm/°C/day) (degree-day coefficient), T_a is the daily ambient air temperature (°C), and T_s is the threshold melt temperature (°C) most often set to 0°C. The melt-rate factor, C, varies with location and snow characteristics. For open areas it ranges from 2 to 10 mm/°C/day, and for forests it is about 2 mm/°C/day. Routines to simulate retention and refreeze are usually coupled to the method. In the absence of shortwave radiation, the degree-day method is physically sound, Bengtsson (1976), as much of the energy supplied to the snowpack is atmospheric longwave radiation, which is dependent on air temperature as are sensible and latent heat transfers. The method is standard for operational rural models. It is robust and has been applied to a variety of spatial scales and environmental conditions.

It is difficult to relate the degree-day melt-rate factor to different urban locations or time periods, since the factor embodies the total energy availability rather than air temperature. A comparison of melt-rate factors from different environments is given in Table 1. The melt factor can vary over short distances. Increased energy availability results in degree-day melt coefficients that are greater than in rural areas. Westerström (1981) measured two factors in Luleå, corresponding to early (1.7 mm/°C/day) and late thaw (6.5 mm/°C/day). The melt rate generally increases with land use intensity. Bengtsson and Westerström (1992) measured the average melt rate during thaw at two locations within Luleå: undisturbed suburban snow had an average degree-day factor of 6 mm/°C/day, whereas snow in a downtown park had a factor of 8.4 mm/°C/day. Sundin et al. (1999) found that the melt-rate factor of plowed snow piled at snow deposits can be 11 mm/°C/day.

A time step of 1 hour is adequate to estimate stormwater runoff, since melt variations within an hour are small and the runoff is delayed because of the transport through the snowpack. A daily melt routine time step is reasonable when considering infiltration into sewers from soil and groundwater as the lags involved can be in the order of days to weeks (Semadeni-Davies, 1998). In this case, the runoff process does not need to be considered in detail and distribution can be restricted to determining the fractional area of different snow coverage, properties, and exposure.

Urban Snow, Table 1 Degree-day melt-rate factors for different environments (Compiled from Gray and Prowse, 1993; Martinec and Rango, 1986; Bergström, 1995; Kuusisto, 1984; Kuchment and Gelfan, 1996; Bengtsson and Westerström, 1992; and Sundin et al., 1999)

Location	Melt rate, C_m, (mm/°C/day)
Rural (Europe, North America)	
Open fields	2–3.5
Forests	1.5–2.0
Alpine	3.5–6
Prairie	1.5–7
Exposed slopes	5–6
Urban (northern Sweden)	
Suburban	1.5–7
Inner city	1.5–8
Plowed snow in piles	5–11

To be able to compute urban melt at high time resolution without using the full energy balance Sand (1990) tried a modified temperature index model which calculates melt on an hourly basis assuming that melt occurs at positive air temperatures ($T_m = 0$°C). The modified routine was based on Bengtsson's (1984) work and includes a simple term for net shortwave radiation and a fairly advanced refreeze approach (Bengtsson, 1982b):

$$M_h = C_t(T_a) + C_r(1 - \alpha)K \qquad T_a > 0$$

where M_h is the meltwater generated (mm/h), C_t is the temperature melt-rate factor (mm/°C/h), C_r is the radiation melt-rate factor (mm m^2/W/day), α is snow albedo, K is incoming shortwave radiation (W/m^2), and T_a is the air temperature.

$$M_{cc} = R(-T_a t)^{0.5} \qquad T_a \leq 0$$

where M_{cc} is the effective loss of water to melt due to refreeze (mm), that is, the change in internal energy; R is a refreeze coefficient ($mm/°C^{0.5}/h^{0.5}$); and t is the number of hours during which the air temperature is at or below freezing. The amended degree-day method was tested in Trondheim, Norway. Thorolfsson and Sand (1991) found that the routine was able to accurately simulate diurnal changes in meltwater release from. Thorolfsson and Killingtveit (1991) incorporated the melt routine into the HBV model structure (Bergström, 1995). HBV was then applied to several Norwegian urban or partly urbanized catchments. It is, however, not straightforward to find proper values of the factors C_t and C_r, as pointed out by Bengtsson (1984).

When energy balance models are applied, the minimum data requirements for computations are air temperature, incoming shortwave radiation, vapor pressure, and wind speed near the ground (Anderson, 1976; Leavesley, 1989). Even so, many uncertain parameters must be included to compute all fluxes. Energy balance snowmelt

models are largely restricted to research applications. Models of the snowpack energy balance are coupled to simple routines to simulate refreezing within the snowpack. Morris (1983) detailed equations for energy, momentum, and mass flows, which were built into the distributed SHE model. Metamorphosis and water flow were simulated in each layer of the snowpack. It is essential to consider refreezing in all models, also the temperature index approach, since the melt following a cold day or night is much delayed.

Summary

Snow distribution in urban environments is extremely nonuniform. Heterogeneity is mainly artificial due to snow handling, but wind patterns and the variable timing of melt (related to the albedo and solar exposure) also play a role. Within the space of a few meters, there may be snow-free ground, almost untouched snow and banks of plowed snow. Most of the snow falling on permanently impermeable surfaces, such as streets and footpaths, is removed. Activities in the city, in particular traffic, result in fallout of pollutants onto the snow. The atmospheric heat exchange, and therefore the snowmelt rate, is affected by buildings. Large areas of the city are shaded from the sun for at least part of the day. In other areas, the incoming radiation is enhanced by multiple reflections. Snowmelt takes place at different rates and is affected by different elements within an urban area.

