Dynamics of glaciers

Definition

Glaciers. Bodies of ice massive enough to thin and spread under their own weight.
Ice sheet. A glacier that covers large parts of a continent or a large island.
Ice shelf. The floating perimeter of parts of an ice sheet grounded in water.
Ice stream. A fast current of ice imbedded in an ice sheet.
Terrestrial ice sheet. Parts of an ice sheet grounded above sea level on land.
Marine ice sheet. Parts of an ice sheet grounded below sea level in water.

Historical background

Glaciers are bodies of ice massive enough to flow under their own weight due to the action of Earth's gravitational field. This definition excludes sea, lake, and river ice, which are moved by wind and water currents, and ice-cemented ground in the permafrost condition, in which ice is trapped in the pores of soil and rock. However, gravity can thin sufficiently thick floating ice and move permafrost down steep slopes. Then these bodies behave like glaciers.

The first recorded scientific studies of glaciers took place in Iceland, the Swiss Alps, and in the mountains of Scandinavia as early as the seventeenth century. Major incentives for these studies were the spectacular appearance of mountain glaciers, the recreational activities these glaciers provided, their essential supply of freshwater to farms and villages, and, later, hydroelectric power provided by this water supply. An early discovery was that these bodies of ice moved downslope, with ice supplied by winter snowfall on the colder upper slopes and lost by summer melting on the warmer lower slopes. It was also noted that these glaciers moved loose material, mostly boulders, gravel, sand, and clay, which could be either carried on the ice surface or entrained in basal ice moving over the bed. Loose material deposited by glaciers is called till.

By the nineteenth century, scientists were pondering the loops of till, now called moraines, that arced around the ends of valleys occupied by glaciers farther upslope. They knew that these glaciers had extended downslope and deposited moraines during a few centuries of unusual cold in Europe that followed a warmer climate in medieval times, which later came to be called the Medieval Climate Optimum. In addition, large boulders called erratics were scattered across the North European Plain and could be traced to source areas in the Scandinavian mountains and elsewhere. These deposits were originally called "drift" on the belief they were transported during the Biblical flood in Genesis. That belief was replaced by the realization that the "flood" had indeed occurred but the water was in its solid state, ice. This is when two new branches of science, glaciology and glacial geology, were born. Glaciologists studied existing glaciers and glacial geologists studied the deposits left by former glaciers. Most of these early scientists were called naturalists, and for them glaciology and glacial geology were the same discipline that studied causes and effects, opposite sides of the same coin.

A Swiss naturalist, Louis Agassiz, did most to popularize the idea that vast sheets of ice spread out from the Alps and the mountains of Scandinavia onto the surrounding lowlands. He came to America and found evidence that a vast sheet of ice had come down from Canada and covered the northeastern USA. The Ice Age Theory was born from such observations by Agassiz and others in the middle and later decades of the nineteenth century. In the early decades of the twentieth century, glacial geology largely separated from glaciology and became incorporated into geomorphology, a branch of geology. These geologists, in mapping glacier deposits in North America, Europe, and western Siberia, soon realized that there had been several massive southward advances of ice, at least four, in these regions. They also found that a smaller advance of ice from the Alps and Scandinavia had occurred at the end of the Medieval Warm Period, but had ended around 1850–1880 when these glacial geologists began mapping

glacier deposits. They called this cold period the Little Ice Age. At the same time, glaciology was being developed as a separate discipline within geology when other scientists who joined explorers to the Arctic and Antarctic regions discovered that Greenland and Antarctica were blanketed by vast sheets of ice, and the highlands of Arctic islands often wore caps of ice. During this period, a whole new scientific vocabulary was developed to describe the great variety of glaciers and the deposits left by them. This encyclopedia presents the new vocabulary, which continues to grow with new discoveries in the twenty-first century.

The primary task of glacial geologists became finding and using ways to date glacial deposits and the landscapes eroded by glaciers, especially by the large continental ice sheets. Dating techniques range from relative ages found by studying organic fossils in stratified deposits linked to glaciers, to absolute ages obtained by counting "varved" layers of sediments deposited seasonally in proglacial lakes, by counting tree rings dating from glacial times, by radiocarbon dating of organic pollen, wood and marine fossils, by other radiometric dating techniques, by seasonal variations of airborne and waterborne trace ions or chemicals usually obtained from cores recovered from glaciers and from sediments on the floors of oceans and lakes, and most recently by dating rocks exposed to damage by "cosmogenic" radiation after glaciers retreated.

The primary task of glaciologists became understanding the mechanisms by which glaciers of all sizes moved over the face of the Earth. This task was undertaken after World War II by physicists, notably in Britain and America, who had been engaged in military applications of ice ("ice ships" that could not be sunk by German torpedoes were the goal of the "Habakkuk Project" in Britain and Canada), and in conducting logistical operations in polar regions (the task of CRREL, the Cold Regions Research and Engineering Laboratory of the U.S. Army in New Hampshire). By 1950, glaciology was being converted from a descriptive branch of geology to an analytical branch of physics. This was the time of the Cold War between East and West, and like the Big Four in that struggle, there was a Big Four in glaciology, John Nye (UK), Louis Lliboutry (France), Petr Shumsky (USSR), and Johannes Weertman (USA). Also notable at that time were John Glen who obtained a "flow law" for glacier ice, Charles Bentley who conducted many of the geophysical measurements (seismic, magnetic, and gravity) along tractor-train traverses across the Antarctic Ice Sheet during and after the International Geophysical Year, Barclay Kamb who determined the other crystal structures of ice that exist at temperatures lower and pressures higher than those found on Earth's surface, Lyle Hansen who developed deep ice drilling and coring technology at CRREL, and Stanley Evans who developed radar-sounding technology. There were many others.

John Nye began by studying flow of glaciers, first in 1951 using plasticity theory in which no flow takes place until a "yield stress" is attained, and then using Glen's flow law. Lliboutry in 1964 produced the first textbook, *Traite de Glaciologie*, that presented a synthesis in which the force balance and the mass balance in glaciers were combined in a systematic way to show how glaciers moved under the force of gravity resisted by "drag" forces at the bed, and how the advance or retreat of glaciers depended on whether accumulation by snowfall at higher elevations was more or less than ablation by melting at lower elevations. Shumsky, largely self-taught and prevented from interacting with the larger glaciological community by Cold War rivalries, created glaciology as a profession in the Soviet Union almost single-handedly. Weertman developed a "sliding law" for glaciers moving over a wet bed and a "flow law" for floating ice spreading under gravity, both in 1957, and was among the first to place the advance and retreat of ice sheets in the larger context of glaciation cycles during the Quaternary Ice Age (the last million years).

These and other glaciologists most active from 1950 to 1970 constitute the Founding Generation of modern glaciology. They trained glaciologists who became a Transitional Generation most active from 1970 to 1990 who trained glaciologists at a time when great advances in technology were being applied to glaciological problems, giving us the present High-Tech Generation from 1990 to 2010. They in turn are training a new generation of glaciologists who will probably become known as the Holistic Generation that incorporates glaciology into climatology with the goal of understanding global climate change, especially rapid change.

A major discovery in the second half of the twentieth century was that ice sheets not only formed on land above sea level, but also formed on land below sea level and produced much the same glacial geology. These "marine" ice sheets had an inherent instability when they ended as floating ice shelves. If the marine bed had become a bowl-shaped depression under the heavy load of ice, the ice-shelf grounding line might retreat irreversibly downslope and rapidly convert the marine ice sheet into a floating ice shelf, which might then disintegrate rapidly, thereby removing the ice sheet from Earth's climate system. This happened to several marine ice sheets shortly after the last glacial maximum and terminated the last glaciation cycle. These ice sheets lost coupling to the bed. Just when ice sheets seemed most stable and permanent, was also when they had depressed their beds farthest below sea level, making them vulnerable to the marine instability. Their rapid collapse into ice shelves that quickly disintegrated into icebergs called attention to the force balance in ice sheets.

The force balance

The force balance describes how glaciers change in shape over time. The fundamental fact of glaciology is that the height of glaciers above the bed is determined by how strongly ice is coupled to the bed. Glaciers thin and spread, a change in shape, when coupling weakens,

thereby changing the balance between gravitational forces causing ice motion and forces that resist motion. Ice-bed coupling weakens first as a frozen bed becomes thawed and then as basal water is able to progressively "float" the overlying ice by drowning bedrock bumps that project up into ice and anchor overlying ice to the bed. In ice sheets, the largest glaciers, ice flow diverges slowly from interior ice domes, gains velocity as it converges on ice streams, and then spreads out as ice lobes grounded on land or as ice tongues floating in water and often imbedded in ice shelves. For sheet flow, gravitational forcing is proportional to the product of ice thickness and ice surface slope, and is resisted primarily by basal drag. For shelf flow, gravitational forcing is proportional to the height of ice floating above water, and is resisted by a tensile stress that resists this gravitational "pulling" for freely floating ice tongues. In ice shelves, additional resistance is provided by shear against the sides of a confining embayment and at basal pinning points where the ice shelf is grounded locally. In stream flow, the gravitational forcing for sheet flow is gradually replaced by the gravitational forcing for shelf flow as a "floating fraction" of ice increases along an ice stream. Gravitational forcing is resisted by a tensile stress that "pulls" upstream ice, a compressive stress that "pushes" downstream ice, side shear against slower moving lateral ice, and basal sliding where ice contacts a thawed bed under ice streams and their terminal ice lobes or confined and pinned ice shelves. Such ice shelves "buttress" ice streams that supply them with ice. Disintegration of a buttressing ice shelf can cause the feeder ice streams to quickly surge, often doubling their velocity, as has been observed for Greenland and Antarctic ice streams in recent years.

Ice velocities shearing against a frozen bed in basal shear, shearing against slower moving ice in side shear, pulling slower ice in tension, or pushing slower ice in compression are linked to gravitational stresses that force ice motion by a "flow law" of ice. The flow law developed by Glen applies to ice shearing over a frozen bed for slow sheet flow. This is analogous to shearing a deck of cards over a tabletop when the bottom card is glued to the table. For floating ice, the flow law applies to ice spreading over the water surface as it thins under the force of gravity. This is analogous to flattening a deck of cards floating in water. Sliding laws apply to ice spreading over a wet bed, but retaining contact with the bed. This is analogous to moving the deck of cards intact over a tabletop when the table is slippery. Weertman developed a sliding law in which only a "film" of water coats bedrock bumps that resist sliding motion, so basal water pressure does not appear in his sliding law. Lliboutry developed a sliding law in which cavities on the lee side of bumps could fill with water and growth of these water-filled cavities could extend ice-bed uncoupling from a local scale to a regional scale. Basal water pressure enters his sliding law. All treatments of glacier sliding on a wet bed spring from these two early efforts. Ongoing efforts center around how to quantify bed roughness and the subglacial hydrology that moves water from sources to sinks on a rough bed. Basal sliding is altered when deformable sediments or till separate basal ice from bedrock. Deformation depends primarily on water content, the size distribution of solid particles, their mineralogy, and on subglacial hydrology that moves basal water from sources to sinks.

Both flow laws and sliding laws of ice begin with a force balance. In deriving a flow law, an external force (such as gravity) is applied to the base of an imaginary triangular pyramid imbedded in ice, and it is balanced by resisting internal forces applied tangent to and normal to the other three triangular faces of the pyramid of ice. Dividing the forces by the areas of faces they contact gives stresses on these faces. These stresses are separated into those that change the size of the pyramid, called confining stresses, and those that change the pyramid shape, called creep stresses (or deviator stresses, because they "deviate" from confining stresses). The flow law is obtained from measuring the rate of ice deformation caused by creep stresses. Simple combinations of creep stresses, such as a compressive stress normal to opposite circular faces of a cylindrical ice specimen or a shear stress parallel to these faces, are applied to the ice specimen and the change in shape of the specimen is measured over time. This change in shape is recorded as strain rates, which are changes in ice velocity measured along the mutually perpendicular axes used to describe the creep stresses as normal stresses or shear stresses. The strain rates are related to the creep stresses in creep experiments in which either temperature is kept constant while stresses change or stresses are kept constant while temperature is changed. Measured strain rates in both cases describe the creep deformation of ice resulting from changing stress and temperature. Creep deformation increases exponentially with linear changes in stress and temperature. This makes creep deformation of ice closer to the purely plastic deformation originally assumed by Nye than to the viscous deformation of fluids in which strain rate varies linearly with creep stress. In sheet flow over a frozen bed, the gravitational deforming stress varies with the product of ice thickness and surface slope, and is resisted by the basal shear stress.

The force balance in sliding laws of ice balances the gravitational driving stress produced by Newton's second law of motion against the resisting force produced by Newton's third law of motion. In Newton's second law, force equals mass times acceleration. Applied to glaciers, it equates ice mass with the product of ice density and ice volume, ice volume being ice height above the bed times unit basal area, and acceleration being the acceleration of gravity resolved along the direction of greatest ice surface slope. In Newton's third law, every force is opposed by an equal and opposite resisting force. Applied to glaciers, the gravitational driving stress causes downslope ice motion that is resisted by a basal drag force equal to the product of the basal shear stress times unit basal area in Newton's third law of motion. When the bed is thawed, a water film between basal ice and the bed cannot transmit the shear stress, so sliding motion of ice must be resisted

by normal stresses acting on faces of bedrock bumps that project up into basal ice. These normal stresses are compressive where ice pushes against bumps and tensile where ice pulls away from bumps. The tensile stress vanishes if water-filled cavities form on the lee side of bumps. When bumps are small, the compressive stress becomes very large because the gravitational driving force acts against a very small area (stress equals force per unit area). This compressive stress crushes ice into water, water occupying a smaller volume for the same mass of ice. The meltwater then flows around the bump and refreezes in the lee of the bump. This process is called regelation (regel means refreeze). The latent heat of freezing is conducted rapidly through small bumps to provide the latent heat of melting for ice being compressed. When bumps are large, regelation shuts down because latent heat is conducted slowly through big bumps. For large bumps, the compressive stress is smaller because the gravitational driving force acts normal to a larger area, so creep in ice moves ice around large bumps. Rates of regelation vary inversely with bump size and rates of creep vary directly with bump size. Basal sliding is controlled by bump sizes for which rates of regelation and creep are the same. These bumps are the "controlling obstacle size" in theories of glacial sliding, since they provide maximum resistance to gravitational forcing.

Ice-bed coupling treated in the force balance is only half the story in understanding the stability and velocity of ice sheets and other glaciers. The other half concerns the mass balance.

The mass balance

The mass balance describes how glaciers change in size over time. These changes, like changes in shape, are partly controlled by the topography of the glaciated landscape. When glaciers occupy valleys, size changes consist mainly in advance and retreat along the valleys. Changes in size of continental ice sheets occur in many directions, with advances in some directions and retreats in others. Glaciers grow in size when accumulation of ice, mostly from snow precipitation over high interior ice elevations, exceeds ablation at low peripheral ice elevations, either by melting when glaciers end on land or by melting and calving of icebergs when glaciers end in water. Glaciers advance when the mass balance is positive and retreat when the mass balance is negative, provided that no major change in ice-bed coupling occurs under the glaciers that may make them thicken because of increased coupling or thin because of decreased coupling. A positive mass balance increases ice volume and a negative mass balance decreases ice volume, apart from changes in the shape of glaciers caused by changes in the force balance.

In mountain glaciers occupying various climatic regimes around the world, advance and retreat of grounded ice margins are very sensitive to changes in the mass balance, and therefore to changes in climate. Typical climatic regimes are cold dry continental climates at high and mid latitudes, cool wet maritime climates at high and midlatitudes, and mixed climates at these latitudes. Continental ice sheets occupy a range of high and midlatitudes and have all these climatic regimes in various sectors. A major effort in documenting climate change since the last glacial maximum (LGM) about 18,000 years ago has been to map and date the looping end moraines deposited by mountain glaciers around the world as these glaciers began their overall retreat, especially during the last 10,000 years called the Holocene when human civilizations arose and attained the advanced industrial societies found today. The rise and fall of many cultures in Africa, Eurasia, and the Americas have been linked to climatic changes documented by changes in dated terminal positions of mountain glaciers around the world caused by changes in their mass balance. An example of this climate research linked to advance and retreat of glaciers has been mapping and dating glacial deposits around the South Pacific rim from Chile in the east to Antarctica in the south to New Zealand in the west by George Denton and colleagues, following earlier correlations in Alaska, Switzerland, and Scandinavia.

Mass balance studies of continental ice sheets are ongoing for both the Greenland and Antarctic ice sheets. These include field studies along ice-sheet margins similar to those conducted for mountain glaciers, monitoring surface changes from Earth-orbiting satellites, and recovering climate records from ice cores. These records consist of measuring ratios of isotopes for oxygen and hydrogen in ice, trace concentrations of ions entrained in the atmosphere by evaporation from oceans, transported by winds, and precipitated with ice crystals over the ice sheets, samples of Earth's atmosphere trapped in air bubbles in ice after surface snow is compressed into ice at depth, and the mineralogy of wind blow dust from volcanoes and deserts around the world. In combination, these measurements give a record of global climate change and guide research seeking the causes of climate change.