Urban meltwater pathways are mostly overland. The infiltration capacity of soils which are permeable in summer can be very much reduced during snowmelt periods. If there is no refreeze, the time for meltwater to flow from the snow surface to the inlets of a conduit is 1 or so hours, refreezing greatly extends this time period. To resolve the melt on hourly basis, some form of energy balance computation is required. If the meltwater input at the bottom of the snowpack is known on an hourly basis, it can be equated to the hourly runoff in the conduit system without any runoff computations. However, the melt rates at different parts of the urban basin must be accounted for by dividing it into elements, each with differing snow and energy characteristics. Thus, snow models must be spatially distributed rather than lumped. Meltwater enters into the urban conduit system either directly from overland flow or indirectly as sewer infiltration. Sewer conduits function as a groundwater drainage system. Recharge-driven sewer infiltration is a slow process. Hence, the contribution of groundwater inflow can be estimated from a degree-day approach or can even be related to the amount of snow available.

U-SHAPE VALLEY

Amit Kumar
Department of Geology, Centre of Advanced Study in Geology, Punjab University, Chandigarh, India

Synonyms

Fjord; Glacial trough

Definition

Glacier erosion greatly modifies the shape of that portion of the river valley, which was occupied by glacier commonly known as U-shaped valley. A glacial valley generally differs from a river valley. Glacial valley is deepened and side slopes are steepened so that its cross section is changed from V-shaped to U-shaped. The U-shaped valley is one of the most well-known geomorphologic features of glaciation. (Figure 1 shows a developed U-shaped valley in Himalaya by Gangotri glacier.)

Synonyms: A glacially eroded valley; also called a glacial trough. It may extend to coastal location and in some cases may have been drowned by the post-glaciation rise in sea level; this submerged glaciated valley becomes a fiord.

U-Shape Valley, Figure 1 U-shape glacial valley developed by Gangotri glacier in Himalayas.

Origin: A glacier flows down in a former V-shaped river valley. As the glacier moves, it erodes the side wall and bottom of the valley. The valley becomes U-shaped with steep sides and a flat base.

VEIN ICE

Chelamallu Hariprasad
Centre for Studies in Resource Engineering, IITB, Mumbai, India

Vein ice is defined as the ice occupying the cracks of soil or rock, below the earth's surface, at which the temperature has been continuously below 0°C for several years at the least. This exists where summer heating fails to reach the base of the layer of frozen ground. Formation of vein ice is the result of thermal contraction cracking.

V-SHAPED VALLEY

Amit Kumar
Department of Geology, Centre of Advanced Study in Geology, Punjab University, Chandigarh, India

Definition

V-shaped valleys are found in the upper part of a river, which is elongate depression of the Earth's surface. Valleys are commonly drained by rivers and slope denudation is typically characterized by the V-shape. Valley evolution is controlled mainly by climate and lithology. The angle of the V-shaped cross section depends on the rate of uplift of rock, the type of rock.

WATER BALANCE IN THE GLACIERIZED REGION

Heidi Escher-Vetter
Commission for Glaciology, Bavarian Academy of Sciences and Humanities, Munich, Germany

Synonyms

Hydrological-balance budget; Hydrological cycle; Water cycle

Definition

Water balance. Relationship between precipitation, evaporation, runoff, and storage for a given catchment.
Glacierized region. Catchment where part of the surface is covered with glaciers.

Introduction

At the Symposium on Glacier Hydrology in Cambridge, 1969, many questions on the topics of water and glaciers were discussed, partly for the first time. Here, Golubev (1973) analyzed the runoff and flow routing for a mountain glacier basin, which was one of the early contributions to this research topic. Some 10 years later, Baumgartner et al. (1983) included the water yield from glaciers in their textbook on the water cycle of the Alps, where they analyzed the reasons and consequences of glacier reduction for the water balance in the climatologic period 1931–1960. Shortly before, Collins (1982) gave an overview of water and mass balance measurements in glacierized drainage basins worldwide for 11 basins with water balance data from 95 glacier regions providing mass balance data.

Determination of water balance

Water balance of glacierized regions differs considerably to that of basins without glaciers. This is due to the fact that glaciers store *solid* and liquid precipitation, as well as meltwater over periods ranging from a few days to centuries and release it during spells of sunny warm weather when no runoff is produced by precipitation. This is the so-called 'compensating effect' of glacial runoff. Chen and Ohmura (1990) have shown that the ratio of summer to annual runoff is smallest and by that the 'compensating effect' largest in basins with 30–50% of ice cover; it increases for higher as well as lower ice cover shares.

In the water balance equation, the glacial influence is accounted for by an additional storage term S, which represents the change of the glacier mass. In a general form, the total balance can be written as

$$P = R + S + E \tag{1}$$

Here, P stands for precipitation, R for runoff, S for the storage term, and E for (net) evaporation. When these quantities are given in mm of water equivalent (mm w.eq.), they represent areal averages for the size of the respective basin. A complete balance is typically obtained for the natural mass balance year, that is, the period between the beginning of October and the end of September of the next calendar year.

There are several possibilities to assess water balance. For one type of investigation, the balance terms are evaluated on the basis of measurements of the individual components. For glaciers with independently determined mass balance data, the storage term S is often the most reliable one, especially when it is based on the direct glaciological method for mass balance determination. The calculation of basin precipitation P typically provides the largest difficulty, in spite of the fact that even in high-mountain regions, there are more precipitation stations than glacier discharge gauges. Discharge records R, on the other hand, succumb to from problems of insufficient calibration or from water losses due to seepage in the ice-free part of the basin. For net evaporation E, there are

Vijay P. Singh, Pratap Singh & Umesh K. Haritashya (eds.), *Encyclopedia of Snow, Ice and Glaciers*, DOI 10.1007/978-90-481-2642-2,

no continuous records available in these remote regions, and numerical values of this typically small quantity are therefore deduced from single experiments. In many studies, E is set constant over the glacier area and longer periods or taken as the residual between precipitation, glacier mass change, and runoff.

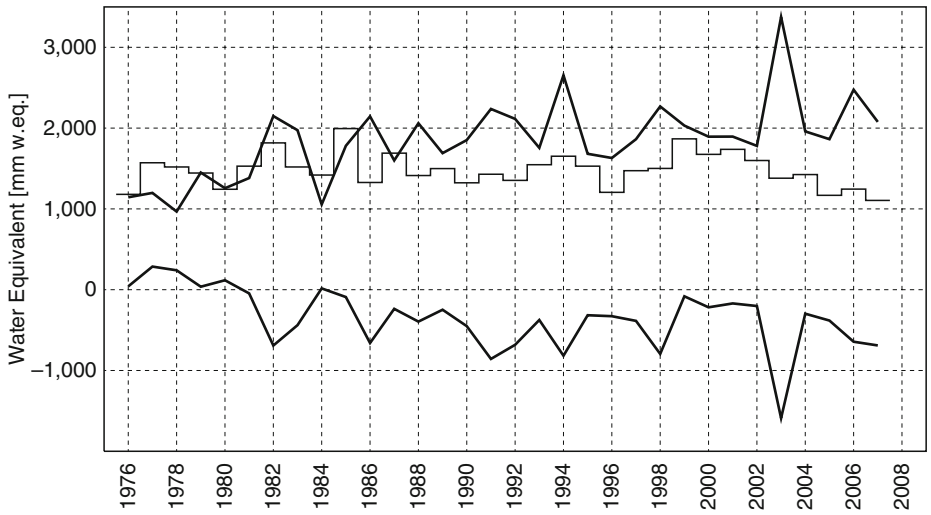
Numerous models have been developed to evaluate water balance. Morris (2006) gives a comprehensive overview of the techniques for predicting runoff from glacierized areas. The choice of the appropriate model depends on the available meteorological and geodetic input data and the temporal/spatial scale of the study. Other modeling tools are necessary for headwater sheds with sizes of some 10 km², than for study areas up to 100,000 km². Conceptual models have to be calibrated, whereas physical models are mainly independent from calibration by time series of runoff, for example. Kuhn and Batlogg (1998) use the calibrated OEZ model to determine monthly precipitation sums, based on monthly means of the water balance for 100 m altitudinal steps. A widely used model type is the so-called HBV/ETH runoff model, which is based on daily means of air temperature and daily precipitation sums. It simulates daily discharge and glacier mass balance with a temperature index method, and it is calibrated with measured discharge and glacier mass balance. A detailed description of some model extensions for the special application in glacierized basins is given by Braun et al. (2000). Another concept also uses a temperature index method in a hybrid form including potential solar radiation (Hock, 1999). Verbunt et al. (2003) have taken this approach as a sub-model of WaSiM-ETH to simulate the discharges in three Swiss high alpine basins with different levels of glacierization (Massa, Rhone, and Dischma basins). For these basins, the altitudinal distribution of snowmelt, ice-melt, precipitation, evapotranspiration and total runoff is discussed.

The highest data requirements are posed by gridded energy balance models, which calculate hourly meltwater amounts, and route the runoff through the glacier with a linear reservoir approach. An example for this approach is the so-called PEV model (Escher-Vetter, 2000), developed and applied for Vernagtferner.

Main characteristics of water balance as observed for the Vernagtferner, Oetztal Alps, Austria

In their comprehensive report on glacier storage, Jansson et al. (2003) characterize glaciers with respect to their short-term, intermediate-term, and long-term storage and the respective influence of these processes on glacier hydrology and water balance. The first timescale, that is, hours to days comprises processes like the diurnal runoff cycle. The intermediate-term storage includes seasonal snow cover and firn water storage within periods from months to years and, on the long-term storage scale, changes in glacier volume up to centuries are considered. For the Vernagtferner, the records presented in Figure 1 show the development of the components of water balance for the intermediate to long-term scale.

In Figure 1, annual values of precipitation, runoff, and glacier storage change are presented for the Vernagtferner basin, Central Alps, (2,640–3,630 m a.s.l., 11.44 km²), from 1974/1975 to 2006/2007. Since the 1970s, the glacierized share was reduced from some 81% to 71% in 2008. For this glacier basin, all balance components can be derived from measurements. Hourly values of total basin discharge observations have been available since 1974. Net mass balance has been determined for every year since 1965, and the separation of winter and summer mass balance provides winter precipitation data for the whole period of Vernagtferner (Escher-Vetter et al., 2009). Summer precipitation is recorded with weighing gauges (Escher-Vetter and Siebers, 2007), and E



Water Balance in the Glacierized Region, Figure 1 Main components of water balance for the Vernagtferner from 1974/1975 to 2006/2007: basin precipitation (step function), glacier storage change (*lower curve*), and runoff (*upper curve*).

(not included in Figure 1) derived from several experiments on the glacier during the last decades. For the period depicted, runoff amounts have nearly doubled from some 1,000 mm w.eq. up to 2,000 mm w.eq., due to the continuing mass losses, largest in 2003 with 3120 mm w.eq.; basin precipitation, however, does not show any trend. Between June and October 90% of the runoff is recorded (Escher-Vetter and Reinwarth, 1995), and the diurnal variation has increased from 2 to 3 $m^3 s^{-1}$ to more than 10 $m^3 s^{-1}$ over the last 30 years due to the reduction of snow and firn storage capacity.

Water balance studies in different climate regions – Arctic, Central Asia, and South America

The Vernagtferner represents the climate region of the European Alps, where a clear distinction is found between the accumulation period (October to April) and ablation period (May to September). This "Alpine scheme" is also found in Scandinavia, Central Asia, and the Arctic, but not in the Tropics, where accumulation and ablation can occur within the same weather period.