The ablation zone of glaciers and ice sheets consists of net melting from surface and basal ice, and calving along vertical ice fronts ending on land and in water. The zone separating the inner accumulation zone from the outer ablation zone is a transition across which summer meltwater soaks into winter snow, transforming dry snow into wet snow. At the base of the wet snow zone is a zone of refrozen meltwater that forms ice superimposed on the ice surface from the previous summer. The snow line occurs when summer melting exposes superimposed ice at the surface. The equilibrium line of the glacier or ice sheet, where the annual mass balance between accumulation and ablation is zero, occurs when summer melting removes superimposed ice. Treating ablation in computer models of ice sheets is complicated by the fact that most ice enters ice streams, fast currents of ice that often cross the ablation zone and end as ice lobes grounded on land or ice tongues floating in water. Ice streams downdraw interior ice, so their surface is lower than flanking ice, which forms ice ridges between closely spaced ice

streams. Shear crevasses separate fast stream flow from the slow sheet flow on either side, so much surface meltwater enters these crevasses and refreezes, instead of draining off the sloping ice surface. If that water is most of the summer meltwater, the "ablation" zone is really still in the accumulation zone of the ice sheet because no true equilibrium line exists. Meltwater filling crevasses to the top will push the cold crevasse walls apart, water being heavier than ice, and will warm the walls by releasing latent heat when meltwater refreezes. This drives the crevasse tips downward and water can drain from the crevasses when the crevasse tips reach the bed and gain access to a subglacial water drainage system. When that happens, the pseudo ablation zone becomes an actual ablation zone because surface meltwater leaves the glacier or ice sheet by way of the basal drainage system. High melting rates can also occur under ice tongues that either float freely or are imbedded in floating ice shelves. In these cases, the floating ice is in an ablation zone even though the surface still has net snow accumulation. The high basal melting rates are caused by warm ocean currents that pass under floating ice. Water-filled bottom crevasses can migrate upward toward the ice surface, and ocean swells that pass under floating ice can cause spectacular calving events along top and bottom crevasses when they meet. Douglas MacAyeal, at the University of Chicago, and his colleagues have studied and modeled these catastrophic ablation mechanisms.

Modeling ice sheets

Modeling past and present ice sheets using high-speed computers began with a steady-state model of the Antarctic Ice Sheet in 1971 by Australian glaciologists, William Budd, Richard Jenssen, and Uwe Radok. They used measurements of temperature, ice accumulation rates, and elevations at the ice surface and measurements of bed topography, mainly along tractor-train traverse routes during the International Geophysical Year in 1958 and thereafter. With this input, their model calculated changing ice temperatures and velocities with depth along ice flowlines in directions of maximum surface slope for specified values of the basal geothermal heat flux. It was the first thermomechanical ice-sheet model. They subsequently applied it to the Greenland Ice Sheet. Their model produced beds that would be nearly wholly thawed or wholly frozen for moderate changes in the unknown basal geothermal heat flux. After Molly Mahaffey showed how ice sheets could be modeled at grid points in the map plane, thermomechanical models proliferated, and became three-dimensional and time dependent. The time dependency showed that basal thermal conditions (basal temperatures for frozen beds and basal melting or freezing rates for thawed beds) depended very strongly on surface conditions, especially accumulation rates, and these basal conditions under present ice sheets were strongly dependent on past surface conditions which were largely unknown. Glacial geology and the climate records extracted from ice cores and cores through ocean and lake sediments showed that past climate conditions, including the elevation of present ice sheets, were highly variable. It was becoming increasingly obvious that these top-down models, using surface conditions as input to extract reliable bed conditions as output, were essentially useless.

Former ice sheets reconstructed from the top down gave unreliable basal thermal conditions, and therefore unreliable ice elevations generated by ice-bed coupling linked to these conditions. Fortunately, glacial geology under former ice sheets could be interpreted to reveal the basal thermal regime, so ice elevations could be reconstructed from the bottom up. Calculating those ice elevations did not require knowing the basal geothermal heat flux or former configurations of the ice sheet through time and were insensitive to surface accumulation rates. Unreliable precipitation rates from models of atmospheric circulation, which depend on knowing the configuration of an ice sheet, did not affect these bottom-up reconstructions. Bottom-up reconstructions of former ice sheets began to restore glaciology and glacial geology to the original cause-and-effect unity they originally had as two sides of the same coin.

An early assumption in modeling ice sheets past and present was that Earth's climate was essentially stable, with the greatest perturbations in climate being the glacial and interglacial maxima of Quaternary glaciation cycles, times when climate changed slowly. This was the guiding assumption of CLIMAP (Climate: Long-range Investigation, Mapping, and Prediction) a project of the International Decade of Ocean Exploration from 1970 to 1980. The last glacial maximum 18,000 years ago and the last interglacial maximum 125,000 years ago were chosen as the primary and secondary goals for reconstructing past climates. Reconstructing ice sheets at these times was needed to provide boundary conditions in models of atmospheric circulation available for CLIMAP. These were the area of ice sheets to determine global albedo, the volume of ice sheets to determine the ocean surface area available for the ocean-to-atmosphere heat exchange, and the elevation of ice sheets to determine the direction and intensity of surface winds and the jet stream. However, records of climate change extracted from ice and sediment cores showed rapid changes within glaciation cycles that had amplitudes comparable to those bracketing glaciation cycles. Perhaps the underlying assumption was wrong. Perhaps Earth's climate is fundamentally unstable, at least within glaciation cycles, and the key to understanding rapid climate change lies in determining what causes the fastest rates of climate change within a glaciation cycle. In this case, ice sheets are not merely passive components of Earth's climate that react slowly to changes in the ocean and atmosphere. Ice sheets may be dynamic components capable of rapid changes independent of the ocean and atmosphere, changes that if big and fast enough could trigger rapid changes in the ocean and atmosphere. This was possible only

from changes in ice-bed coupling at the base of ice sheets. Bottom-up modeling had to constrain top-down modeling.

Holistic ice sheet modeling

In holistic ice sheet modeling, ice sheets must be treated as part of Earth's climatic and tectonic system, and all dynamic components of ice sheets must be modeled and coupled to this system. For example, when ice leaves an ice sheet by calving into icebergs, that ice is entering the oceanic part of the system, and the energy needed to melt that ice must be extracted from ocean water down to the draft of the icebergs. That heat is then unavailable to heat the atmosphere in the ocean-to-atmosphere heat exchange that drives global climate.

Flow in ice sheets consists of slow sheet flow diverging from interior ice domes that mostly converges to become fast stream flow toward ice margins and ends as ice lobes grounded on land and ice tongues floating in water. If ice tongues enter confining embayments, they may merge to become floating ice shelves that are grounded along the sides of the embayment and may be pinned locally to the seafloor at sites that produce ice rumples and ice rises on the ice-shelf surface. Ice rumples are produced when basal ice scrapes across pinning points and ice rises are produced when pinning points penetrate basal ice so basal ice must flow around pinning points. Ice sheets impact most strongly on the ocean and atmosphere when ice shelves either disintegrate catastrophically or release gigantic icebergs. Both events have occurred in parts of the Greenland and Antarctic ice sheets in the last 10 years. These iceberg outbursts can discharge billions of tonnes (metric tons) of ice in periods of weeks to a few years. For each gram of ice, about 10 calories are needed to reach the melting point and another 80 calories are needed for melting. This sensible and latent heat must be extracted from the sensible heat of ocean surface water, where the ocean-to-atmosphere heat exchange takes place. Melting outbursts of icebergs reduces the heat exchange, which then changes climate. These considerations show why glaciologists must study ice sheets as a single dynamic system that may be inherently unstable, with some changes in ice sheets being big and fast enough to trigger changes in Earth's climate. Changes of this magnitude are recorded by the glacial geology of past ice sheets and by climate records in ice and sediment cores.

Holistic ice-sheet modeling that includes transitions from sheet to stream to shelf flow and mechanisms for disintegrating ice shelves and calving gigantic icebergs is necessary to understand how ice sheets may control climate change. Key to this modeling activity is understanding conditions at the base of ice sheets that require bottom-up ice-sheet modeling. Foremost among these basal conditions is the production of basal water and its transport from sources to sinks. Basal water controls ice-bed coupling, and therefore the height of ice above the bed. Models of Earth's tectonic activity combined with modern technology for mapping the distribution and depth of basal water by radar and seismic sounding allow the geothermal heat flux to be mapped for the first time. High rates of geothermal heat output are source areas for basal water. Other source areas are sites of heavy crevassing along ice streams where surface meltwater can enter crevasses, drive the crevasses to the bed by forcing crevasse walls apart, and then flood the bed with surface meltwater. Transport of basal water from sources to sinks occurs beneath ice streams, which discharge up to 90% of the ice and where basal water uncouples ice from the bed and allows fast sliding velocities. Sinks of basal water occur around the perimeter of ice lobes at the ends of terrestrial ice streams and across ungrounding lines of marine ice streams where they become afloat as ice tongues and ice shelves. For marine ice streams, discharge of basal water at the melting point, combined with warm ocean water pumped under ice shelves by tidal cycles, will melt floating ice free from basal pinning points. Confined and pinned ice shelves can buttresses ice streams that supply them. Basal melting and iceberg calving remove pinning points and allow faster ice discharge rates from ice streams and faster ice calving rates from ice shelves. Ice sheets are then downdrawn faster, with no changes in surface conditions other than those caused by lowering the ice surface. Rapid downdraw has the capacity to trigger rapid changes in global climate. Ice shelves can disintegrate catastrophically when external forcing, such as an ocean swell passing under an ice shelf, produces a "tipping point" in the force balance.

When confined and pinned ice shelves disintegrate, they reduce compressive stresses that buttress ice streams supplying the ice shelves. These ice streams may then be able to increase their discharge velocity up to 100-fold, by analogy with surging mountain glaciers. Surges of mountain glaciers last from a few months to a few years, until their ice accumulation regions have become depleted. Ice streams drain much larger areas so their surges can last much longer. Surging mountain glaciers have been studied in some detail, notably by Charles Raymond, Barclay Kamb, and colleagues. During a surge, the glacier thins upslope and advances downslope due to a massive reduction in upslope ice-bed coupling. This occurs independently of the mass balance of surging glaciers, and there is no change in local climate that might trigger surges. These observations can be applied to the ice streams that drain ice sheets. Lobes along the southern margin of the former Laurentide Ice Sheet that blanketed most of North America are surge-like extensions of terrestrial ice streams, and ice-rafted sediments deposited across the North Atlantic have been traced to marine ice streams that may have surged. Some Greenland and Antarctic ice streams appear to be surging, without changes in external conditions.

A key to predicting when and where ice sheets may begin to lower rapidly and discharge vast quantities of icebergs is to monitor changes in ice surface elevations from Earth-orbiting satellites. Surface elevations decrease

fastest at the heads of ice streams. Stream flow is transitional between fully grounded sheet flow and fully floating shelf flow. Ice streams have a concave surface, the only surface that can provide a smooth transition from the high convex surface produced by sheet flow and the low flat surface produced by shelf flow. The gravitational driving stress in sheet flow is proportional to the product of ice height above the bed and the ice surface slope, whereas in shelf flow it is proportional to the height of ice floating above water. In stream flow, gravitational forcing changes downstream from the forcing causing sheet flow to the forcing causing shelf flow. Therefore, a floating fraction of ice increases along marine ice streams from essentially zero at the head of ice streams to essentially unity at their ungrounding lines. Along terrestrial ice streams, the floating fraction increases from zero to nearly unity at their minimum-slope surface inflection line, and then decreases as basal water flows out from beneath terminal ice lobes.

Ice-bed uncoupling in sheet flow is only partial, and occurs when a frozen bed thaws. A melting bed separates a fully frozen bed from a fully thawed bed, with thawed patches growing in number and size as ice flows across a melting bed. The opposite condition exists as ice flows across a freezing bed that separates a fully thawed bed from a fully frozen bed. Melting lowers the ice surface by up to 20% and freezing raises the surface by up to 25%. In both cases, the ice sheet remains intact. Once the bed becomes thawed, further melting of basal ice must drown the bedrock bumps that retard basal sliding and fluidize basal till or sediments, causing them to deform rapidly. Drowning occurs first in ice streams, which generally lie along linear depressions in the subglacial landscape. Although slow sheet flow occurs over some 90% of past and present ice sheets, ice streams discharge up to 90% of the ice. Therefore, ice streams can collapse an ice sheet. As the floating fraction of ice increases over time, ice streams propagate into an ice sheet, pulling out more ice, until the high convex surface of sheet flow collapses to become the low flat surface of shelf flow. The ice surface lowers nearly to sea level if the ice sheet is a marine ice sheet grounded below sea level. Then a calving bay can migrate into ice downdrawn by surging ice streams and carve out what remains of the ice sheet. This terminates a glaciation cycle, as happened when a calving bay migrated up a stagnating post-surge ice steam in Hudson Strait and carved out the heart of the vast Laurentide Ice Sheet centered over Hudson Bay about 8,000 years ago. There is no inherent reason why the same process cannot collapse and disintegrate the ice sheets now covering Antarctica and Greenland, since large parts are grounded below sea level, especially in Antarctica. In this event, global sea level would rise by 70 m, submerging Florida, making Memphis, Tennessee, an ocean port, and converting New England into an island. Whole countries would disappear, from Denmark to Bangladesh, triggering vast migrations of populations that cause worldwide social, political, and economic upheavals.

Summary and outlook

Three facts should guide our understanding of the velocity of glaciers, especially for the large continental ice sheets covering Greenland and Antarctica today. (1) Ice height above the bed is controlled by the strength of ice-bed coupling, reducing ice thickness by some 90% when coupling vanishes. (2) Ice-bed coupling vanishes along ice streams that end as floating ice shelves and drain up to 90% of an ice sheet. (3) Because of (1) and (2), ice sheets can rapidly collapse into ice shelves that can suddenly disintegrate into icebergs, thereby removing ice sheets from Earth's climate system and forcing abrupt climate change and rapidly rising sea levels.

GLACIER POTHOLE

Rajesh Kumar
Remote Sensing Division, Birla Institute of Technology, Extension Centre, Jaipur, Rajasthan, India

Glacier pothole is a smooth cavity or hole formed on the rocks by eddy currents of water bearing stones, gravels, and sand. The glacier melt water passing through the crevasses in the glaciers sometimes forms whirlpool at the bottom of the glacier. This water is under very high pressure and carries morainic debris likes large erratic boulder

Glacier Sliding, Figure 1 The sketch showing the sliding of the glacier ice under gravity flow on the inclined bed of glacier.

gravels and sand which erodes the underlying bed of the rocks giving rise to the formation of glacier potholes. The erosion is not only caused by the big boulder or gravels but also by the turbid melt water under high pressure and eddy flows. As the potholes are formed through the crevasses/moulin, it also reflects the surging of the glaciers that generate the crevasses.

Potholes are round and almost invariably contain the rounded rock materials that have drilled them (Figure 1). In glacial setting, they may be partially filled by glacial sediments. The initiation of potholes can also be explained as cavitations in very fast flowing deep melt water streams. The resulting cavities subsequently enlarge and deepen by rock materials caught in the turbulent vorticities. It is still not very clear whether erosive mechanism plays an important role in the formation of potholes or not.

GLACIER SLIDING

Rajesh Kumar
Remote Sensing Division, Birla Institute of Technology, Extension Centre Jaipur, Jaipur, Rajasthan, India

Sliding of the glacier over bedrock, as shown in Figure 1, occurs only in glacier with ice at the pressure melting point and with enough over pressured water at the base to reduce friction between the ice and substrate. Soft, deformable, water saturated sediments at the base of glaciers enhance basal slippage, hence the faster movement of the glaciers.

The other mechanism for the glacier sliding is internal slippage (Figure 2) along fractures that can occur in any part of the glacier, but is most effective toward the terminus, where thrust faults are developed. In old glacier ice, large crystals are formed strongly elongated down slopes. This is a form of movement and, hence, a contribution to the sliding of glaciers.

The glacier slides at different speeds depending on local environmental conditions Polar glaciers move very slowly like the debris laden margins of the temperate glaciers. The temperate glaciers move usually at a rate of few centimeters per day, however, a few steep glaciers may reach velocities upto 3.0–6.0 m/day.

GLACIER SURGING

Synonyms

Glacier surge dynamics; Glacier surge processes, morphology, and landforms; Surge-type behaviour; Surging

Definition

Glacier surging is a quasiperiodic oscillation between long periods (tens to hundreds of years) of slow flow, called *quiescent phase* or *quiescence*, and shorter periods of typically 10–1000 times faster flow, called *surge phase, active phase*, or *surge*. During a surge, the flow velocity increases abruptly, and fast flow is maintained over some time (1–15 years) and over a wide area. The switch from slow to fast flow is an internally triggered ice flow instability, reflecting sudden changes within the glacier system. These changes can sometimes be associated with external factors (e.g., weather, climate, and earthquakes), but only if the glacier system is already close to a critical threshold. During a surge, a large volume of ice is transported from the *reservoir zone* (upper part) to the *receiving zone* (lower part) of the glacier, which sometimes results in a marked frontal advance. During the surge cycle (from surge through quiescence to the next surge), the morphology and surface characteristics of a glacier undergo dramatic changes that result in morphological features diagnostic for surging: these can be used to identify surge-type glaciers in their quiescent phases, even if a surge proper has not been observed. Only a small percentage of glaciers worldwide exhibit surging behavior, and these surge-type glaciers are clustered in specific glacierized regions. Although surging is more common in valley glaciers, outlets from ice sheets have also been reported to surge.

A *surge-type glacier*, *surge glacier*, *galloping glacier*, or *pulsating glacier* in Russian literature experiences glacier surging or displays morphological evidence that it did so in the past. A surge-type glacier can either be in its surge phase or in its quiescent phase.

A *surging glacier* is in the surge phase of its surge cycle and experiences fast flow and possibly a marked frontal advance. However, this term is sometimes used interchangeably with *surge-type glacier*.

A *normal glacier* or *non-surge-type glacier* does not exhibit surge behavior.

Surge onset/initiation and *surge termination* refer to the start and the end of a surge phase.

A *surge bulge* is a region of thickening that can develop between the reservoir and receiving zones, and which travels downglacier as the *surge front* after surge initiation. Sometimes, a *fore-bulge* develops in the region of compression directly downstream of the surge bulge.