Killingtveit et al. (2003) summarize recent and ongoing water balance studies in Svalbard and comment extensively on the uncertainties of individual terms. For two differently glacierized catchments (Bayelva, 55% of 31 km²/De Geerdalen, 10% of 79 km²), the average water balance terms for the hydrological years 1990/1991 to 2000/2001 amount to P = 624/548 mm w.eq., S = 245/49 mm w.eq., R = −1,050/−539 mm w.eq., and E = −37/−72 mm w.eq. The same quantities for the period 1974/1975 to 2004/2005 for the Vernagtferner are for P = 1,525 mm w.eq., S = 305 mm w.eq., R = −1,790 mm w.eq., E = −120 mm w.eq. (Braun et al., 2007), showing the typically larger quantities in the Central Alps.

For the Indian part of the Satluj basin, Singh and Jain (2002) determined the average contribution of snow and ice melt to runoff from the water balance. For this 22,305 km² Himalayan catchment, the period from 1986 to 1996 was analyzed. The hydrographs at Bakhra Dam show that 83% of the total runoff is recorded between April and September. On an average, 59% of the runoff is contributed by snow and ice melt, emphasizing the importance of glaciers in this large catchment.

For the smaller Beas River basin at the Pandoh Dam (5,278 km², 15% glacierized), Kumar et al. (2007) calculated the water budget for the period 1990–2004. Here, snow- and glacier-melt runoff contributes about 35% of the annual runoff, which reaches its maximum with more than 600 $m^3 s^{-1}$ on average in July and August.

The glacier fed catchments, Yanamarey (1.3 km²) and Uruashraju (3.4 km²) of the Cordillera Blanca, Peru, show the typical features of tropical glacier basins. 35% of the average discharge of the <10% glacierized Querococha basin is provided by glacier melt in February and March (Mark and Seltzer, 2003), and specific discharge for the period 1956–1996 amounts to 870 mm a^{-1}.

For the Zongo Glacier, Peru, Francou et al. (1995) analyzed the monthly components of the water balance with respect to El Niño-Southern Oscillation events from September 1991 to August 1993. For this tropical glacier, the early and late wet season, that is, October–December and March–May, are most important for the annual mass balance in contrast to midlatitude glaciers, where the summer months mainly determine the balance.

Summary and outlook: water balance in glacierized regions under changed climate conditions

Glaciers are important storages of water. They change the water balance of drainage basins considerably, as they shift the precipitation from small-term to long-term periods. In this way, they can become important sources of water for drinking or irrigation purposes, especially in arid regions. The examples from different climate regions (Arctic, Alps, Himalayas, and Andes) show this very clearly. At the present time, these water reservoirs are reduced markedly due to climate change, and complete losses within the next 100 years in some mountainous parts of the world cannot be excluded. This will not only change water balance, but also living conditions for mankind.

WESTERLIES AND THEIR EFFECTS ON MARITIME ICE CAPS AND GLACIERS

Robert D. McCulloch
School of Biological and Environmental Science, University of Stirling, Stirling, Scotland, UK

Synonyms

Polar convergence zone low pressure storms; Westerly air circulation; Westerly storms

Definition

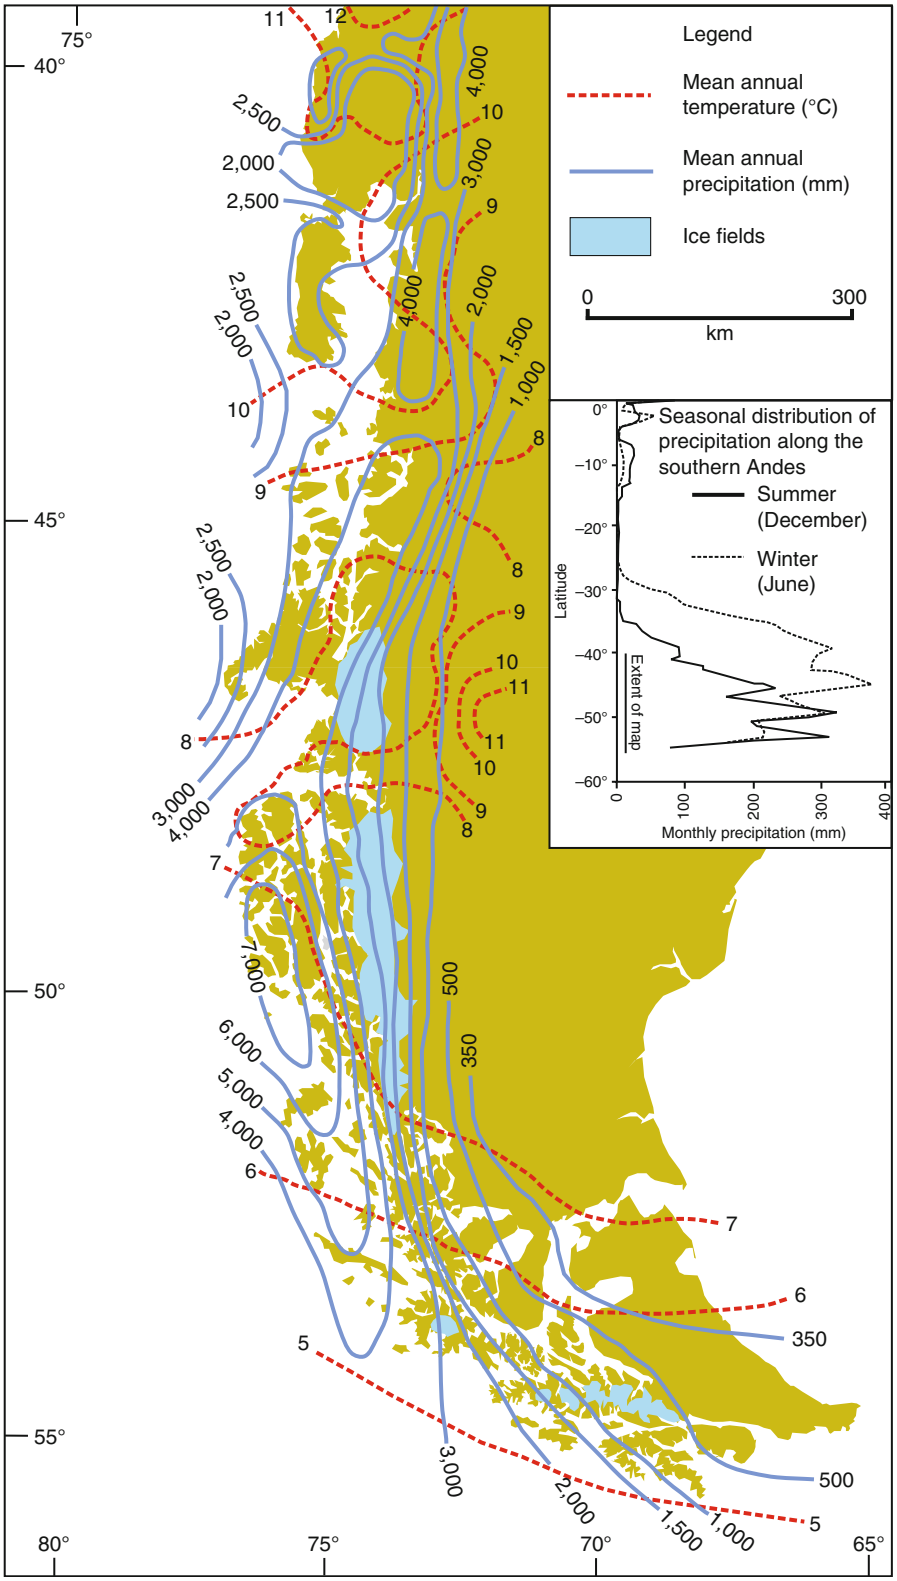
Westerlies: A meteorological phenomenon where the thermal gradient between the mid-latitudes and the polar regions leads to increased baroclinicity and increased thermal winds in a westerly direction along the polar front in both hemispheres. Warmer mid latitude air mixes with colder polar air at the polar convergence zone leading to the formation of westerly storms, known as the westerlies. The westerlies are further distorted by orography along topographic barriers such as the southern Andes, the Rockies, Norway, and the New Zealand Alps leading to increased precipitation on the western flanks of the mountains and dry conditions on the eastern lee side further characterized by westerly katabatic winds.