Introduction

Average ice flow velocities for valley glaciers are generally less than a few hundreds of meters per year (m a^{-1}) and for outlet glaciers up to several kilometers a year (Paterson, 1994). Most glaciers have seasonal velocity fluctuations, with the faster flow occurring in the early melt season. Theoretically, glaciers discharge ice from the accumulation area to the ablation area in order to maintain a steady-state glacier profile: this is the balance flux. The corresponding velocity, the balance velocity, is controlled by mass balance conditions and glacier geometry (Clarke, 1987). Studies that model glacier and ice sheet response to climate change often assume that these ice masses flow with speeds corresponding to their balance velocities. Although this is approximately true for most glaciers, in some glaciers the balance flux is much higher than the measured fluxes. If this occurs over a prolonged time, a flow instability can occur through a series of positive feedback mechanisms in the glacier system, which results in pulsating behavior with sudden switches between slow and fast flow. Pulsating glaciers include unstable tidewater glaciers, ice streams, and surge-type glaciers (Clarke, 1987). The latter have internally triggered flow instabilities with a semi-regular cyclic recurrence period (Meier and Post, 1969). The surge cycle involves long periods (tens to hundreds of years) of quiescence, with slow flow velocities much lower than the balance velocity (10–500 m a^{-1}), interspersed with short (1–15 years) active periods, or surges, in which a 10–1000-fold increase in flow results in average velocities of more than 500 m a^{-1}, greatly exceeding the balance velocity (Meier and Post, 1969; Clarke, 1987; Dowdeswell et al., 1991).

Surge behavior has been identified since 1599 for Vernagtferner, Austrian Alps (Hoinkes, 1969), since the eighteenth century in Iceland (Thorarinsson, 1969) and the Caucasus (Glazovskiy, 1996), and for centuries in the oral history of the Tlingit, Alaska (Cruikshank, 2005). The first scientific reports on surging are from observations in Svalbard and Alaska (De Geer, 1910; Tarr and Martin, 1914). Progress in the overall understanding of glacier surging has been summarized in four overview papers (Meier and Post, 1969; Raymond, 1987; Sharp, 1988; Harrison and Post, 2003).

Glacier surging is of great importance in the understanding of ice flow dynamics, as the sudden switches between the slow and fast flow modes reflect dramatic changes in the ice flow processes that are caused by only small changes in the driving stress (Raymond, 1987). It is still elusive what exactly triggers these sudden switches in flow mode, but a number of controlling processes have been identified and substantiated by field evidence. Surging is further considered analogous to modern and past ice stream behavior, where switches between flow modes occur with a cyclicity of hundreds to thousands of years (Boulton and Jones, 1979). Surge-type glaciers are also important as their behavior can obscure the climate signal, and because they can cause a number of natural hazards.

The surge cycle

From detailed field and remote sensing measurements and observations of a small number of well-studied surge-type glaciers, integrated with common patterns from general observations on a large number of surge-type glaciers, a generalized description of glacier surging has been developed that encompasses all surge-type glaciers, although individual surge behavior can vary. This common pattern

is one where the generic surge cycle can be divided into the following three phases:

1. *The buildup phase*, where the glacier profile steepens as a result of a restricted outflow (Meier and Post, 1969). In this phase, the glacier can be divided into an active thickening zone (reservoir zone) and nearly motionless depleted zone (receiving zone), separated by a boundary zone, also called the trigger zone or Dynamic Balance Line (DBL) (Dolgoushin and Osipova, 1975). The reservoir and receiving zones usually do not coincide with a glacier's accumulation and ablation zones, which are separated by the equilibrium line, but instead, the DBL is located where the glacier outflow is restricted (Clarke et al., 1984). A marked ramp of ice, a surge bulge, up to tens of meters in height can form at this boundary (Dolgoushin and Osipova, 1975; Clarke et al., 1984; Murray et al., 1998). In the late stages of this phase, the glacier is on the verge of flow instability and basal shear stress is high. Short periods of speedups, called "mini-surges", can appear, in conjunction with basal water pressure fluctuations and vertical uplift of the glacier surface (Kamb and Engelhardt, 1987). However, it is not clear if these "mini-surges" are directly correlated with the main surge event, as similar sudden switches in flow speed have also been observed in non-surge-type glaciers as a result of seasonal changes in water input to the glacier (e.g., Iken, 1981).
2. *The surge phase*, where the ice is transported from the reservoir to the receiving zone, and ice velocity increases abruptly (Kamb et al., 1985) or gradually (Murray et al., 2003). A surge often initiates in the upper regions and propagates downglacier as a surge front, but sometimes a surge propagates upglacier too (Hodgkins and Dowdeswell, 1994). Above the surge front, ice flow is extensional, resulting in transverse crevassing, while below the surge front ice flow is compressive. A glacier in full surge is often completely crevassed. When the surge front reaches the terminus a marked frontal advance can take place (Meier and Post, 1969). During the surge phase, the glacier becomes less steep due to down-draw in the upper region and thickening of the lower region. The surge termination can either be abrupt, with a sudden slowdown to pre-surge velocities and accompanied by a measurable drop in the ice surface and outburst floods (Kamb et al., 1985), or gradual and extending over months to years (Murray et al., 2003).
3. *The stagnation and depletion phase* is in the first (tens of) years after a surge, where the glacier is virtually stagnant. Crevasses close during this phase, and rapid depletion of the lower regions and a frontal retreat can cause temporary acceleration in the overall ablation rate (Yde and Knudsen, 2007). Part of the lower glacier can detach and be left as dead ice (Weidick, 1988). During this stagnation phase, the glacier surface may look irregular and pitted, partly due to the recent closing of crevasses and related surface drainage patterns (Liestøl et al., 1980; Sturm, 1987; Weidick, 1988). The ice may also become debris-covered, and medial moraines in the ablation zone tend to tower high above the depleted glacier surface (Dolgoushin and Osipova, 1975).

Individual surge characteristics

There is a large variability in the duration of quiescent and surge phases as well as in the velocity development during surges. Although for most individual glaciers the surge cycle (recurrence period of the surges), surge propagation (velocity development), and surge extent and/or maximum advance are similar, large variations occur between and within regions (see Table 1). Even two surge-type glaciers that share accumulation areas do not necessarily surge simultaneously (Paterson, 1994). In fact, the behavior of surge-type glaciers is so diverse and includes such a wide range of surge phenomena, that some argue that it might be necessary to redefine the classical concept of glacier surging and broaden it into a spectrum of flow instabilities. In such a spectrum, glacier surging is part of a continuum that ranges from normal (slow) glacier flow to permanently fast glacier flow.

The highest recorded surge velocity is 125 m d^{-1} for Brúarjökull, Iceland, which also had one of the fastest frontal advances of 10 km in 1 year with maximum advance rates of 1–5 m h^{-1} (Thorarinsson, 1969). The largest recorded advance was ~21 km and observed for Bråsvelbreen, Svalbard (Schytt, 1969) and the fastest daily frontal advance was 105 m d^{-1} for Medveziy glacier, Pamirs (Dolgoushin and Osipova, 1975). In contrast, surge velocities of only 0.1–5 m d^{-1} have been recorded in other regions (Table 1).

Typical surge cycles vary dramatically between regions (Figure 1). The recurrence period of surges in Svalbard is much longer than in other regions (50–500 years instead of 15–50 years), and the surge phase lasts 3–15 years as compared to 1–3 years in other, more temperate, regions (Dowdeswell et al., 1991 and 1995). Furthermore, most Svalbard surge-type glaciers have an overall "sluggish" character, with lower surge velocities, slow initiation, and slow and indistinct termination (Dowdeswell et al., 1991; Murray et al., 2003). A possible exception to this is the 2003–2005 Skobreen-Paulabreen surge, though it is believed to have had a long (>10 years) initiation phase (Benn et al., 2009). For Greenland and the Karakoram, longer surge and quiescent phases have been inferred as well, though not for all glaciers (Weidick, 1988; Jiskoot et al., 2001; Yde and Knudsen, 2007; Hewitt, 2007). Icelandic glaciers have irregular quiescent intervals; 5–30 years for some glaciers, and up to 100–140 for others, while surge advances can be up to 6 years (Björnsson et al., 2003). Mass balance, hence climate, can influence the recurrence interval of surges (Dowdeswell et al., 1995; Harrison et al., 2008) and is suggested to have caused

Glacier Surging, Table 1 Surge characteristics of a selection of surge-type glaciers worldwide, sorted by geographic region: [1]Svalbard, [2]Pamirs, [3]Karakoram, [4]Alaska, [5]Yukon Territory, [6]Greenland, [7]Iceland (After Jiskoot et al., 2001)

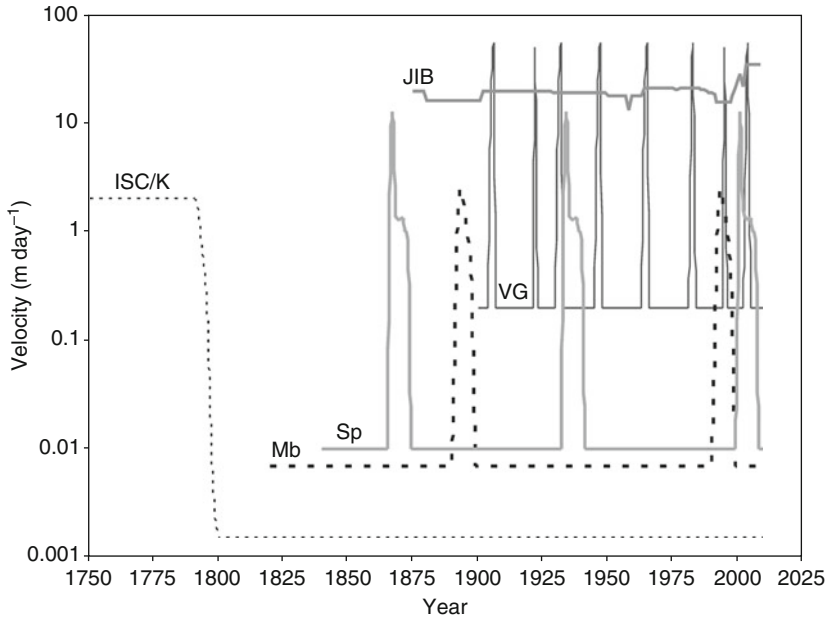
Note: Trapridge[a] is from the 1940s surge and Trapridge[b] from the 1980s to 2000s slow surge (Frappé and Clarke, 2007).



Glacier Surging, Figure 1 Schematic typical velocity fluctuations (logarithmic scale) of ice streams and surge-type glaciers (ISC/K = Ice stream C/Kamb ice stream, Antarctica; JIB = Jakobshavn Isbræ, Greenland; Mb = Monacobreen, Svalbard; Sp = Sermeq peqippoq, East Greenland; VG = Variegated Glacier, Alaska. Timing of pre-1990s surges of Mb and Sp are based on estimated quiescent phases of 100 years (Mb) and 60 years (Sp).

glaciers to change from having surge type to having normal behavior (Jiskoot et al., 2000; Hansen, 2003).

Very short pulses in flow velocity, usually up to a few weeks, that travel downglacier as kinematic waves, are by some coined "mini-surges" (Kamb and Engelhardt, 1987). Dynamically mini-surges show strong similarities to real surges, and some, but not all, may precede a surge (Kamb et al., 1985). Some Greenland glaciers are suggested to have a "periodic" surge on top of a "permanent" surge (Weidick, 1988).

Surges can be differentiated on the basis of the velocity development and concomitant surge characteristics. In a broad sense, surges can either have a two-phase surge cycle, with an abrupt switch between quiescent velocities to surge velocities, sustained fast flow during the surge, with possible fluctuations, and a rapid surge termination (Kamb et al., 1985; Eisen et al., 2005), or a three-phase surge cycle, with a long quiescent phase, an acceleration phase over months to years to peak surge velocity, and a deceleration phase where velocities gradually decline to quiescent phase velocities (Murray et al., 2003; Jiskoot and Juhlin, 2009). These two types of surge cycles and their development have been used to hypothesize that there are at least two different types of surge mechanisms: the Alaskan-type for two-phase surges, and the Svalbard-type for three-phase surges (Murray et al., 2003). Variegated Glacier, a temperate land-based soft-bedded glacier in Alaska, and Monacobreen, a soft-bedded polythermal (subpolar) glacier in Svalbard, can be used as archetypical examples of these types of surge behavior.

Variegated Glacier 1982–1983 surge

Variegated Glacier's surge proper started in the upper glacier with frequent icequakes and increased motion in January 1982, but was preceded by mini-surges for months (Kamb et al., 1985). The location of surge initiation coincided with a bedrock sill. After initiation, a steep (15°) surge front traveled downglacier, creating a leading edge of extremely high longitudinal compression (Raymond, 1987). Rapid velocity increase occurred in early spring, and was followed by rapid deceleration in late June and gradual deceleration until September. Renewed acceleration occurred between October 1982 and May 1983, culminating in peak velocities in June 1983. The surge terminated abruptly at the height of the melt season (mid-July 1983). Surge velocities varied between 10 and 50 m d^{-1}, with maximum velocities of up to 65 m d^{-1} (Kamb et al., 1985). Dye trace experiments, borehole water level measurements, and proglacial hydrological observations revealed that before the surge, the water drained subglacially in an effective low-pressure conduit system, while during the surge high water pressures around overburden occurred consistently, and the basal water flow was retarded and laterally dispersed (Kamb et al., 1985). Peaks in water pressure coincided with oscillatory pulses in glacier movement, and sudden increases in horizontal flow were accompanied by vertical uplifts of the glacier surface, while slowdowns were accompanied by small increases in proglacial discharge. Surge termination was marked by a drop in the ice surface, and coincided within days with a massive outburst flood of

turbid water. After the surge termination, the effective low-pressure drainage system was reestablished, but mini-surges occurred a year after surge termination. Variegated Glacier's 1982–1983 surge occurred in two annual cycles with the peak surge velocities in the second summer. At least two other surges (1964/1965 and 2003/2004) occur in this configuration (Eisen et al., 2005; Harrison et al., 2008). It has undergone eight 1–2-year surges, where the surge intervals of ~15 years appear to be regulated by cumulative mass balance and glacier geometry, at least as long as the preceding surge was "complete" (Harrison et al., 2008). The surge advance is generally ~2 km, and surge velocities 100-fold quiescence velocities.

Variegated Glacier's surge is characterized by a direct link between the subglacial water system and velocity development, and both the winter initiation and summer termination of the surge are rapid events. Surge development and characteristics of a number of other Alaskan glaciers (Harrison and Post, 2003), Medvezyi glacier, Pamirs (Dolgoushin and Osipova, 1975), and Sortebrae, East Greenland (Jiskoot et al., 2001) are similar to that of Variegated Glacier.

Monacobreen 1990s surge

Monacobreen had a months-long acceleration phase (September 1991 to March 1992), and years-long deceleration phase (January 1994 to October 1997 and beyond), punctuated by an increase in flow rate between December 1995 and May 1996 (Murray et al., 2003). Both the surge initiation and termination transitions appear very gradual. The surge started gradually but simultaneously over the entire lower region of the glacier and then propagated upglacier: there was no evidence of a surge front traveling downglacier (Murray et al., 2003). The spatial pattern of both velocity and strain rates were very consistent, and velocity highs and lows remained fixed in location throughout the surge. There was no evidence of elevated subglacial water pressure, or short-lived velocity fluctuations. The increase in velocity during the acceleration phase was about three times faster than its decrease in the deceleration phase. Quiescence velocities are estimated 0.006 to 0.008 m d^{-1}, while maximum measured surge velocities were only 5 m d^{-1}. Surge advance was about 2 km and surge duration 7–11 years (Murray et al., 2003).

Surge development and characteristics of a number of other Svalbard glaciers (Murray et al., 2003), Trapridge Glacier, Yukon Territory (Clarke et al., 1984), as well as Sermeq peqippoq, East Greenland (Jiskoot and Juhlin, 2009) are similar to that of Monacobreen.

Slow surges

Some glaciers have a very slow, incomplete surge-like development, which can only be classified as a "surge" with high-accuracy geodetic measurements. In these glaciers, the surge phase lasts 20 years or more and surge velocities are only five to ten times higher than in quiescence. No marked frontal advance occurs. However, a measurable down-draw of the upper region occurs and a volume is transported from the reservoir to the receiving zone. These "slow" or "partial" surges have only been measured in polythermal glaciers in the Yukon Territory and Svalbard (Frappé and Clarke, 2007; Sund et al., 2009).

Morphological evidence for surging

Many glaciers are situated in remote locations, and even with the modern capabilities of remote sensing a surge may be completely missed or be well under way before it is detected. In addition, a glacier in surge often becomes inaccessible for field research because of rapid movement and crevassing. Fortunately, surge-type glaciers show distinctive geometries and surface characteristics resulting from the changes taking place throughout the surge cycle. This morphological evidence for surge behavior can be detected, both in the surge and quiescent phases, from high-resolution satellite imagery and aerial photographs.

Morphological evidence for surging exists primarily in the form of the appearance of surge-type glaciers (their gradient, overall geometry, surface features, and crevasse patterns) and of surge-related features in the glacier forefield. Whereas some of these morphological features are diagnostic for surging, others could potentially be caused by other dynamic behavior and should only be used in combination with other clear evidence for surging.

Surface gradient and geometry

The surface gradient of a surge-type glacier gradually becomes steeper during quiescence, and rapidly becomes shallower during the surge. Most surge-type glaciers show rapid down-wasting of the frontal area just after a surge, and extensive stagnant tongues during the rest of the quiescent phase (Clapperton, 1975; Meier and Post, 1969). During the surge phase, the glacier gradient is subject to a rapid down-draw of the upper regions and a thickening and potential advance in the lower region. Both end members of the glacier surface gradient are an indication that surge-type glaciers have no steady-state profiles (Paterson, 1994). Trimlines (remnants of snow, ice, and debris left hanging on valley walls), truncated and hanging tributaries, and double cone-shaped snow-avalanche deposits are indications of the dramatic drop in glacier surface during surges (Liestøl, 1969; Dolgoushin and Osipova, 1975; Gardner and Hewitt, 1990).

In some surging glaciers the surge bulge, or surge front, propagates as a wave downglacier and steepens with time. While on Variegated Glacier the ice compression below the surge bulge resulted in the formation of thrust faults, on Trapridge Glacier and Bakaninbreen, pronounced forebulges developed (Clarke et al., 1984; Sharp, 1988; Murray et al., 1998). The latter two are polythermal glaciers, and the surge bulge is at the boundary between a melted and a frozen bed (Clarke et al., 1984; Murray et al., 2000).