Introduction

Air circulating north and south of the subtropical high pressure zones in the northern and southern hemispheres, respectively, generally blows in a westerly direction in both hemispheres, giving rise to the prevailing westerly winds. The temperature gradient between the mid-latitudes and the polar regions leads to the development of the polar front and increases wind speeds and the formation of a jet stream. The ascending air and low pressures at the latitudes of the jet streams are caused by the baroclinic instability of the jet streams, which produce surface convergence and uplift creating low pressure storm cells that may be modified by orography (Barry, 2008). Understanding the behavior of the westerlies and their effect on glaciers is key to understanding the reorganization of hemispheric ocean-atmosphere circulation patterns at the end of the last glaciation because their latitude and strength are influenced by such factors as the strength of the subtropical high pressure and the location of sea ice in the Southern Ocean (Yuan and Martinson, 2000).

During the Northern hemisphere winter (November–January), Arctic sea ice advances and in the Southern Hemisphere the Antarctic sea ice retreats with the rise in the austral summer temperatures. The situation between the poles is reversed during the boreal summer and austral winter (May–July). This seasonal expansion and contraction of sea ice and the strength of the subtropical high lead to latitudinal shifts in the position of the northern and southern polar convergence zone and the polar fronts. The jet streams are dynamically unstable and the position of the polar fronts may also change. This constant shifting northwards or southwards results in different weather patterns. In the northern hemisphere, the polar fronts shift southward to bring winter storms to much of the U.S. In the summer months, the polar front shifts northward and warmer subtropical air circulates farther north.

There is an advantage in exploring the relationship between westerly air circulation and glaciers in southern South America. The mountainous crest of the southern Andes supports ice fields and glaciers that are sensitive to climate and an extensive suite of landforms and sediments are created by processes of glacial erosion and glacial deposition. These provide a record of Quaternary glaciations from which we can infer paleo-climatic change. During the Last Glacial Maximum (LGM), an ice sheet, approximately 1,800 km long, built up along the north–south axis of the Andes (Clapperton, 1993; Figure 1).



Westerlies and their Effects on Maritime Ice Caps and Glaciers, Figure 1 Climate map of Patagonia indicating the core of the westerly precipitation centered around 50°S. The inset chart indicates the extent of the seasonal latitudinal migration of the westerly precipitation belt (from McCulloch et al., 2000).

In the southern hemisphere, the southern Andes span several climatic zones from subpolar in the south (55°S) to warm temperate in the north (36°S). South of 36°S, the southern Andean mountains lie athwart the southern westerlies and experience precipitation all year from the westerly storms. This zone of westerly storm tracks reaches the southern Chilean coast laden with moisture from the warm Pacific, and the point of maximum precipitation is found at c. 48–50°S (Barry, 2008). Through a combination of frontal and orographic precipitation, the highest rainfall is experienced on the western flanks of the southern Andean Cordillera (Figure 1). This generates a strong lee-effect on the eastern flanks of the Andes seen in the increased dryness of Argentina.