If the surge front reaches the glacier margin, the margin steepens and becomes convex (Dolgoushin and Osipova, 1975; Hagen, 1987; Raymond, 1987), and a considerable

advance can occur (Meier and Post, 1969). While convex fronts are typical for land-based surging glaciers, calving glaciers develop near-vertical ice cliffs (Hagen, 1987). Complex lobating of the glacier front and spreading of the glacier tongue have also been associated with surges, as well as thrusting of the surging glacier tongue over others or over dead ice (Kotlyakov, 1980; Sharp et al., 1988; Weidick, 1988).

See Table 1 for down-draw and thickening, surge-front propagation speed, and terminal advance measured for surge-type glaciers worldwide.

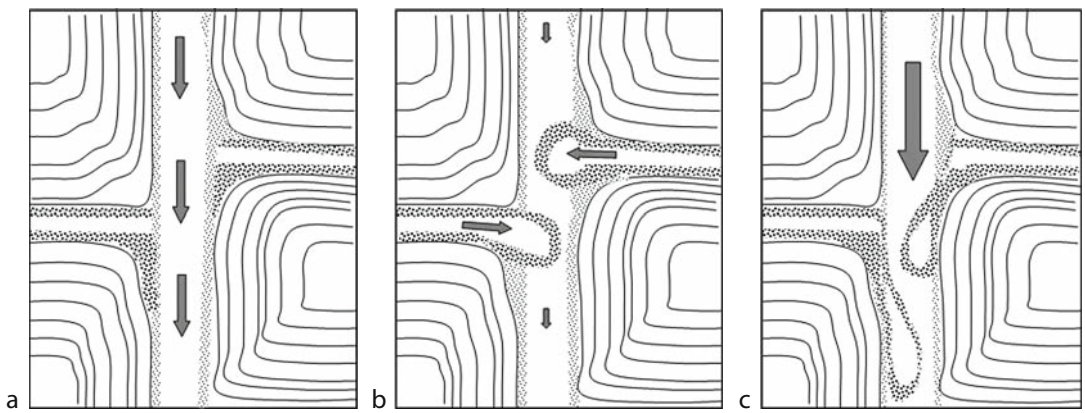
Surface features of surge-type glaciers

A range of surface features are indicative of surge-type glaciers. Most of these surface features can be observed any time during the surge cycle, but they are best developed during or just after a surge.

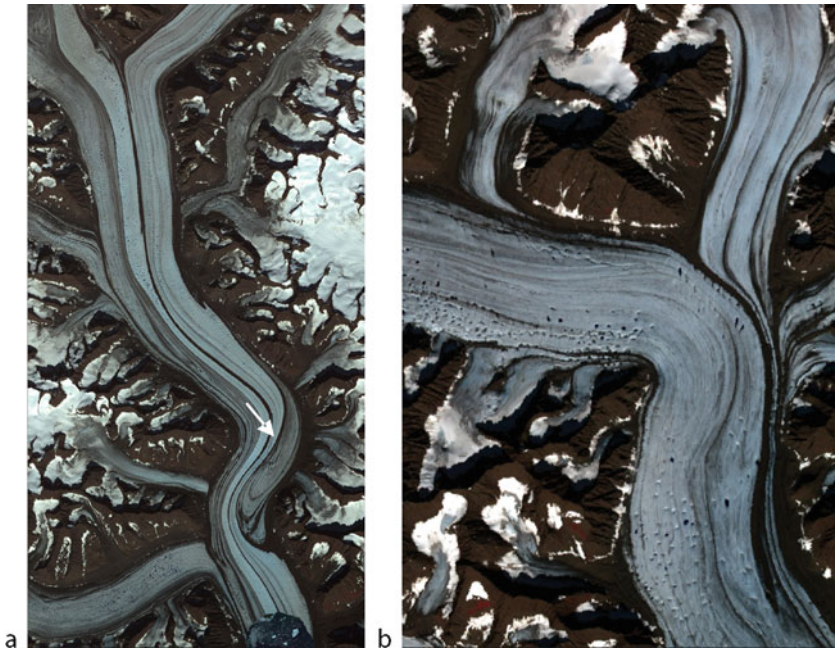
Crevasse patterns in a surging glacier are chaotic and often affect the entire glacier (Meier and Post, 1969). Characteristic crevasse patterns, fractured and pinnacled ice, and their evolvement during the active phase have been observed on numerous surging glaciers, and the orientations of crevasses have been used to investigate tectonic processes typical of surges (Sharp et al., 1988; Hodgkins and Dowdeswell, 1994). Peak crevasse density is often found at the surge front and a mixture of longitudinal and transverse crevassing behind the propagating surge front indicates high compressional stresses as the front arrives and extension as it is passing (Thorarinsson, 1969). In Variegated Glacier, extensional tectonics in the upper part lead to transverse crevassing, superimposed extensional and compressional tectonics at the surge front to intersecting transverse and longitudinal crevasses, while compressional tectonics in the terminus area lead to longitudinal crevassing (Sharp et al., 1988). Large transverse crevasses ("bergschrund") near valley walls are associated with the depression of the glacier surface during surge (Lefauconnier and Hagen, 1991). Active marginal shear is an expression of the block-like "plug flow" indicative of sliding through basal decoupling (Post, 1969; Kotlyakov, 1980; Kamb et al., 1985; Reeh et al., 1994). Transverse crevasses over the width of the glacier can separate the stagnant upper glacier from the surging lower part (Gardner and Hewitt, 1990). From the distribution of crevasse patterns, surge initiation zones have been derived (e.g., Hodgkins and Dowdeswell, 1994; Jiskoot et al., 2001).

Looped and contorted medial moraines are probably the most spectacular surface features of surge-type glaciers, and are considered diagnostic for surging (Meier and Post, 1969). Surge-type medial moraines only develop if supraglacial debris is available and if tributary glaciers are present. Due to the alternating flow regime in surge-type glaciers, a distinct pattern of elongated medial moraine loops is formed (Figure 2). During quiescence, tributaries protrude onto the surface of the stagnant trunk and form bulging moraine loops. During surges, these moraine loops are extended and transported downglacier on the trunk, and are transformed into elongated "tear-shaped" medial moraines (Gripp, 1929; Post, 1972; Figures 1 and 3). Straight medial moraines and loops on the lower tongue can be transformed into tight "accordion" folds during surges (Post, 1972). In late quiescence, medial moraines and moraine loops often stand as prominent ridges above the ice surface of wasted glacier tongues.

Undulations, lakes, and pothole fields can form on surge-type glaciers in quiescence as a result of the highly irregular glacier surface, closing crevasses, and drained supraglacial lakes (Meier and Post, 1969; Liestøl et al., 1980). Potholes or pits are deep circular to elliptic depressions with diameters in the order of 10–100 m (Sturm, 1987). Whereas potholes and lakes generally develop near the equilibrium line on normal glaciers, they are found far down into the ablation area or over the entire surface of surge-type glaciers (Meier and Post, 1969; Weidick, 1988). This gives some surge-type glaciers the appearance



Glacier Surging, Figure 2 Schematic development of surge-related elongated moraine loops. (**a**) normal flow, (**b**) stagnant trunk and active tributaries creating bulging moraine loops, and (**c**) surging trunk forming elongated tear-shaped moraine loops (After Gripp, 1929; Croot, 1988).



Glacier Surging, Figure 3 East Greenland surge-type glaciers on ASTER images of August 2004. Both glaciers flow downward. (**a**) Sortebræ with elongated tear-shaped moraine loop (arrow) ~10 years after its surge, and (**b**) glacier in quiescence covered in potholes.

of "Swiss cheese" (Weidick, 1997, personal communication, Figure 3). Supraglacial lakes can also develop in early surge, but often drain annually. After such annual drainage on Storstrømmen, NE Greenland, the pressure ridges formed from these lakes by katabatic wind were passively transported downglacier and formed a series of curved ridges, which could be used to estimate surge velocity (Reeh et al., 1994). Ice marginal and ice-dammed lakes can also be associated with surging (Kotlyakov, 1980; Hagen, 1987), especially if these suddenly develop and show extreme turbidity (Jiskoot et al., 2001). Some marginal lakes drain suddenly during surge termination, and can form jökulhlaup features and staircases of strandlines (Kamb et al., 1985; Sharp, 1988).

Proglacial features of surge-type glaciers

Iceberg production, dimensions, and debris content can all be regulated by the process of surging. While in quiescence iceberg production of calving surge-type glaciers can be much lower than that of normal glaciers, in surge, the iceberg production is enhanced due to an increased ice flux and the advance and increased flotation of the calving terminus. Dowdeswell (1989) argues that chaotic crevassing and close spacing of crevasses in surging glaciers enhance the disintegration of ice near the glacier margin, resulting in the production of smaller icebergs. However, Storstrømmen, NE Greenland, produced large tabular icebergs with tidal cracks (Reeh et al., 1994). This difference could be due to a fact that most Svalbard tidewater glaciers are grounded, whereas Storstrømmen is free floating (Reeh et al., 1994). Icebergs calving from glaciers in surge may also contain more debris-rich basal ice than normal glaciers (Dowdeswell, 1989), as the basal ice of surging glaciers is particularly debris rich (Clapperton, 1975).

The proglacial drainage system can undergo rapid changes in discharge and fluvial geometry during a surge. Release of large quantities of turbid water and debris-laden floods are recorded in conjunction with surges, and especially with outburst floods at the surge termination (Kamb et al., 1985; Hagen, 1987; Sharp, 1988). These events cause rapid changes in the proglacial glaciofluvial system and occasionally erosion of alluvial fans (Dolgoushin and Osipova, 1975). There is also evidence of triggering of landslides and mudflows by glacier surges (Kotlyakov, 1980; Gardner and Hewitt, 1990).

Push moraines and proglacial till features are useful in distinguishing between normal and surge-type glaciers in the quiescent phase, as long as they are prominent and not destroyed by subsequent surges. De Geer (1910) and Gripp (1929) already suggested that the extensive push moraines on Spitsbergen were the result of unusually fast glacier flow. These push moraine complexes consist of a series of arclike ridges marking the position of the farthest surge advance, and are evidence of a correlation between glaciotectonics and surging (Croot, 1988). Of note are the "Usherbreen type" moraines, where the surging glacier gradually moved over old terminal ridges to form marked concentric moraine crests (Hagen, 1987). Also in other regions, surge-related push moraine complexes have developed, as well as thrust-block moraines

(Evans and Rea, 2005). However, some push moraine complexes simply indicate the position of the glacier margin during the Last Glacial Maximum or the Little Ice Age (Lefauconnier and Hagen, 1991).

Surging glaciers have characteristic ice marginal sediment sequences, tectonic structure, and architecture (Sharp, 1988; Croot, 1988; Boulton et al., 1996), mostly by thrusting and glaciotectonism of fast advancing ice pushing into a preexisting foreland wedge. This results in a combination of brittle (faulting) and ductile (folding) deformation styles (Benediktsson et al., 2008). In some proglacial areas, dead ice overlain by till evolves into chaotic hummocky topography, on which distinctive rectilinear patterns of till ridges or debris bands can be observed. These are crevasse-fill ridges and reflect the orientation of crevasses in the surging glacier (Sharp, 1988). Smaller-scale features, such as drumlins, flutings, and accordion-eskers, are also related to surging and fast flow. Proglacial signatures of surging can even be found in marine environments (Boulton et al., 1996). On the basis of observations in the forefields of Icelandic surge-type glaciers, Sharp (1988) developed a sedimentation model, and Evans and Rea (2005) a landsystems model for surging glaciers. The sedimentation model links the following glacial sedimentation types to surging behavior: (1) high rates of bedrock erosion, (2) looped and accordion-style moraines, (3) thrusting and overriding of thick sediment sequences in the marginal zone, (4) extensive glaciotectonism, and (5) the formation of crevasse-fill ridges. According to the landsystems model, the geomorphological and sedimentological signature can be arranged in three overlapping zones: (a) an outer (distal) zone of thrust-block and push moraines, (b) a zone of hummocky moraines, and (c) an inner (proximal) zone of flutings, crevasse-squeeze ridges, and concertina eskers with hummocky outwash and remains of overridden zone (a) and (b) signatures.

Classification of surge-type glaciers from morphological evidence

Because of the degree of uncertainty of identifying surge-type glaciers on the basis of morphological evidence, a surge probability index with six classes, rather than a binary surge type and non-surge-type (normal) classification, was developed (Ommanney, 1980). Surge probability is based on the strength of surge evidence, which ranges from an observed surge to complete absence of surge-related morphological evidence. Regional surge classifications with two to six class probability indices have been used for statistical analysis of glacial and environmental controls on surging (e.g., Clarke et al., 1986; Jiskoot et al., 2001).

Hazards related to glacier surging

Surging is associated with a wide range of natural hazards, including outbursts of glacier-dammed lakes (Bruce et al., 1987), deadly rock/ice avalanches (Haeberli et al., 2004), damming and freshening of fjords (Motyka and Truffer, 2007), and overriding of forests (Fleisher et al., 2006). Discharge of large volumes of icebergs from surging glaciers (Table 1) can affect shipping and exploration, and if surging glaciers in the Denali Fault region were to damage the Alaska Pipeline, a major environmental hazard would result.

Why do glaciers surge?

Glazyrin (1978) and Clarke et al. (1984) proposed that downstream resistance to sliding is the cause of surge-type glaciers' unstable flow behavior. Factors that control resistance to sliding and restrict outflow fall into two groups: fixed factors (bedrock topography, valley shape, etc.), and changeable factors that can vary their degree of resistance or spatial location or both (Murray et al., 2003). Possible restrictions in outflow therefore include: (a) factors intrinsic to the glacier (thermal regime, efficiency of hydrological system, etc.), (b) bedrock and substrate properties, (c) valley shape, and (d) interaction with tributary glaciers.

"Sticky spots" are a special type of higher-than-average bed friction. Ideas about "sticky spots" range from bedrock bumps, cavities, thermal lows, and local pressure dips in hard beds to absence of water, increased substrate stiffness or local absence of deformable till (Alley, 1993; Murray et al., 2003; Kjær et al., 2006). Some consider "sticky spots" to be ephemeral in nature, that is, that they can be created and destroyed in response to variations in subglacial water pressure; however, the spatial distribution of velocity lows (sticky spots) and highs (slippery spots) remained fixed throughout the surge of Monacobreen (Murray et al., 2003).

Tributaries that protrude into a quiescent trunk can cause significant longitudinal compression upstream of the confluence, and this process may have the potential to block outflow of the trunk (Gripp, 1929; Glazovskiy, 1996; Jiskoot et al., 2001; Hewitt, 2007). Although statistical tests of the presence of tributaries and surge potential have been inconclusive, entrance angle, slope, depth, relative size, and entrance location may be important factors in determining whether or not a tributary can block a trunk, or vice versa (Kargel et al., 2005).

Flow in surge-type glaciers is governed by longitudinal stresses (pushing and pulling) rather than by basal shear stress alone (Budd, 1975; McMeeking and Johnson, 1986). Local stress gradients can be very sharp at the surge front, and surges tend to initiate at this discontinuity between high and low drag. According to a longitudinal stress model (McMeeking and Johnson, 1986), the rapid up- and downglacier spreading of the low drag region during the surge results in the basal and longitudinal stresses to fall below a critical value, at which the surge terminates. In addition, the attenuation of longitudinal stresses over longer distances might hold a clue to geometrical controls on surging (Jiskoot et al., 2000).

Although they may not be the primary trigger of surges, large rockslides may increase the basal shear

stress to a critical value to enhance sliding, and it has been suggested that they can cause surge-like accelerations (Hewitt, 2009). Since widespread occurrence of rockslides can coincide with the occurrence of large magnitude earthquakes, the long contested "Earth Quake Advance Theory" (Tarr and Martin, 1914) might have some validity after all, though likely only very exceptionally (Post, 1967).

Geographic distribution of surge-type glaciers and controls on surging

Only about 1% of glaciers worldwide are of surge type (Jiskoot et al., 2000), but ongoing research, especially that using advances in remote sensing, adds small numbers of surge-type glaciers to the existing lists on an almost yearly basis. Surging occurs in a wide variety of glacier types and sizes; however, the spatial distribution of surge-type glaciers is nonuniform on both global and regional scales (Post, 1969; Clarke et al., 1986). Most areas are devoid of surge-type glaciers, but clusters of surge-type glaciers exist in Alaska, the Yukon Territory, the Central Andes, Tien Shan, Pamirs, Kamchatka, Karakoram, Iceland, Svalbard, the Canadian and Russian High Arctic, and peripheral to the Greenland Ice Sheet. Within these regions surge-type glaciers are believed to comprise between $<1\%$ and 90% of the total glacier population (Liestøl, 1969; Weidick, 1988).

This geographic clustering suggests that some environmental control(s) exist(s) that make glaciers more likely to exhibit surge-type behavior in certain regions than in others (Post, 1969). Mass balance characteristics in relation to glacier geometry and thermal regime, as well as substrate and topography are likely to be different for surge-type glaciers and can be tested through glacier population analysis. Potential controls cover a range of dependent (glacier system-related) and independent (environmentally related) variables that relate to the distribution of glaciers and affect glacier movement.

According to Raymond (1987), the geometrical evolution of a glacier should be the overriding surge control, with critical geometries for both surge initiation and termination. Budd (1975) suggested that the product of glacier slope and balance flux over width controls surge potential, where this product is constant, irrespective of glacier geometry. Although long glaciers, those in tectonically active mountain ranges, and those with particular hypsometries have a higher likelihood of surging (Post, 1969; Glazyrin, 1978; Clarke et al., 1986; Jiskoot et al., 2000), neither a single characteristic nor combinations thereof can explain the distribution of surge-type glaciers satisfactorily. Combinations of factors that raise the likelihood of surging appear to be regionally specific, and might be an expression of different surge mechanisms (Murray et al., 2003). Since statistical studies use glacier inventory data that include surge-type glaciers in all stages of their surge cycle, the question of critical geometry will likely not be answered with this type of analysis.

Surge mechanisms

The occurrence of surging in a wide range of glaciers and environments suggests that flow instabilities could potentially occur in different components that control glacier flow. Since the 1970s, glaciologists have focused on three broad groups of ideas about the instability mechanisms:

1. Thermal instability
2. Hydrological instability in the subglacial drainage system
3. Instability of a deformable substrate

These surge mechanisms reflect the different types of glaciers that have been observed surging: glaciers overlying different types of beds, valley glaciers versus outlet glaciers, and polar/polythermal and temperate glaciers. Any surge theory should encompass any combination of these three potential instability mechanisms. It was not until the 1980s that any of the proposed surge mechanisms were firmly based on direct measurements of surge/quiescence behavior and on the laws of physics. "Plug flow" (ice flow being relatively uniform across glacier during a surge) and strong shear margins were an indication that basal motion rather than internal deformation or fast creep is the dominant flow process during a surge (Clarke, 1987). This suggests that high basal water pressures might be instrumental in all three mechanisms.

Thermal instability

Robin (1955) argued that surges could be explained by the oscillation of the basal temperature between subfreezing conditions where no sliding is possible, and melting conditions, where sliding is possible. Some surging glaciers have "cold ring" thermal regimes, which is a polythermal structure with an inner core of temperate ice surrounded by a zone of cold ice frozen to bedrock (Schytt, 1969; Clarke et al., 1984). This cold ring may act as a frozen dam during quiescence, which may give in and lead to surging when the zone of temperate ice spreads due to increasing thickness and frictional heat generated in the buildup phase. Alternatively, the polythermal structure has also been suggested to act as a cold-dam preventing the discharge of subglacial water (Murray et al., 2000). As the surge progresses, the progressive thinning of ice will conduct heat from the bed into the cold ice again, through which sliding, and hence the surge, will discontinue.

Hydrological instability

Hydrological instability through lubrication by a subglacial water film (Weertman, 1969) is untenable, because such a water film is not stable under increasing water pressure (Walder, 1982). Instead, cavitation (ice-bed separation through the "hydraulic jack effect") could be controlling sliding velocity, whereby sliding is a multi-valued function of basal shear stress and effective pressure (Lliboutry, 1968; Bindschadler, 1983). Subglacial drainage systems can be distinguished by two types of pressure–flux relations: one

in which water discharge and water pressure are inversely related (the larger the water flux, the lower the pressure: a conduit system of R channels where drainage is fast and localized) and one in which these are directly related (the larger the water flux, the higher the pressure: a linked-cavity system where drainage is slow and dispersed) (Kamb, 1987). Rapid switches between these two drainage systems can occur. A multi-valued sliding law is one where two states of stable sliding velocity exist for the same basal shear stress: "slow sliding" for drainage through conduits and "fast sliding" for drainage through linked cavities. At critical values for the basal shear stress and effective pressure, expressed as an instability parameter or index, sliding could become unstable and switch to the fast sliding mode (Bindschadler, 1983; Kamb, 1987; Fowler, 1987). Thus, rapid switches between fast and slow subglacial drainage systems can result in rapid switches in mode of flow (e.g., at the onset or termination of a surge). This disruption of the hydrological system was originally proposed to explain surges in glaciers overlying hard beds only (Kamb, 1987). However, later observations suggest that most, if not all, surging glaciers are underlain by a soft bed (Harrison and Post, 2003), and that, at critical basal shear stress over soft deformable beds, rapid switches in subglacial drainage systems in till can initiate surges as well (Fowler, 1987; Eisen et al., 2005).

Soft bed deformation

Surges on deformable beds may be triggered in the region of elevated shear stress and water pressure through the destruction of subglacial drainage paths or drainage paths in the subglacial sediment (Boulton and Jones, 1979; Clarke et al., 1984), essentially making this mechanism a hydrologic instability as well. The elevated water pressure results in an increase in till deformability and increasing flow velocities. Because the deformation itself will destroy any possible water drainage ways, the water pressure will remain high and facilitate sustained fast motion. This rapid bed deformation can be pervasive and deep-seated (Truffer et al., 2000), but can also occur through plowing at the ice sediment or the sediment–bedrock interface (Fischer and Clarke, 1994; Kjær et al., 2006), or along internal stratigraphic boundaries (Fleisher et al., 2006). A requirement for this type of instability is the presence of a thick enough layer of fine-grained till and a substantial amount of water stored subglacially at high pressures (Truffer et al., 2000; Fowler et al., 2001). Progressive thinning of the till layer throughout the surge will result in decreased till mobility and eventually leads to surge termination.

Alaskan-type surges: temperate glacier surges regulated by subglacial hydrology and till failure

The velocity development of Alaskan-type surges is bimodal, with sudden switches between the slow and fast flow modes. Alaskan-type surges are generally of short duration (1–3 years) and have short quiescent phases (in the order of decades).

Kamb et al. (1985) postulated from the link between vertical and horizontal velocity, and hydrological characteristics during Variegated Glacier's 1982–1983 surge, that ice flow fluctuations were caused by the process of ice-bedrock separation (basal cavitation). The surge trigger would be a sudden switch in the subglacial drainage system from a conduit-dominated system to a distributed linked-cavity system, which would occur when the main conduit system outgrows itself, destabilizes, and collapses as a result of a sensitive relation between basal shear stress and water-flux-related stability of this fast and efficient drainage system (Kamb, 1987). Surge termination would occur when the conduit system reestablished through frictional heating by large volumes of water. Although this mechanism is, in retrospect, not supported by field observations, the central idea of a sensitive relationship between evolving basal shear stress and subglacial drainage system stability (whether under hard-bedded or soft-bedded glaciers) still holds (e.g., Eisen et al., 2005).

Since bed observations of Alaskan surge-type glaciers suggest that most, if not all, are underlain by a layer of deforming till (Harrison and Post, 2003), the Alaskan-type surging mechanism can clearly not be through ice-bedrock separation. Instead, a soft-bedded surge mechanism was proposed, in which surging in temperate glaciers is associated with the disruption of a soft deformable bed and the drainage system therein (Eisen et al., 2005, building on prior research). This surge mechanism is based on the fact that large amounts of water can be stored englacially, and can gradually move downward into the subglacial till (Lingle and Fatland, 2003), weakening the till's shear strength. At some critical basal shear stress (related to glacier morphology) a surge is promoted by the pervasive failure of the till. This will subsequently destroy the drainage system within the till, redistributing stress and till failure over a larger region, and rapidly leading to a widespread dramatic increase in soft bed deformation. The termination of an Alaskan-type surge is related to a combination of the progressive decrease of the basal shear stress due to the change in glacier morphology during the surge, and a sudden and large increase in the water flux, reestablishing the efficient subglacial drainage system and strengthening the till (Eisen et al., 2005).

Svalbard-type surges: thermally regulated soft bed deformation

Svalbard-type surges have a typical three-phase surge cycle development, a long surge duration (>3 years), and long quiescence (several decades to over a century).

Observations of polythermal regimes and deforming sedimentary beds beneath Svalbard surge-type glaciers (Murray et al., 2000), and the fact that polythermal glaciers overlying sedimentary beds have higher probabilities of surging (Jiskoot et al., 2000), led to the hypothesis of a thermally regulated soft-bedded surge mechanism for

this region. This was verified by measurements on Bakaninbreen in quiescence (Murray et al., 2000) and Monacobreen in surge (Murray et al., 2003), but similar basal conditions also occur beneath Trapridge Glacier, Yukon Territory (Clarke et al., 1984). In East Greenland, a combination of Alaskan and Svalbard-type surges have been observed, and coincide with a transition in thermal regime from temperate to polythermal (Jiskoot et al., 2001; Jiskoot and Juhlin, 2009).

The thermally regulated surging mechanism develops as follows (Fowler et al., 2001; Murray et al., 2003): (1) During quiescence, the glacier is cold-based or polythermal. An increasing area of ice in the reservoir area thickens and reaches the pressure melting point. (2) Once the pressure melting point is reached, basal meltwater is produced. This leads to elevated pore water pressures and weakening of the underlying till, causing till deformation and dilation (weakening through expansion due to opening of pore spaces), which enhances water storage and further weakening. (3) Frictional heat produced by enhanced deformation results in further melting and rising of pore water pressures. (4) The positive feedback between basal motion and meltwater production continues and results in rapid basal motion and full surge development. (5) Through redistribution of ice during the fast flow, ice in the initiation zone will thin until increased heat loss results in refreezing at the glacier bed.

The restricting factors in the weakening of till layers are the thickness of the till layer, and the supply of water (Fowler et al., 2001; Kjær et al., 2006), while the restricting thermal factors are ice thickness and basal movement producing frictional heat. Since these factors change slowly, but progressively, glaciers with a thermally induced soft bed deformation surge mechanism have a typical three-phase surge cycle development.

Timing of surges related to surge mechanism

For Alaskan-type surges (temperate glaciers), surge initiation coincides with low water input into the system when the subglacial drainage system is not yet fully developed and is draining water ineffectively, while surge termination coincides with an abundance of meltwater and the reopening of channels (Kamb et al., 1985; Eisen et al., 2005). This suggests initiation in winter, or at least during absence of abundant surface water, and termination in summer (Raymond, 1987; Harrison and Post, 2003). More specifically, for Variegated Glacier, it has been calculated that surge termination timing is a combined function of total sum of positive degree days (PDD) and record hot days in the late ablation season (Eisen et al., 2005). In contrast, thermally regulated surges are not dependent on the influx of surface meltwater, but on reaching an overall critical thickness, and could therefore start and terminate in any season. However, no systematic comparative studies exist on the seasonality of surge initiation and termination related to surge mechanism.

Summary

Surge-type glaciers have a surge cycle that involves long periods of quiescence, with flow velocities much lower than the balance velocity, interspersed with short surges, in which 10–1000-fold increase of flow results in average velocities greatly exceeding the balance velocity. It is still elusive what exactly triggers these sudden switches in flow mode, but controls that have been identified and for which field evidence exists are thermal regime, configuration of subglacial hydrology, and bed deformation. Basal shear stress, the amount and distribution of subglacially stored water, and type of subglacial drainage system (within or above a soft deformable bed) appear crucial in the process of surging. Two main surge mechanisms have been verified by observations on surging glaciers in different regions: the Alaskan-type mechanism, a hydrological instability in temperate, soft-bedded glaciers, caused by till weakening and a switch in the subglacial drainage system, and the Svalbard-type mechanism, a thermally induced soft bed instability in polythermal (subpolar) surge-type glaciers.

Distinguishing surge-type from normal glaciers by remote sensing can be achieved for glaciers with clear development of the following surface features diagnostic for surging:

- A surge advance
- Elongated "tear-shaped" moraine loops and/or sheared off tributaries
- Trimlines of former ice surface hanging above the present ice surface
- A marked surge bulge
- A completely crevassed glacier (that was not entirely crevassed before)
- A sudden increase in iceberg production
- Potholes covering large parts of the glacier

Only a small percentage of glaciers worldwide are of surge type, and these tend to occur in geographical clusters. No single factor or combination of glacial or environmental factors has been found conclusive determinants of surging. Instead, controls on surging might be regional and related to specific surge mechanisms.

There still remain a number of unresolved questions in the understanding of surge behavior, and many that were posed in Raymond (1987) have not been conclusively answered. Some key questions include: (1) what are the triggers of the flow instabilities leading to surges; (2) which factors control surge initiation, propagation, and termination; (3) what are the critical thresholds between real surges and slow surges, and (4) how are restrictions in outflow related to surging? In the historic line of asking the questions: *What are glacier surges?* (Meier and Post, 1969), *How do glaciers surge?* (Raymond, 1987) and *How much do we really know about glacier surging?* (Harrison and Post, 2003) perhaps future overview papers could address the questions *Why and when do glaciers surge?* and *Why don't all glaciers surge?*

GLACIER SYSTEM

Rajesh Kumar
Remote Sensing Division, Birla Institute of Technology, Extension Centre Jaipur, Jaipur, Rajasthan, India

Each glacier system has its own unique characteristics but with common aspects, such as an accumulation zone and an ablation zone. In order for the glacier to be in equilibrium and have a net zero mass-balance, the mass balance

of water equivalent entering the accumulation zone at higher altitudes in the form of snow must equal to water equivalent leaving the ablation zone. The bigger glaciers also possess the tributary glaciers and have larger glacier system. Hence, glacier's systems are inputs, stores, transfers, and outputs.

Glaciers gain mass as solid precipitation (snow) in the accumulation zone that transform into ice and then flow downhill as gravity flow. Apart from the snow fall, the accumulation zone also gets input from the snow avalanche from the valley side and by the accretion of rime ice by the direct freezing of atmospheric moisture onto the glacier. While coming down, it loses altitude and hence spreads into a higher temperature zone, which is called as ablation zone. The loss of glacier mass is by melting, as a result of warm air temperatures or applied pressure, evaporation, wind erosion, or by calving into icebergs along a floating ice front.

Glacier temperature is an important factor while considering the glacial system. Melt water, erosion, and deposition rates are directly related to the thermal behaviors in the glacier system.

GLACIER TOE

Rajesh Kumar
Remote Sensing Division, Birla Institute of Technology, Extension Centre Jaipur, Jaipur, Rajasthan, India

Glacier toe is the lowest end of a glacier and alternatively called as glacier snout or terminus (Figure 1). The surface streams growing from the snow and ice fields enter into the moulin or crevasse to become the englacial or subglacial flows and emerge out at the glacier toe. Due to this meltwater path, ice caves are formed at glacier toe (Figure 2). There is a general assumption that glacial erosion ends near the toe of a glacier where moraine deposition begins. The glacier toe fluctuations are also representative of the glacier's advance or retreat.

The movement of a glacier's toe back toward the glacier's origin shows the glacier retreat, and forward from the glacier origin reflects the advance of the glacier. If there is no change in the glacier toe position, it is roughly an estimate of glacier in zero balance.

GLACIERS OF THE KARAKORAM HIMALAYA

Kenneth Hewitt
Cold Regions Research Centre, Wilfrid Laurier University, Waterloo, ON, Canada

Definition and introduction

The South West Central Asian mountain system supports several major concentrations of glaciers at high altitude. The largest is in the Greater Karakoram-Hindu Raj, with almost 18,500 km^2 of perennial snow and glacier ice (Table 1). Here are some of the largest valley glaciers outside high latitudes. There are over 5,000 individual glaciers, but the ten largest comprise a third of the cover. Available measurements show maximum ice thicknesses exceeding 1,000 m on glaciers longer than 60 km, and over 500 m in glaciers half as long (Hewitt et al., 1989).

Glaciers of the Karakoram Himalaya, Table 1 Estimates of the perennial *snow and glacier* areas of the Karakoram and adjacent ranges of the South West Central Asian Mountain System (after von Wissmann, 1959)

Mountain range	K. Hewitt Revised (2007)	von Wissmann
1. Greater Karakoram ("Mustagh")[a]	15,500	(13,655)
2. The Western Karakoram[b]	2,950	(1,480)
Karakoram total	*18,450*[c]	*(15,135)*
3. The Hindu Raj[d]	950	(2,300)
4. Hindu Kush[e]	2,500	(3,900)
Total	21,900	(21,335)
Adjacent areas:		
5. Aghil Mts (Upper Yarkand River)		(1,700)
6. W.Tibet, Depsang, Pangong etc. (upper Indus basin)		(2,200)
7. Himalayan Deosai Mts/Ladakh/ Zanskar etc.		(1,700)
8. Nanga Parbat		(690)
9. Hazara. Indus and Swat Kohistan		(170)
Indus-Yarkand Basins	Total	(27,795)
10. Kun Lun		(14,500)
11. Pamir		(11,980)
Total, SWC Asian Systems		(54,275)

[a]West of the Upper Shyok River to the Hunza valley, north of the main Indus and south of the Shaksgam and Shimshal Rivers.
[b]West of the Hunza River to the Karambar, south of the Chapursan and north of the Gilgit – includes the Batura (740).
[c]*Karakoram draining to Yarkand River* about 1,500 km^2, leaving about 16,000 to Indus.
[d]West of the Karambar, south and east of the Yarkhun River (upper Chitral).
[e]Includes both Pakistan (Chitral) and Afghanistan slopes, but not very large glaciers. The share draining to the Indus is about 2,000 km^2. The remainder flowing to the Amu Darya ("Oxus").

The glaciers may comprise more than 2,000 km^3 stored ice volume and are major stores and sources of surface water in this extreme continental, dry region. However, most glaciers are nourished largely or wholly by snow avalanches from steep rock walls. This makes it difficult to separate permanent snow-covered and snow avalanche source areas from glacier ice and ice streams-proper, or to identify the full extent of the latter. Glacier-ice itself probably comprises less than half the total basin area estimates. Avalanche nourishment is related to another typical

feature, vast areas of debris-covered ice in the lower ablation zones.

The glaciers are part of a range of cryosphere conditions and features. The entire mountain area is covered with seasonal snowfall varying in duration and depth with elevation. Its melting provides about half of stream flows in an average year. Permafrost at intermediate altitudes is more extensive than glaciers and there is widespread patterned ground, hundreds of rock glaciers, erosion, and deposition forms left by snow avalanches. Most, if not all, of the region was glaciated in the Quaternary (Shroder et al., 1993; Kuhle, 2004). Glacier fluctuations in the Holocene also left their mark, especially "Little Ice Age" (LIA) advances (Kick, 1989).

An unusual concentration of surging glaciers is found (Hewitt, 2007a), and a history of ice dams and glacial lake outburst floods (Hewitt, 1998). Scientific work goes back 150 years, but coverage has been patchy in time and space (Visser, 1928; Mason, 1930; Paffen et al., 1956; von Wissmann, 1959; Batura Investigations Group, 1979; Goudie et al., 1984; Hewitt, 2007b).