Glacier dynamics are controlled by a complex relationship between elements of the hydrological cycle; temperature, precipitation, cloud cover, wind speed, and humidity (Benn and Evans, 1998). The large amounts of precipitation falling on the high Andean mountains sustains a number of ice fields; the North Patagonian ice field, the larger South Patagonian ice field, and the numerous, though smaller, Cordillera Darwin ice fields. These ice fields are supported by the accumulation of winter precipitation (falling as snow) exceeding the summer ablation, which may affect the entire accumulation area of the ice field. This climatic regime produces temperate maritime ice fields and leads to a rapid turnover of ice through the glacier system. This leads to a greater sensitivity of the ice fields and outlet glaciers to fluctuations in climate and in particular the latitudinal position of the westerly storm tracks (Hulton and Sugden, 1995).

Glaciological modeling experiments and paleoecological evidence suggests that the core of the southern hemisphere westerlies moved north by some 5° latitude during the Last Glacial Maximum (Hulton et al., 2002). Such a migration makes sense in the light of an expansion of sea ice limits during the last glaciation (Lamy et al., 2004) and appears to be necessary to bring the levels of precipitation required to sustain the expanded and continuous Patagonian ice field to the north of the present day North Patagonian ice field. Ice sheet modeling experiments indicate that a reduction in temperature alone is unlikely to have been sufficient to drive glacier advances in the area of the Chilean and Argentine Lake Districts (approximately 42–40°S) (Hulton et al., 2002).

Glaciological modeling also suggests that as the large continuous Patagonian ice sheet formed along the southern Andes, there was a corresponding intensification of the rain shadow to the east of the Andes as the westerly precipitation was forced over a higher and colder topography. Detailed glaciological modeling by Hubbard et al. (2005) has suggested that during the waning stages of the Patagonian ice sheet after c. 14300 ^{14}C years BP, the precipitation from the westerlies was able to drive across or between the reduced and dividing ice fields giving rise to the expansion of smaller mountain glaciers on higher mountain peaks to the east of the main Andean mountain chain.

Following the Last Glacial Maximum (LGM), rapid retreat of the northern extent of the Patagonian ice field and the ensuing spread of humid-temperate vegetation suggests that the westerlies moved south some 1,500–1,800 years after the first step of deglaciation and reached their present latitude (approximately 50°S) by 14300 ^{14}C years BP (McCulloch et al., 2000). It is likely that the westerlies moved south of their present latitude in the early Holocene between 11400 and 9500 ^{14}C years BP, when the Magellan region in the far south of Patagonia, experienced a phase of aridity and increased frequencies in fires (Whitlock et al., 2007). Under such circumstances, the surrounding oceans would have also been warmer and this period coincides with an Antarctic Holocene optimum recognized in the early loss of ice shelves such as that in George VI Sound at the base of the Peninsula (Bentley et al., 2005). A mid-Holocene expansion of humid-temperate vegetation, and glacial landform evidence for Neoglacial glacier advances around the North and South Patagonian ice fields suggest that the core of the westerlies had shifted close to its present day focus at approximately 50°S (McCulloch et al., 2000).

Summary

The distribution of westerly storm tracks in the northern and southern hemisphere is controlled by the intensity of the subtropical high and the extent of polar sea ice. This in turn, when coupled with changes in global temperatures during glacial-interglacial cycles, leads to a greater sensitivity in the behavior of mid to high latitude temperate maritime glaciers due to large fluctuations in precipitation driving changes in the glacier mass balance system.

WGMS (WORLD GLACIER MONITORING SERVICE)

Wilfried Haeberli
Geography Department, University of Zurich, Zurich, Switzerland

Worldwide collection of information about ongoing glacier changes was initiated in 1894 with the foundation of the International Glacier Commission at the Sixth International Geological Congress in Zurich, Switzerland. In 1986, the World Glacier Monitoring Service (WGMS) started to maintain and continue the collection of information on ongoing glacier changes, when the two former services – PSFG (Permanent Service on Fluctuations of Glaciers) and TTS/WGI (Temporal Technical Secretary/World Glacier Inventory) were combined.

The World Glacier Monitoring Service (WGMS) collects standardized observations on changes in mass, volume, area, and length of glaciers with time (glacier fluctuations), as well as statistical information on the distribution of perennial surface ice in space (glacier inventories). Such glacier fluctuation and inventory data are high priority key variables in climate system monitoring; they form a basis for hydrological modeling with respect to possible effects of atmospheric warming, and provide fundamental information in glaciology, glacial geomorphology, and quaternary geology. The highest information density is found for the Alps and Scandinavia, where long and uninterrupted records are available. Data are published in the biennial Glacier Mass Balance Bulletin and the quinquennial Fluctuations of Glaciers. A recent overview was published by the United Nations Environment Programme (UNEP) and WGMS (Zemp et al., 2008a, b). Together with the GLIMS (Global Land Ice Measurement from Space) initiative and NSIDC (National Snow and Ice Data Center) at Boulder, Colorado, WGMS runs the GTN-G (Global Terrestrial Network for Glaciers) as part of the Global Terrestrial/Climate Observing System (GTOS/GCOS) under the Umbrella of World Meteorological Organization (WMO), Food and Agricultural Organization of the United Nations (FAO), International Council for Science (ICSU), UNEP, and United Nations Educational, Scientific, and Cultural Organization (UNESCO).

WINTER ACCUMULATION GLACIER

Amit Kumar
Department of Geology, Centre of Advanced Study in Geology, Punjab University, Chandigarh, India

Winter accumulation glacier

In the high land areas, winter precipitation in the form of snow is the major source to form the glaciers. The glaciers that receive heavy solid precipitation during winter period and also fallen precipitation accumulates over the glacier and adds to its mass, are known as winter accumulation glaciers. In general, majority of glaciers fall under this category. Only a few glaciers have accumulation in summer time. Thus, at the places where accumulation occurs primarily in the winter season and ablation during summer season are commonly known as winter-accumulation type glaciers.