Glacier climates

Three weather systems affect the region at different times of the year. Two systems bring the snowfall that nourishes the glaciers. A westerly circulation and cyclonic storms dominate the winter, while monsoonal air and storms can bring high altitude snowfall in summer (Mayewski and Jeschke, 1979; Barros et al., 2008). These systems are affected by continental anticyclones over and to the west of the Tibetan Plateau. Meanwhile, anticyclonic conditions bring high levels of solar radiation and nocturnal heat loss critical in summer especially, when clear-versus-cloudy weather is decisive in glacier ablation, direct solar radiations accounting for 80–85% of it. The three very different weather systems vary in relative strength from year to year, and with global climate change.

Equally important are topo-climates; conditions modified by high elevations, relief, and slope orientation. There are strong gradients in precipitation and thermal conditions with elevation (Figure 1). Watersheds of the larger glaciers are in the highest parts of the Karakoram between 6,500 and 8,000 m or more. These glaciers have globally extreme elevation ranges from 3,500 to over 5,000 m. Some termini reach below 2,500 m above sea level (asl); 1,500 m lower than the largest glaciers of Nepal, for example.

Low down, valleys are rain shadowed and semi-arid or arid, with as little as 170 mm annual precipitation. Glacier headwaters just a few kilometers away can receive snowfall up to 2,000 mm water equivalent (w.e.). Average daily temperatures above freezing occur for 7–8 months around 2,500 m asl; between 8 and 4 weeks at 3,800 and 4,800 m respectively, and are rare or absent above 5,000 m. Steep slopes and differences of orientation lead to further variability (Hewitt, 1993).

Mass balance considerations

Glacier mass balance is the relation between accumulation of snow on the upper glacier and ablation on the lower, moderated by the flow of ice in between. Measurements in the central Karakoram show rather more than half of high altitude snow accumulation in winter and somewhat less than half in summer (Wake, 1989). The glaciers are intermediate between the "summer accumulation types" of the Greater Himalaya and "winter accumulation" of

Glaciers of the Karakoram Himalaya, Figure 1 A predominantly avalanche-fed glacier; the upper Choktoi. This tributary of the Panmah Glacier, viewed from 4,500 m asl is hemmed in by rock walls and ice falls up to 7,200 m such that most of the snow descends to the glacier in avalanches. (Photo: Hewitt, June, 2005.)

the Caucasus to the west (Ageta and Fujita, 1996). Precipitation maxima occur in the accumulation zones between 5,000 and 6,000 m asl, much higher than in most of the world's mountains (Barry, 1992, 234).

The interface between the accumulation and ablation zones or equilibrium line altitude (ELA) is usually close to the firn limit, the greatest elevation(s) at which ablation removes all seasonal snowfall and temporarily exposes glacier ice. In the Karakoram, it is usually found at around 5,000 m and in late August, but much higher on south-facing slopes and lower on north-facing ones. The ELA was observed spread out between 4,700 and 5,300 m asl on the Batura Glacier (Batura Investigations Group, 1979).

On avalanche-nourished glaciers, the ELA is lower than the firn limit. Many Karakoram glaciers commence well below 5,000 m asl, linked to the perennial snow zone only by avalanche tracks (Figure 2). Indeed, the larger fraction of glacier ice derives from snow avalanched through 1,000 m elevation or more. However, there are no studies of the contribution of avalanche nourishment to mass balance and little is known of the relative scales and roles of winter, spring, and summer avalanches. They differ in thermal properties, the proportions of powder and wet snow, and debris content.

Ablation zones also involve large gradients with elevation. Some melting occurs for 8–10 months at around 2,500 m asl; for only 4–8 weeks in the most extensive and critical ablation zone areas, and declines to a few days near the ELA. Ablation rates are high under favorable conditions. On the Biafo Glacier, at 4,080 m asl in July, 50–90 mm of ice loss were recorded on clean to dusty ice in clear or slightly cloudy conditions (Hewitt et al., 1989; Hewitt, 2005). Annual ablation here is 5–7 m (w.e). Potential ablation is highest towards glacier termini. Locally, as much as 18.4 m/year was measured near the Batura Glacier terminus (Batura Investigations Group, 1979), but heavy supraglacial moraine suppresses overall melting to just a few centimeters annually. This partly explains the low altitude penetration of many termini (Figure 3). However, dust and thin layers of dirt are more important hydrologically, being decisive in the mid- to upper ablation zones where 70–80% of ablation occurs. Dust particles enhance local absorption of solar radiation and a thin veneer of wet mud can increase ablation rates by over 40% compared to clean ice (Mattson and Gardner, 1989). Dust and dirt on ice surfaces are very sensitive to weather conditions, being quickly washed away on cloudy days, even without rain, and quickly built up again on sunny ones. This also makes them more sensitive to climate change.

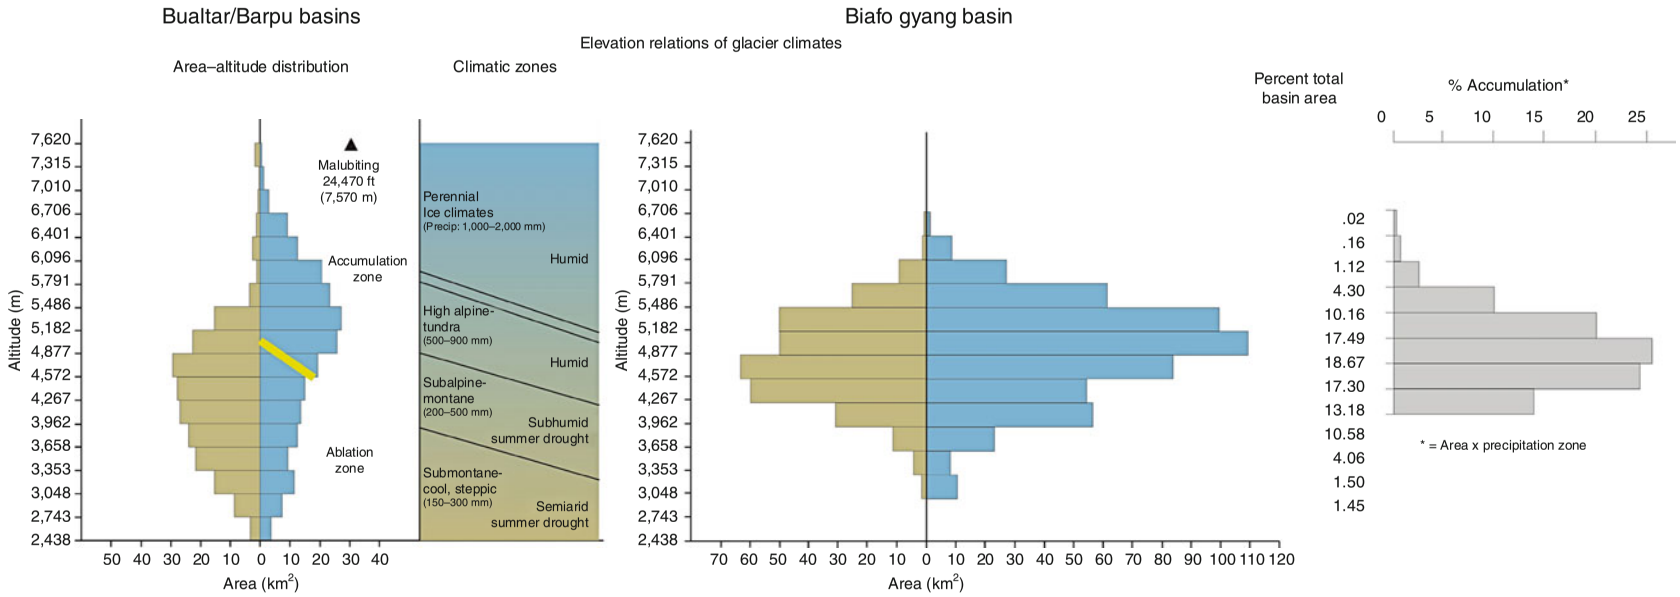
To summarize: mass balance in the Karakoram depends critically on events in certain elevations, roughly:

1. 4,500–6,000 m asl for accumulation and glacier nourishment
2. 3,500–4,300 m for ablation, where the most extensive exposed ice areas occur and where dust and dirt enhance ablation
3. below 3500 m, where most ice areas are protected by heavy supraglacial debris

Glacier thermal regimes

Climatic complexity has an indirect effect through ice thermal regimes. Paterson (1994) recognizes four classes,

Glaciers of the Karakoram Himalaya, Figure 2 Rapid buildup of supraglacial moraine in the mid-ablation zone of an avalanche-fed glacier: the Ghondogoro Glacier, Masherbrum range, viewed from 3,800 m asl (Hewitt, July, 2005).



Glaciers of the Karakoram Himalaya, Figure 3 Area-altitude distribution of Karakoram glaciers, and vertical organization of the climatic environment. The Bualtar-Barpu basin in the Rakaposhi Range, Hunza Karakoram, represents the commonest, largely avalanche-fed system. The much larger Biafo Glacier, in the central "Mustagh" Karakoram, is one of the few with a predominance of direct snowfall-fed ice streams from vast high altitude accumulation basins. Most of the measurements and dimensions cited in the text come from investigations in these two basins or nearby areas (after Hewitt, 2005).

commonly identified with different climatic regimes: "polar," "temperate," maritime, and continental. However, all four are present in the Karakoram, usually two in the same glacier, sometimes all four (Batura Investigations Group, 1979; Hewitt, 2005). Ice temperatures affect the deformation rate of ice, which increases with warming of ice below the melting point. Sub-zero ice tends to be frozen to the bed. Unfreezing can dramatically increase movement through sliding at the bed. At present the distribution and full influence of thermal regimes is not known.

Glacier hazards

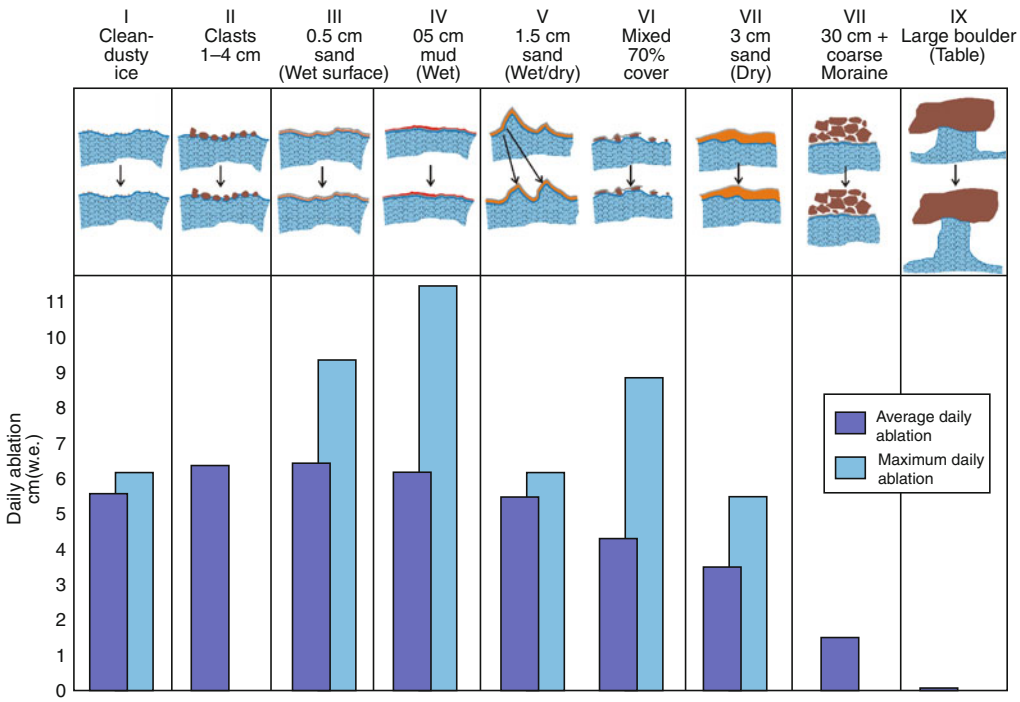
Among the distinctive and extreme glacial phenomena is a high concentration of glaciers that surge, and a history of glacier dams and outburst floods. In the past 150 years, 32 glacier surges are documented involving 20 glaciers. At least half the surges are of tributary glaciers whose main glacier does not surge, something not yet reported elsewhere (Figure 4). Known surges involve avalanche-fed glaciers. Theories of surging do not invoke a relationship to nourishment, but avalanched snow seems likely to affect the thermal character and debris content of glaciers – which are considered important factors (Sharp, 1988).

Over the past 200 years, 62 glaciers have formed partial or complete cross-valley barriers on Karakoram rivers. More than 60 glacier lake outburst floods (GLOFs) have been reported (Hewitt, 1982). GLOFs from the larger of these ice dams can far exceed weather-generated floods. However, the dangerous moraine-, or dead-ice-ponded lakes associated with rapid retreat in the rest of the Himalaya are locally significant throughout the Karakoram, but the most dangerous ones arise with large tributary glaciers advancing across and damming main river valleys.

Glacier activity and dangers are also affected by catastrophic rock slope failures in glacier basins (Hewitt, 2009b). Some 29 are known to have spread in part or whole over glaciers, and 11 between 1986 and 2009. It is certain the numbers are underestimated due to difficulties of observation, and because active ice rapidly disperses the landslide debris. If recent observations are at all representative, it seems likely that this has been a significant factor in glacier behavior, contributions to denudation, and deposition in the Quaternary.

Concluding remarks: a climatic and/or glacier anomaly?

Various studies suggest glacier fluctuations in the Karakoram are out-of-phase with events elsewhere in the Northern Hemisphere. It is suggested that only minor advances occurred here during the last major Wisconsinian/Wurm glaciation (Shroder et al., 1993), and that LIA advances culminated decades later (Kick,



Glaciers of the Karakoram Himalaya, Figure 4 Differential ablation rates due to the thickness and composition of surface dust, dirt, and debris on Biafo Glacier at 4,080 m asl in July 1986. Measurements were made at experimental plots over a 10-day cycle in sunny (maximum rates) and intermittently cloudy weather (after Hewitt, 2005).

Glaciers of the Karakoram Himalaya, Figure 5 Legacies of tributary glacier surges at Panmah Glacier, Mustagh Karakoram. The complex lobes, ridges, and crevasse patterns in the ice stream are the result of four surges (*arrows*) into the main glacier (see Hewitt, 2007a). They occurred in 1994, 2002, and 2005. The ice lobe from a 1970s event 10 km up the glacier to the right had arrived here when the recent ones occurred. The main glacier is 2.5 km wide and some 12 km of its length are shown. (Photo: Hewitt, July, 2005.)

1989). These views do involve contested evidence. Quaternary glacial sequences involve mistaking post-glacial landslide deposits for former ice positions (Hewitt, 1999, 2009a). The LIA anomaly is based on records from glaciers that surge and, therefore, not necessarily in phase with climate fluctuations anyway (Hewitt, 2007a).

Nevertheless, in recent decades reports from the Karakoram suggest little or no disappearance of ice, let alone a catastrophic reduction, unlike the rest of the Himalaya. Some 10% of the ice cover was lost between the early twentieth century and the 1980s. Since the mid-1990s, however, more than 30 glaciers have advanced, and substantial ice storage and reduced melting is indicated in the heavily glacierized Hunza and Braldu basins, and some glaciers on the Yarkand basin, north slope (Archer and Fowler, 2004; Hewitt, 2005; Liu et al., 2006). Glacier change there is, probably due to changes in seasonal snowfall, summer storminess and ablation, and high altitude warming. Yet, through 2009 at least, ice cover is being sustained and may be increasing. A major problem is lack of monitoring of high altitude climate and other controlling conditions in glacier basins to help disentangle the various forcing factors, and how they could affect future ice behavior.

GLACIERET

Rajesh Kumar
Remote Sensing Division, Birla Institute of Technology, Extension Centre Jaipur, Jaipur, Rajasthan, India

Glacierets are very small glaciers or ice masses of indefinite shape in hollows and have little or no movement for at least two consecutive years. Sometimes, it is also termed as a dead glacier. The thickness of the ice is also very less as compared to the normal glaciers. Glacierets are formed either by drifted snow or by snow that has avalanched from above and also under the heavy accumulation in certain years. Glacierets are also formed during the recession stage of the glaciers that has been associated with the climatic conditions and is responsible for the glacier recession after the little ice age. Glacierets commonly occupy cirques that were formed during past glaciations (Figure 1).

GLACIERIZATION

Rajesh Kumar
Remote Sensing Division, Birla Institute of Technology, Extension Centre Jaipur, Jaipur, Rajasthan, India

The word "glacierization" is frequently used as a process of glacier formation and growth, but it also has a meaning of "the covering of large land area by glaciers or ice sheets," that is, the process of glacier growth and development. The growth and decay of glacierization is driven by forces affecting the seasonal cycles of snowfall and snowmelt. The external controlling forces are likely to be variations in the earth's orbit that cause differences in the solar radiation received. Radiational control of snowmelt is also modulated by the seasonal cycles of snow albedo and cloud cover.

GLACIOEUSTASY

Amit Kumar
Department of Geology, Centre of Advanced Study in Geology, Punjab University, Chandigarh, Punjab, India

Glacioeustasy deals with the theory of sea levels rise and fall on the global scale in response to the melting of ice during interglacials and the accumulation of ice during glaciations. The implications of the changing of relative sea level are global in scope. The growth and decay of ice masses, such as glaciers and ice sheets, have direct influence on the changes in sea level. Since the last ice age, sea levels have gradually risen due to decrease in ice mass on the earth.

GLACIOFLUVIAL

Rajesh Kumar
Remote Sensing Division, Birla Institute of Technology, Extension Centre Jaipur, Jaipur, Rajasthan, India

The deposits and landforms or the streams that result by the action of melting glacier are known as glaciofluvial. The fluvial means "produced by the action of a stream," therefore, glaciofluvial simply means "produced by the actions of glaciers."

Glaciofluvial deposits are materials moved by glaciers and subsequently sorted and deposited by streams flowing from the melting ice. The deposits are stratified and may occur in the form of outwash plains, moraines (lateral, medial, and terminal), U-shape valleys, glacial and proglacial lakes, and terraces. Glacial and proglacial lakes are found in a variety of environments and in considerable numbers. Apart from the erosional lake, many lakes are formed as streams and dammed by the ice itself, by glacial deposits, or by a combination of these factors.

GLACIOGENIC DEPOSITS

Rajesh Kumar
Remote Sensing Division, Birla Institute of Technology, Extension Centre Jaipur, Jaipur, Rajasthan, India

The materials having heterogeneous sediments composed of an unconsolidated, heterogeneous mixture of clay, sand, pebbles, cobbles, boulders, and mounds of gravel deposited directly by the retreating glacier ice is called as till. Glacial drift is a general term for the coarsely graded and extremely heterogeneous sediments of glacial origin. Glacial till is that part of glacial drift, which was deposited directly by the glacier.

Till is commonly massive, ideally unsorted and unstratified sediment that may be deposited at the terminal moraine, along the lateral and medial moraines and in the ground moraine of a glacier (Figure 1). It is differentiated on particle size distribution, color, composition, cast shape, roundness, orientation and imbrications, and structure of the deposit. Sometimes, till plains also appear as extensive flat plains of till that form when a sheet of ice becomes detached from the main body of the glacier and melts in place depositing the sediments it carried. Glacial till can form very good soil for the crops to grow. Till may also contain alluvial deposits of gems or other valuable ore minerals.

Glaciogenic Deposits, Figure 1 Glaciogenic deposits, also called as Glacier Till is observed in Suru Basin, Jammu and Kashmir, India. (Photograph by Dr. Rajesh Kumar on July 1, 2008.)

GLACIOHYDRAULIC SUPERCOOLING

Fiona Tweed
Department of Geography, Staffordshire University, Stoke-on-Trent, Staffordshire, UK

Definition

Glaciohydraulic supercooling describes a process that occurs when the pressure melting point of water ascending the adverse slope of a subglacial overdeepening rises faster than the water is heated by viscous dissipation resulting in water remaining liquid below 0°C.

Theory and historical perspective

The theory of glaciohydraulic supercooling was first introduced by Röthlisberger (1972) and further developed by Röthlisberger and Lang (1987), Alley et al. (1998) and Lawson et al. (1998). Beneath thick *ice* at the base of a glacial overdeepening, the melting temperature is depressed by *overburden pressure* and water can continue to be liquid below 0°C (see Figure 1). The pressure gradient forces water to ascend the adverse slope of the overdeepening, and as the *overburden pressure* lessens, the pressure-dependent melting temperature gradually rises. If the adverse bedslope is more than 1.2–1.7 times the gradient of the ice-surface slope (Alley et al., 1998), then the heat generated for the water to remain in thermal equilibrium and the rate of increase in water temperature will be insufficient to match the changing pressure melting point and water will become supercooled (discussed in detail in separate chapter). As supercooled water approaches the *glacier* margin, it can freeze to the *glacier*, resulting in *ice* growth that constricts *meltwater conduits*, forms *frazil ice* and creates *anchor ice* terraces (Lawson et al., 1998; Evenson et al., 1999; Roberts et al., 2002; Tweed et al., 2005).

Glaciohydraulic supercooling has been well-documented at Matanuska Glacier, *Alaska* (Strasser et al., 1996; Lawson et al., 1998; Alley et al., 1999; Evenson et al., 1999), at Bering Glacier *Alaska* (Natel and Fleisher, 1994; Fleisher et al., 1997), and at several glaciers in Iceland (Roberts et al., 2002; Tweed et al., 2005) during normal meltwater flow conditions and during *glacier* floods. Criteria considered indicative of the process comprise water temperatures consistently below freezing despite ambient air temperatures well above freezing; *frazil* crystals and flocs in the discharged water and the growth of *anchor ice* terraces around artesian meltwater vents (Evenson et al., 1999). There is still debate regarding the significance of glaciohydraulic supercooling for the formation of thick basal *ice* sequences beneath temperate glaciers (Lawson et al., 1998; Tweed et al., 2005; Cook et al., 2007) and the role of supercooling in the *dynamics of glaciers* and the development of contemporary and Quaternary landforms and sediments (Lawson et al., 1999; Alley et al., 2003; Larsen et al., 2006; Cook et al., 2006; Knight and Cook, 2008).

GLACIOISOSTASY

Amit Kumar
Department of Geology, Centre of Advanced Study in Geology, Panjab University, Chandigarh, India

Glacioisostasy is defined as the alteration of the earth crust (lithosphere) through unloading and uploading of ice mass

during major glacial cycles, which attributed to addition and removal of glacial ice. In simplest term glacioisostasy represents the loading or unloading of ice. The worldwide process of glacial isostatic balance results in the process whereby the Earth's shape and gravitational field are made to order in retort to the large-scale changes in surface mass load.

GLACIOLACUSTRINE

Himali Panthri
Department of Geology, D.B.S (P.G) College, Dehradun, Uttarakhand, India

Definition

The term glaciolacustrine is used for the processes and sediments involving a lake that receives meltwater from a glacier.

Lakes are very common in glaciated landscapes. Unique to the glacial lakes is the fact that they receive a major portion of their annual water and sediments from meltwater. Lakes with some portion having direct contact with ice are called *ice contact* lakes, while those located at some distance from ice and fed by outwash streams are known as *noncontact* or *distal* lakes. Glaciolacustrine environments are generally divided into *marginal (proximal)* and *basinal (distal)* ones.

Basinal sub-environments are similar in all glacial fed lakes. Deltas form at the margins of both ice contact and noncontact lakes. Deposition in marginal sub-environment is dominated by mass movement and underflows. Subaqueous fans build where meltwater enters a lake at or near the base of the ice. Ice cliffs or ice ramps (where lake water covers stagnating ice) exist along ice contact lake margins.

In general, deposits formed by sediments carried in bed load of streams are called *glaciolacustrine bed load deposits* (e.g., delta) and those formed by suspended sediments in streams are called *glaciolacustrine suspended deposits*. *Bed load deposits* are the primary deposits during summers when the stream carries greater discharge due to melting while the *suspended deposits* are the major ones during winters due to less melting. Biogenic activities like pelletization, burrowing, may modify glaciolacustrine sediments.

GLACIOLOGY

Peter G. Knight
School of Physical and Geographical Sciences, Keele University, Staffordshire, UK

Definition

Glaciology is the scientific study of ice, including glaciers, sea ice, and snow.

The scope of glaciology

Defined broadly, glaciology is the scientific study of ice in all its forms, including glaciers, snow, ice in the atmosphere, ground ice in permafrost regions, sea ice, river ice, the ice that creates problems when it forms on the wings of aircraft, and the ice that keeps drinks cool on a summer afternoon. Attracting the attention of investigators from a wide range of disciplines, including Engineers, Geographers, Geologists, Physicists, Chemists, Meteorologists, Mathematicians, and Climatologists, glaciology is a broad subject. Defined in this way the term glaciology is synonymous with the term cryospheric science: the science of ice in the environment. However, cryospheric science includes distinct subfields that are usually considered independently. For example, permafrost scientists working on frozen ground (geocryologists) do not usually describe themselves as glaciologists. Their work is quite different from glacier scientists. They publish in different journals, using different methods and addressing different questions. In popular usage, the term glaciology is therefore sometimes used more narrowly to include mainly the study of ice in glaciers. However, this narrow definition is incorrect. The World Data Centre for Glaciology that was established after the Geophysical Year of 1957–1958 has become the present-day National Snow and Ice Data Centre (NSIDC) and describes its area of interest as "the world's frozen realms: the snow, ice, glaciers, frozen ground, and climate interactions that make up Earth's cryosphere." (NSIDC, online). The major international organization for glaciology is the International Glaciological Society, which had its roots in the former "Association for the Study of Snow and Ice" and declares itself "open to all individuals who have a scientific, practical or general interest in aspects of snow and ice study" (IGS, online). Under the heading of glaciology it has published papers on topics ranging from ski design to ice on other planets, written by authors from disciplines as diverse as medical physics and marine dynamics. In the first issue of the Journal of Glaciology, the editor wrote

that it was partly in an endeavor to make the word "glaciology" universal and to combat the use of the word "cryology" for the scientific study of ice that the society adopted its title. He wrote: "It is argued by some that 'glaciology' has come to mean the study of glaciers, but the Latin *glacies* denotes ice and it cannot be right to appropriate the word for a single branch of the wide range of ice study. Neither do the Germans use *Glaziologie* nor the French *Glaciologie* in this restricted sense." (Seligman, 1947 p. 35). Technically, then, glaciology includes the study of ice in all its forms. In practice, however, some areas of glaciology are so strongly established as distinct subfields that they are rarely described under the heading of glaciology. These include not only the study of ice in specific environments (such as geocryology), but also the study of ice as a material in its own right: glaciology includes under its broad definition the interests of ice physicists, chemists, and materials scientists, but the course outlines for most postgraduate level courses entitled "glaciology" focus much more on ice in environmental settings, and on the responses of the cryosphere to environmental change, than on the atomic or molecular characteristics of the material. The primary focus of many scientists who currently describe themselves as glaciologists lies within the broad areas of snow (including avalanches), glaciers (including ice sheets and mountain glaciers), and sea ice. These are often combined with a broad interest in environmental change, the reconstruction of past environments, and the impact of glacial phenomena on landscapes. Definitions of the scope of glaciology are therefore somewhat contested, and the correct definition of the term is different from the use of the term that is frequently adopted in practice.

The history of glaciology

Glaciology is a relatively modern discipline. Clarke (1987), Walker and Waddington (1988), and Cunningham (1990) provide useful reviews of its early history. A major landmark was the publication in 1840 of Louis Agassiz' work drawing together a body of understanding that had been emerging over the previous decades and establishing clearly for the first time the idea that glaciers fluctuated over time, that they had previously been much more extensive than at present during a so-called ice age, and that their effects on the landscape could be identified in landforms and sediments in formerly glaciated areas (Agassiz, 1840). This "Glacial Theory" underpins our modern understanding of the subject. The majority of the core concepts in the study of glaciers were established relatively early in the development of the discipline. Lliboutry (1994) noted that all of the processes of glacial erosion that are known today had been recognized before the end of the nineteenth century, and Clarke (1987) argued that much of the progress that was made in the latter part of the twentieth century could have been made much earlier if modern technology had been available to nineteenth century science.

The role of technology in glaciology

Glaciology is a very technology-based discipline. Much of it is concerned with laboratory experimentation, field instrumentation, or computer-based numerical modelling. Huybrechts (2006) argued that the development of ice-sheet models able to describe the time-dependent flow and shape of ice sheets has closely followed technical progress in computer power, ice-drilling, remote sensing, and geophysical dating techniques. This close association of glaciology and technology was notable even in the early history of glaciology. Louis Agassiz used a mechanical drill to probe 60 m below the surface of Unteraargletscher in 1842, but as new technologies developed the depth to which glaciers could be drilled and the success with which ice cores could be extracted steadily improved. Recent work in Greenland and Antarctica has resulted in cores more than 3,000 m long being extracted from the ice sheets. Hot-water drilling has also opened up possibilities for accessing and instrumenting the bed beneath glaciers through boreholes. Fischer and Hubbard (2006) review a variety of instruments including water pressure sensors, sediment samplers, penetrometers, tiltmeters, and ploughmeters that can be emplaced in this way. Laboratory experimentation, as well as field research, has benefited from developing technologies. Glen's (1952, 1955) compression experiments on laboratory ice were another landmark in the history of glaciology. Iverson (2006) has argued that major progress in solving some longstanding glaciological problems could be made experimentally, and that an expansion of the experimental ethic would hasten progress in glaciology. It is partly the inaccessibility of many of the environments in which glaciological problems need to be addressed that has engendered this reliance on technology. Field observations can be supplemented, or sometimes replaced, by laboratory experimentation and computer-based numerical modelling, and where field observations are required they can be made more effectively within a better technical framework. Any review of the current status of the discipline is therefore closely tied not only to the dominant scientific questions but also to the available scientific technology.

Current issues in glaciology

As a broad and dynamic discipline, glaciology is concerned with a wide range of research topics. A great deal of modern glaciology is concerned with the interaction between the cryosphere and other components of the global environmental system, such as climate and sea level. The focus is partly on reconstructing ancient environments but largely on predicting the future responses of ice masses to climate change, and of sea-level to changes in ice volume. This area of research brings together scientists from many different areas of the discipline. For example, it involves both measuring and modeling ice dynamics, which require the coordination of fieldwork, remote sensing, and theoretically derived data.

It also involves the work of glacial geologists, geomorphologists, meteorologists, oceanographers, sea-ice specialists, and permafrost scientists in recognizing the impacts of climate change on the cryosphere and the impact of cryospheric changes on indicators such as landforms, ocean currents, atmospheric composition, and the sedimentary record.

Clarke (2005, p. 270) wrote that it "would be wrong to leave the reader with an impression that glaciology is a mature science, now dedicating itself to minor janitorial tasks. Glaciologists are inspired by the knowledge they have gained – much of it very recent – but they are challenged by what remains to be understood." Sugden (2006, p. 188) wrote that "a report card on the progress of glacial studies over the past 40 years or so might read 'encouraging progress, but surprisingly large gaps in knowledge remain'". Glaciologists are currently involved in addressing some of the biggest questions in Earth science, and we do not yet have the knowledge or understanding that we need to reach reliable answers. Even within one particular narrowly defined area of glaciology, the relationship between glaciers and climate change, it is easy to identify a large number of big unanswered questions and unsolved problems that go to the heart of the discipline. For example, we are only just beginning to make sufficiently accurate measurements of the mass balance of the world's ice sheets to be able to start making confident assertions about whether they are growing or shrinking, which will be a fundamental control on the future of global sea level. Measurement of ice-sheet dimensions and dynamics using both ground-based measurements and satellite remote sensing is crucial to progress in this area. Predicting future ice-sheet behavior will depend on a clear understanding of how glacier dynamics relates not only to climatic driving forces but also to subglacial conditions, especially thermal regime, hydrology, and bed mobility. Our knowledge in these areas remains far from complete. Sugden (2006) suggested that the lack of an effective theory of glacier sliding and the lack of basic data about the beds of current ice sheets brings into question the predictive power of any ice sheet model. Recent discussions about the role of glaciohydraulic supercooling in linking glacier dynamics, hydrology, sediment flux, and geomorphology (e.g., Alley et al., 2003) have highlighted the fact that there are very big questions in glaciology where new theory is still being developed and where our ability to make direct observations that would allow us to test those theories is limited. One of the most exciting prospects for the future is the development of new observation-based diagnostic criteria that can be used to ground-truth, test and calibrate theoretical and numerical models.

Conclusion: Prospects for the future

Several previous reviewers of the state of glaciology have drawn attention to the particular contributions of certain groups of scientists to the progress of the discipline. For example, Paterson (1994) in his keystone text book referred to the outstanding contributions of mathematical physicists. Iverson (2006) commended the value of laboratory experiments. Others have flagged up ice coring, numerical modelling, remote sensing, or geophysics as the next great hope for progress in glaciology. They are all right: each approach makes its own special contribution. However, the difficulty of defining and delimiting glaciology that emerged at the opening of this article gives us a clue as to what might in the end be the best way forward for the discipline as we attempt to address almost overwhelmingly large questions about the complex global system of which the cryosphere is a part. Glaciology draws together the efforts of scientists from a wide range of disciplines with a wide range of approaches, and the best hope for the discipline to address its outstanding problems lies in collaboration between different types of glaciologist and the coordinated application of a range of techniques. Sugden (2006) in outlining six Grand Challenges facing the discipline includes among them the challenge of reopening the kind of discussion among the wider cross-disciplinary community that proved its value in previous decades. Specifically, Sugden alludes to the link between glaciological theory and field-based empirical evidence. It is here, in conversations between numerical modellers and theoreticians on the one hand, and experimentalists and fieldworkers on the other, between those who collect empirical data and those who can (and must) use such data to calibrate and test their models and theory, that the most exciting parts of the near-term future of glaciology lie. For the longer term, where glaciology is required to go will continue to depend on what questions face the broader community of Earth and Environmental Scientists, what observations, experiments, and models are required to address them, and what technologies exist, or need to be developed, to carry out that work.

The term glaciomarine refers to sediments and processes related to environments where marine water and glacial ice are in contact. Under this environment there is a possibility of action of glaciers and the sea, or the action of glaciers in the sea, which finally results in melting and deposition processes. In high latitude, icebergs produced by calving of large glaciers into the ocean often contain drift; as the icebergs drift in the ocean and melt, they release load in the form of sediment that has been transported to the oceans. Such sediments may contain large dropstones, transported by and dropped from icebergs, in the midst of fine-grained sediments.

GLACIOSTATIC PRESSURE/STRESS

Divya Dudeja
Department of Geology, DBS College, Dehradun, Uttarakhand, India

A glacier flow in response to the stresses setup in the ice mass by the force of gravity. Each point within the glacier is subjected to stress as a result of the overlying ice. This stress can be divided into two components, namely, shear stress and vertical stress. Shear stress causes movement of the ice over its bed and is related to both the weight of the overlying ice and surface slope of the glacier called as glaciodynamic stress. Vertical stress due to static weight of the overlying ice column is called as glaciostatic stress or pressure.

Glaciostatic pressure increases with depth into the glacier as the overburden of ice increases. As it increases, shear stress also increases with respect to the bed. Glaciostatic pressure created by vertical load of ice on substratum is irrespective of ice movement. Assuming constant ice thickness over a level surface, the glaciostatic pressure would be equal and uniform in all directions.

Glaciostatic stress show variations over an irregular bed of a glacier. Undulations of the glacier bed will result in marked stress variations, because the magnitudes of the normal stress and shear stresses acting across a surface depend on its orientation relative to the applied force. Therefore, for a rough bed there will be areas where stresses are higher than average and others where they are lower than average. The pushing or pulling effect of the upstream and downstream ice also affects the stress. This effect is known as the longitudinal stress, which is compressive if the ice is slowing down and tensile if the ice is accelerating. Because the longitudinal stress is, by definition, approximately parallel to glacier flow and the surface slope, its principal effect is to modify the shear stress but if bed roughness is high, the longitudinal stress will also significantly affect the glaciostatic stress.