Y

YEAR-ROUND ABLATION PATTERN

Rijan B. Kayastha
Himalayan Cryosphere, Climate and Disaster Research Center (HiCCDRC), Kathmandu University, Dhulikhel, Kavre, Kathmandu, Nepal

Definition

An ablation pattern which shows ablation in a whole year below the equilibrium line is called year-round ablation pattern. Most tropical glaciers show year-round ablation pattern and the seasonality controls accumulation, whereas most Himalayan glaciers in Nepal show summer accumulation as well as ablation type characteristics. Most glaciers in the European Alps are winter accumulation and summer-ablation type glaciers. Year-round ablation pattern occurs only where the seasonal climatic variations is very less, such as on the Puncak Jaya massif in the Indonesian territory of Irian Jaya (4° 05′ S., 137° 11′ E.; 4,884 m).

YOUNGER DRYAS

Sven Lukas
Department of Geography, Queen Mary University of London, London, UK

Synonyms

Deglaciation; Greenland Stadial 1 (GS-1); Lateglacial; Stadial; Termination I

Definition

The Younger Dryas (YD, c. 12.9–11.7 ka) represents the last return to cold, stadial conditions prior to early Holocene warming and is characterized by abrupt climate change. It marks the final phase of Termination I and is also referred to as Greenland Stadial 1 (GS-1).

Introduction

The YD is characterized by abrupt climate change both at its beginning and end (e.g., Alley, 2000; Bakke et al., 2009). This period is the most pronounced of a series of climatic fluctuations following the global last glacial maximum as identified in marine sediment cores (LGM *sensu* Mix et al., 2001). The name YD can be traced back to the occurrence of the plant species *Dryas octopetala* L. (mountain avens) that is particularly abundant in pollen counts obtained from sediment successions deposited after the demise of the last ice sheets in North Western (NW) Europe. Since this plant thrives under arctic and alpine climatic conditions, its prominence in pollen profiles allowed early reconstructions of severe cold conditions in NW Europe as early as the 1930s (Mangerud et al., 1974). The YD forms part of a period referred to as the Lateglacial, which comprises a succession of alternating interstadial (warm) and stadial (cold) phases: the Oldest, Older, and Younger Dryas (stadials) and the Bølling and Allerød (interstadials). Although originally devised in Denmark, the terminology was adopted across NW Europe (cf. Mangerud et al., 1974) and is widely used to this day, albeit with the Bølling and Allerød being referred to as one interstadial complex (cf. Liu et al., 2009). Because this climatostratigraphical terminology is – strictly speaking – only valid for Scandinavia, where it was devised, Lowe et al. (2008) suggest that when making global correlations of climatic events, the YD should be referred to as "Greenland Stadial 1 (GS-1)" to avoid ambiguities regarding synchroneity.

The YD is a key period in the late Quaternary and has been the focus of paleoclimatic research for several decades. This is due to this period (a) having experienced a number of drastic changes that can be observed in

Vijay P. Singh, Pratap Singh & Umesh K. Haritashya (eds.), *Encyclopedia of Snow, Ice and Glaciers*, DOI 10.1007/978-90-481-2642-2,

numerous proxy records, including geomorphological, biological, and chemical changes in terrestrial, ice core, marine, and lacustrine settings and (b) being characterized by very abrupt, or rapid, changes in reconstructed air temperatures. This makes it an ideal role model for rapid climate change that humanity may face (Steffen et al., 2004; Seager and Battisti, 2007).

Characteristics of the Younger Dryas

In order to constrain *rates of change* that may be used as input data for predictive numerical climate models, it is of paramount importance to establish the duration of climatic oscillations using numerical dating methods. Historically, however, the YD has been very difficult to date for two main reasons: Firstly, the period is relatively brief, lasting c.1,200 years, and thus just below the resolution of most dating methods. Secondly, there are a number of problems associated with the most precise dating method in this context, radiocarbon dating; these are the marine reservoir effect and a major radiocarbon plateau, both of which increase the error associated with this method (cf. Walker, 2005) and complicate reliably dating the onset and end of the YD. Because of aforementioned shortcomings, annually resolved records have been extensively studied to fill this gap. Three key records with the required resolution exist, namely ice cores (e.g., Alley, 2000; Rasmussen et al., 2006; Lowe et al., 2008), varved lake sediments (e.g., Brauer et al., 2008) and tree-ring chronologies (e.g., Friedrich et al., 2004).

According to a new chronology that has been constructed by layer counting in the three most highly resolved Greenland ice cores (Rasmussen et al., 2006; Lowe et al., 2008), the YD has been dated to 12,896–11,703 ka GICC05 b2k ("Greenland Ice Core Chronology 2005 before AD2000"). This corresponds well with an age of 11,590 a BP for the end of the YD as identified in the Hohenheim Oak and Pine Chronology from Central Europe (Friedrich et al., 2004).

A number of archives with continuous or near-continuous sedimentation records show similar magnitudes of change both during the beginning and end of the YD; however, temperatures during the first half of the YD, after an initial drop, remained fairly stable (e.g., Brooks and Birks, 2000; Bakke et al., 2009). The second half of the YD saw a much less stable pattern where the temperature regime "flickered" between warmer and colder temperatures before the final transition to the present interglacial (Bakke et al., 2009). Irrespective of the proxies used, the rates of change are of the order of several degrees celsius in a few years to a decade.

Triggers – atmosphere or ocean?

The origin of the YD is still a matter of debate. A widely accepted hypothesis is that its cause lies in a weakening or shutdown of the meridional overturning circulation (MOC) in the North Atlantic (Rahmstorf, 2002; Denton et al., 2005; Tarasov and Peltier, 2005). The original hypothesis holds that large volumes of freshwater, stored in proglacial ice-dammed Lake Agassiz in front of the Laurentide Ice Sheet (Teller et al., 2002), were released suddenly and led to a reduction of the salinity contrasts that drive the MOC (Rahmstorf, 2002). Such sudden inputs of freshwater into the ocean happened periodically during deglaciation, intimately tied to cyclic climatic fluctuations like Heinrich Events (cf. Rahmstorf, 2002), although the exact causal links are still not established.

In recent years, a number of alternatives for the sources and routing of freshwater have been discussed. Tarasov and Peltier (2005), using numerical modeling, strongly suggest that a substantial amount of meltwater and icebergs was most likely discharged into the Arctic Sea. Other potential sources include the release of water from an ice-dammed lake in the hinterland of the Lena and Yana rivers (Spielhagen et al., 2005) or increased meltwater runoff and calving of the Greenland Ice Sheet contributed, perhaps significantly, to YD cooling (Jennings et al., 2006). It is likely that a combination of these sources, perhaps time-transgressively, might be responsible for the episodic input of freshwater into the oceans, leading to the climatic fluctuations observed.

Although the "oceanic trigger hypothesis" remains popular, several problems exist: Firstly, it is disputed whether the MOC is the major conveyor along which heat transport to northerly latitudes, and Europe in particular, occurs (e.g., Seager et al., 2002; Seager and Battisti, 2007). Secondly, the two largest events, labeled meltwater pulse 1a and 1b, occurred several hundreds of years before and after the YD, respectively (Fairbanks, 1989), failing to provide the desired clear link (cf. Wunsch, 2006).

In the light of these discrepancies, changes in atmospheric circulation patterns have been invoked to be a cause, rather than an effect, of rapid climate change and hence of the YD: these changes, possibly initiated by the growth and presence of continental ice sheets during the Quaternary (cf. Wunsch, 2006), together with a dynamical displacement of the sea ice edge (Li et al., 2005; Bakke et al., 2009), could be a key factor in cooling associated with the YD. Air masses moving across the sea ice would have been chilled and deprived of moisture (cf. Brauer et al., 2008), linking well with observations of a windy, cold, and dry YD across Europe and in the Greenland ice cores (cf. Alley, 2000). Although the exact links are at present still only tentative (cf. discussion in Brauer et al., 2008), changes in atmospheric circulation could also explain reconstructed changes in MOC activity since wind shear is known to have an impact on ocean circulation (e.g., Dickson et al., 2000; Seager et al., 2002; Timmermann and Goosse, 2004; Seager and Battisti, 2007). Shifts in seasonality, with stronger cooling during the winter half (cf. Denton et al., 2005; Lie and Paasche, 2006), may be explained through the presence of sea ice as well. In order to solve this debate, more sophisticated climate models and a more systematic use of paleo-wind proxies such as dunes (cf. Kasse, 2002) have been suggested (e.g., Wunsch, 2006).

The most recent hypothesis regarding the triggering mechanism for the YD is the proposal that an extraterrestrial impact (ETI) may have contributed to atmospheric cooling (Firestone et al., 2007).

Global Younger Dryas?

Glacial landforms, most notably ice-marginal moraines, have been extensively used to establish synchronous response to climate change in terrestrial settings. Across Europe, the cooling associated with the YD led to the growth of glaciers in mountain ranges (e.g., Thompson Davis et al., 2009) and a readvance of the Scandinavian ice sheet (e.g., Tschudi et al., 2000).

The existence of the YD cold event in the North Atlantic region is well documented and accepted (cf. Isarin and Renssen, 1999; Seager and Battisti, 2007), apart from a few areas where the evidence remains equivocal, for example, bizarrely, Greenland (cf. Miller, 2008). However, its occurrence and impact has been controversially debated elsewhere on Earth (e.g., Barrows et al., 2008; Lowell and Kelly, 2008; Mahaney et al., 2008). The center of attention in the debate around a global YD event has been whether geomorphological and biological systems responded synchronously to a global trigger or asynchronously to local factors, a question that is highly significant in the context of explaining triggers and forcing of rapid climate change; in particular, it could introduce further uncertainties regarding the prediction of future climate change.

In order to determine whether these events were synchronous or asynchronous, it is necessary to obtain detailed paleoclimatic records from different parts of the world that are independently and securely dated. The key problems in solving this debate are twofold: Firstly, prominent, singular moraine ridges are usually selected for dating, but such landforms are likely to have been subject to postdepositional erosion, therefore not representing the time of glacier retreat but that of landform stabilization (Ice-Cored Moraines). Secondly, glacier response to climate change is in the order of years to decades and depends on a number of local factors (cf. Lukas and Benn, 2006). However, the resolution of cosmogenic surface exposure dating, the method commonly used to date boulders on moraines, is at least one order of magnitude lower than glacier response and also of quite coarse resolution when dating a short period like the YD: within error, ages could place a moraine on the YD-Holocene transition, so that unequivocal dating is not straightforward (cf. Miller, 2008, and references therein). Hence, one could argue that the methodological repertoire is at present insufficient to satisfactorily answer the question of global synchroneity of glacier advances during the YD.

Conclusions

The YD is a central time period characterized by rapid climate change. It is documented in a large number of terrestrial, marine, and lacustrine records.

However, a large number of uncertainties and white spots still exist when compared to more recent periods of glacier advances, for example the "Little Ice Age." This is partly due to the geographical spread of areas investigated (some "type sites" have been covered numerous times, others remain untouched to this day) and partly due to limitations in dating, for example an absence of dateable material, but also problems such as postdepositional erosion that may blur otherwise clearer signals.

Despite having been the focus of much research in the past 30 years, much still remains to be learned – and much exciting research still to be carried out – regarding triggers (atmosphere and/or ocean), extent (amphi-North Atlantic or global), impact on various systems and its power as a tuning-tool for numerical models.