The gravity spreading model demonstrates that the total glaciotectonic stress needed to push glacial material from behind, permitting proglacial sediment failure and glaciotectonic thrusting, is obtained by the translation of compressive stress due to the weight of a spreading ice mass. Besides glaciodyanamic stress, the horizontal cumulative compressive stress transferred from the normal stress, that is, glaciostatic stress also forms one of the important components of the total glaciotectonic stress field. Failure can take place on a plane when the total glaciotectonic stress exceeds or equals the shear resistance.

GLACIOTECTONIC STRUCTURES, LANDFORMS, AND PROCESSES

James S. Aber[1], Andrzej Ber[2]
[1]Emporia State University, Emporia, KS, USA
[2]Polish Geological Institute – Polish Research Institute, Warszawa, Poland

Introduction

Glaciotectonics involves glacially induced deformations in the Earth's crust, which include all manner of folds, faults, and dislocations (Aber and Ber, 2007). Disturbed strata range from unconsolidated sediments, to well-indurated strata, to solid crystalline rocks. Glaciotectonism refers to the processes by which proglacial and subglacial deformations are created. The driving cause for these deformations is the combined weight of glacial ice and forward movement of the glacier or ice sheet, which together exert differential stress on the substratum. Such stress and changes in stress may be imposed in the advancing, maximal, and retreating phases of glaciation, during which the local direction of ice movement may shift substantially. The results in many cases are complex patterns and styles of superposed deformation (Pedersen, 2000).

Glaciotectonic structures and landforms were recognized and investigated beginning in the mid-nineteenth century at several classic sites: Norfolk, England (Lyell, 1863), Møns Klint, Denmark (Figure 1), and Martha's Vineyard, United States (Figure 2). Slater (1926) was the first person to specialize in the subject; he coined the term glacial tectonics, which is generally shortened to glaciotectonics (American) or glacitectonics (British)

Glaciotectonic Structures, Landforms, and Processes, Figure 1 Møns Klint, southeastern Denmark, as seen from the beach. Upper Cretaceous chalk masses are thrust up from below sea level. Sommerspiret, seen here, stands in vertical position >100 m high. Long known to geologists, the ice-shoved origin of the cliff structures was demonstrated first by Johnstrup (1874). The description and origin of Møns Klint continue to generate intense scientific interest and controversy (e.g., Pedersen, 2000). Photo by JSA.

nowadays. The study of glaciotectonics expanded significantly in the middle twentieth century, primarily in Europe and North America, and by the late twentieth century had become an integrated part of glacial theory. Observations of glaciotectonics associated with modern glaciers played a key role for interpretation of ancient structures and landforms.

Most glaciotectonic disturbances are relatively shallow, typically <200 m deep, and include all manner of ductile and brittle styles of deformation (Figure 3). Ductile structures are most typical of unconsolidated or fine-grained strata that are deformed under high confining pressures. Common representatives of ductile structures are various folds, intrusions, diapirs, and contortions. Brittle deformations such as joints, faults, breccia, and fissures are most characteristic of well-consolidated or coarse-grained strata that are deformed under low confining pressure. Detailed structural analysis is applied for study of glaciotectonic

structures. This includes three stages: descriptive analysis (geometry, orientation, and structural patterns), kinematic analysis (measurements of strains and dislocations), and dynamic analysis (origin of the deformation).

The depth of deformation was often determined by a weak layer in the subsurface, such as a bed of shale, chalk, lignite, salt, clay, peat, or other soft material. Other weak zones or horizons include the lower limit of permafrost and position of a confined aquifer. Such weak layers represent décollements, above which strata were displaced and deformed, and below which no deformation took place. In some cases, even deeper deformation happened in which a décollement is situated 1 km or more beneath the surface. Glaciotectonic deformation within the substratum is often marked at the surface by distinctive landforms. In other cases, deformations may be completely concealed within the subsurface and have no morphologic expression in the landscape.

Glaciotectonic landforms

Considered broadly, glaciotectonic landforms may be largely constructional in nature, in other words, built up above the surrounding terrain, or destructive in origin as a result of removal of material. The former comprise various types of ice-shoved ridges, hills, and push moraines. The latter include ice-scooped basins, troughs, and depressions. The hill-hole pair is a basic glaciotectonic landform consisting of an ice-scooped depression and ice-shoved hill. Ideally, the size, shape, and volume of the ice-shoved hill correspond closely with dimensions of the adjacent basin, so that a direct genetic link is apparent (Figure 4). Large and small hill-hole pairs are found on land as well as the continental shelf as deep as 200–300 m below modern sea level (Sættem, 1990). At these depths, the glaciotectonic landforms were surely created when the ice sheet was marine based.

Ice-shoved ridges are commonplace in many formerly glaciated regions as well as in close proximity to modern glaciers, although distinct source basins cannot always be identified. Such composite ridges and push moraines range in size from >200 m in relief and thousands of square kilometers area to small, inconspicuous features. The latter often were overridden by subsequent ice advance, so were smoothed, reduced in size, and covered by till. The term cupola-hill is applied to such modified ice-shoved hills, which are in many cases streamlined into drumlin shapes.

Among the largest and best developed composite ridges are those found along the Missouri Coteau in southern Saskatchewan, Canada. The Dirt Hills and Cactus Hills are nearly ideal examples of late Wisconsin age (Figure 5). Cretaceous strata, mainly sandstone, mudstone, and lignite, are thrust upward >200 m above normal stratigraphic positions. Remarkable agreement exists between structural features, ridge trends, and the overall outlines of the Dirt Hills and Cactus Hills, which demonstrates that surface morphology is a direct expression of bedrock structures (Kupsch, 1962).

Hvideklint on the island of Møn represents a typical small cupola-hill, in which the internal structure is strongly disturbed, but the surface landform is indistinct (Aber, 1979). A cliff section reveals detached masses of upper Cretaceous chalk that are thrust, folded, and sheared

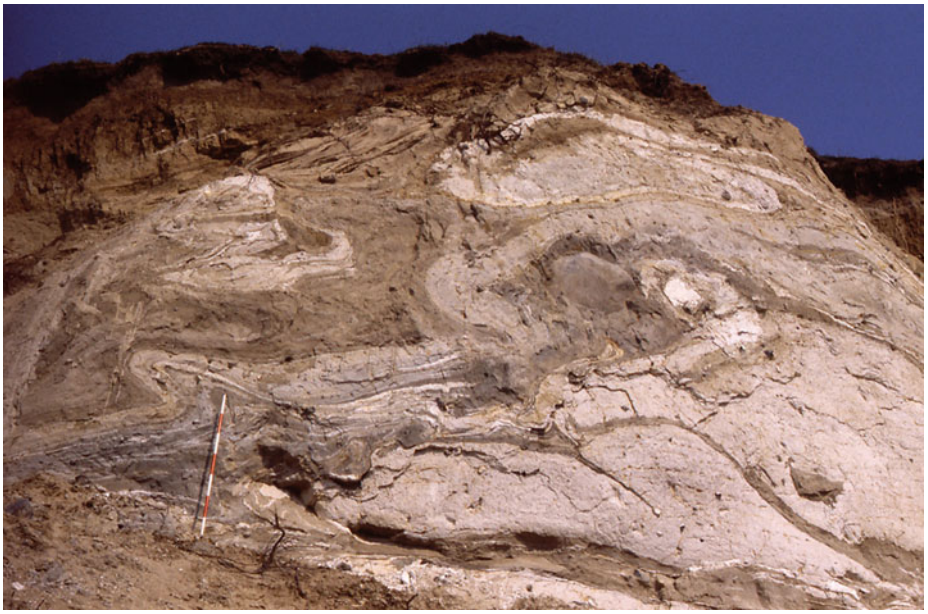
together with various Pleistocene strata (Figure 6). The disturbed section is overlain by two till layers. The lower till layer was deposited and deformed by the same ice advance that brought the chalk blocks from the northeast. The upper till layer is discordant and represents a later glacier readvance by an ice lobe coming from the east-northeast.

Elbląg Upland is an exceptionally large cupola-hill located on the margin of Gdańsk Bay in northern Poland. It covers nearly 400 km^2, stands almost 200 m above the surrounding lowlands, and has a volume of roughly 40 km^3. These dimensions place Elbląg Upland among the largest glaciotectonic landforms in the world (Aber and Ruszczyńska-Szenajch, 1997). The core of the upland consists entirely of disrupted, displaced, and uplifted Pleistocene strata, many of which were derived from below sea level beneath Gdańsk Bay (Figure 7). The upland was subjected to multiple ice advances, and primary glaciotectonic deformation may have taken place in an interlobate position between converging ice lobes.



Glaciotectonic Structures, Landforms, and Processes, Figure 6 Cliff section at Hvideklint on the island of Møn, Denmark. Chalk, till, and sand are stretched, folded, and sheared into a glaciodynamic mélange. Note the overturned and "rolled" folds of chalk-banded till. Scale pole marked in 20-cm intervals. (Adapted from Aber and Ber, 2007.)

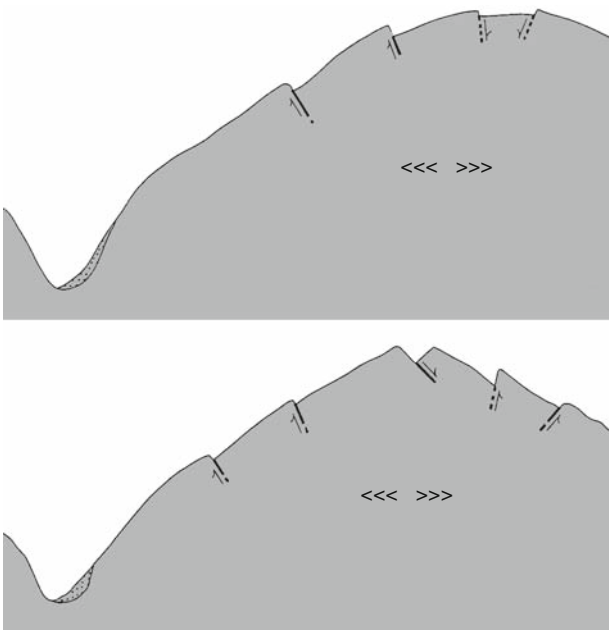
(**b**) Discordant cap of sandy till with rounded pebbles and cobbles derived from underlying stratified drift. Scale pole marked in feet; photos by JSA.

A subsequent readvance overrode the upland, deposited a discordant cap of diamicton, and molded several dozen drumlins.

The term push moraine has been applied widely to many kinds of ice-shoved hills and ridges. The term is here restricted to those ice-shoved hills that are composed largely or completely of proglacial outwash and other glaciogenic strata into which the ice advanced (Aber and Ber, 2007). A prime example of this case is Brandon Hills in southwestern Manitoba, Canada. The internal structure of Brandon Hills consists of stratified drift blocks that are tilted, faulted, folded, and truncated below a cover of sandy till (Figure 8). Brandon Hills were created when a late Wisconsin readvance pushed up blocks of outwash sand and gravel left during a previous ice retreat. The readvance then overrode and eroded the ice-shoved ridges and laid down the discordant cap of till.

Most glaciotectonic structures and landforms are developed in relatively soft sedimentary strata. In some cases, however, well-consolidated bedrock was disturbed with the creation of distinctive landforms, as consequences of glacial loading and unloading. In northern Sweden, for example, the Pärve Fault was reactivated at the close of the last glaciation; it forms a continuous fault scarp 150 km long and up to 10 m high (Lundqvist and Lagerbäck, 1976).

Alpine glacial erosion, through overdeepening of valleys, may lead to structural collapse of the valley sides and mountain crest along normal faults, resulting in small, bedrock ridges and troughs. Sackung (plural: sackungen) is derived from the German word for "sagging," which describes the process of lateral spreading of the mountain side into the excavated glacial valley (Figure 9). Sackungen are commonly developed in crystalline rocks of the Alps and Rocky Mountains and also may form in well-consolidated sedimentary strata (Figure 10).



Glaciotectonic Structures, Landforms, and Processes, Figure 9 Idealized cross sections of sackungen on mountain sides and crests adjacent to a glacier-carved valley (on left). Small arrows indicate sense of fault displacement; large arrows show lateral spreading of mountain mass. (**a**) Ridge-top graben, (**b**) Double-crested ridge. Concealed glaciotectonic structures

Glaciotectonic structures of diverse types and sizes underlie many glaciated plains without any morphologic expression at the surface (Figure 11). These structures may be produced in situ (autochthonous) within the

Glaciotectonic Structures, Landforms, and Processes, Figure 10 Sackung on the crest of the Culebra Range looking south toward Trinchera Peak (4,121 m) in the background. A deep cleft is marked by snow patches in the right foreground. Bedrock is well-consolidated arkosic and quartzose sandstone that is overturned and dips steeply toward the west (arrows in lower left corner). Sangre de Cristo Mountains, southern Colorado, United States. (Taken from Aber, 2008.)

substratum or within detached masses (allochthonous) during their transportation and deposition (Figure 12). Displaced megablocks, rafts and floes, various intrusions and diapirs, and basement structures may be attributed to the impact of glacial loading and movement (Aber and Ber, 2007). Stalker (1976) first applied the term megablock to large, relatively thin, slightly deformed masses of displaced bedrock in the Canadian Prairie region (Figure 13). Similar rafts are well known in many parts of central and eastern Europe. The largest known megablock is located at Esterhazy, Saskatchewan, Canada (Christiansen, 1971). The disrupted material consists of Cretaceous shale, claystone, and siltstone resting in places on till and covered with drift. The megablock covers $\sim$1,000 km^2 with an average thickness of 60 m.

A complete listing of concealed glaciotectonic structures is not possible, because so much variety exists in type, style, and size. Intrusions, diapirs, wedges, and other soft-sediment deformations are commonly found in glaciogenic sequences, but rarely give rise to distinctive landforms. They range from millimeter-sized features to structures hundreds of meters in extent. Diapirs typically form where clay or silt layers, buried beneath denser sand, gravel, or till, are mobilized by high-pressure pore water induced by overriding glacier ice (Figure 14). Among the deepest known glaciotectonic deformations are dislocations and folds in salt beneath the Finger Lakes region of New York (Figure 15). In the northern Finger Lakes, salt was displaced southward by repeated ice loading, which led to thickening of salt south of the Finger Lakes at depths $>$1 km (White, 1992). When the last glaciation retreated, salt flowed into anticlines beneath the longest and deepest of the ice-carved Finger Lakes troughs.

Poland contains several excellent examples of deeply buried basement structures that were reactivated during repeated glaciations and may have contributed to surficial glaciotectonic deformations as well. In North America, basement faults and seismic zones follow patterns of glaciation, wherein discrete crustal blocks responded differentially to glacial loading and unloading. This is

Vertical scale exaggerated; a, b, and c may occur anywhere under the ice. (Taken from Aber and Ber, 2007, Figure 7–4.)

especially apparent along the southern margin of the Laurentide Ice Sheet from the midcontinent to the Altantic continental shelf (Aber and Ber, 2007).

Distribution of glaciotectonics

Glaciotectonic structures and landforms are found throughout regions of former continental ice-sheet glaciation, but they are not randomly distributed. A distinct zonal pattern is found in both North America (Dyke and Prest, 1987; Aber et al., 1995) and Europe (Aber and Lundqvist, 1988; Ber, 2006). Three major geomorphic zones are developed (Figures 16 and 17):

- Outer zone – all manner of large and small glaciotectonic phenomena in drift and soft sedimentary bedrock on both land and continental shelves
- Intermediate zone – small, isolated glaciotectonic features found mainly in locally thick drift of the last glaciation
- Inner zone – widespread, small- and moderate-sized glaciotectonic features developed in older drift

The outer zone is underlain predominately by soft, poorly consolidated Mesozoic and Cenozoic sedimentary strata consisting mainly of Cretaceous, Paleogene, or Neogene bedrock. Thick and nearly continuous Pleistocene strata mantle the bedrock. Large looped end moraines, drumlin fields, older drift, and multiple till sequences are abundant. All kinds of large and small glaciotectonic features are commonplace; most of the examples given above come from the outer zone of glaciation.

The intermediate zone in Europe includes the Fennoscandian Shield of southern Sweden and Finland and the Caledonian Mountains of Norway and western Sweden, and in North America the Canadian Shield and northern Appalachians make up the intermediate zone. Drift cover is thin and patchy, and scoured crystalline rocks crop out over vast areas. Small glaciotectonic structures are occasionally found, and faults in crystalline bedrock are common. In both North America and Europe, the outer and intermediate zones are separated by transitional belts of varying width and lateral continuity. These transitional belts are underlain by consolidated Paleozoic sedimentary bedrock.

Within the inner zones of glaciation, drift is again moderately thick and continuous with drumlins and Rogen moraine common. Exposures of Precambrian and

Glaciotectonic Structures, Landforms, and Processes, Figure 13 Megablock of Cretaceous strata (light tone) exposed within thick glacial strata along the bluff of the Oldman River, near Taber, south-central Alberta, Canada. The upland surface is a nearly flat glacial plain. Note people standing at the base of the megablock, which is a shear zone in the underlying glacial sediment. Another megablock can be seen in the background. (Adapted from Aber and Ber, 2007.)

Paleozoic bedrock make up only a small part of the landscape. Interstadial and interglacial sediments are found in many places below till of the last glaciation, and multiple Weichselian till sequences are known. Glaciotectonic structures are common within such overridden deposits (Figure 18), and even small ice-shoved hills are found.

The distribution, types, and sizes of glaciotectonic phenomena are related in a general way to availability of erodible or deformable strata, namely thick Pleistocene deposits or soft sedimentary bedrock. The three zones are the results of multiple Pleistocene glaciations and represent long-term, cumulative modifications of the continental substratum by ice sheets.

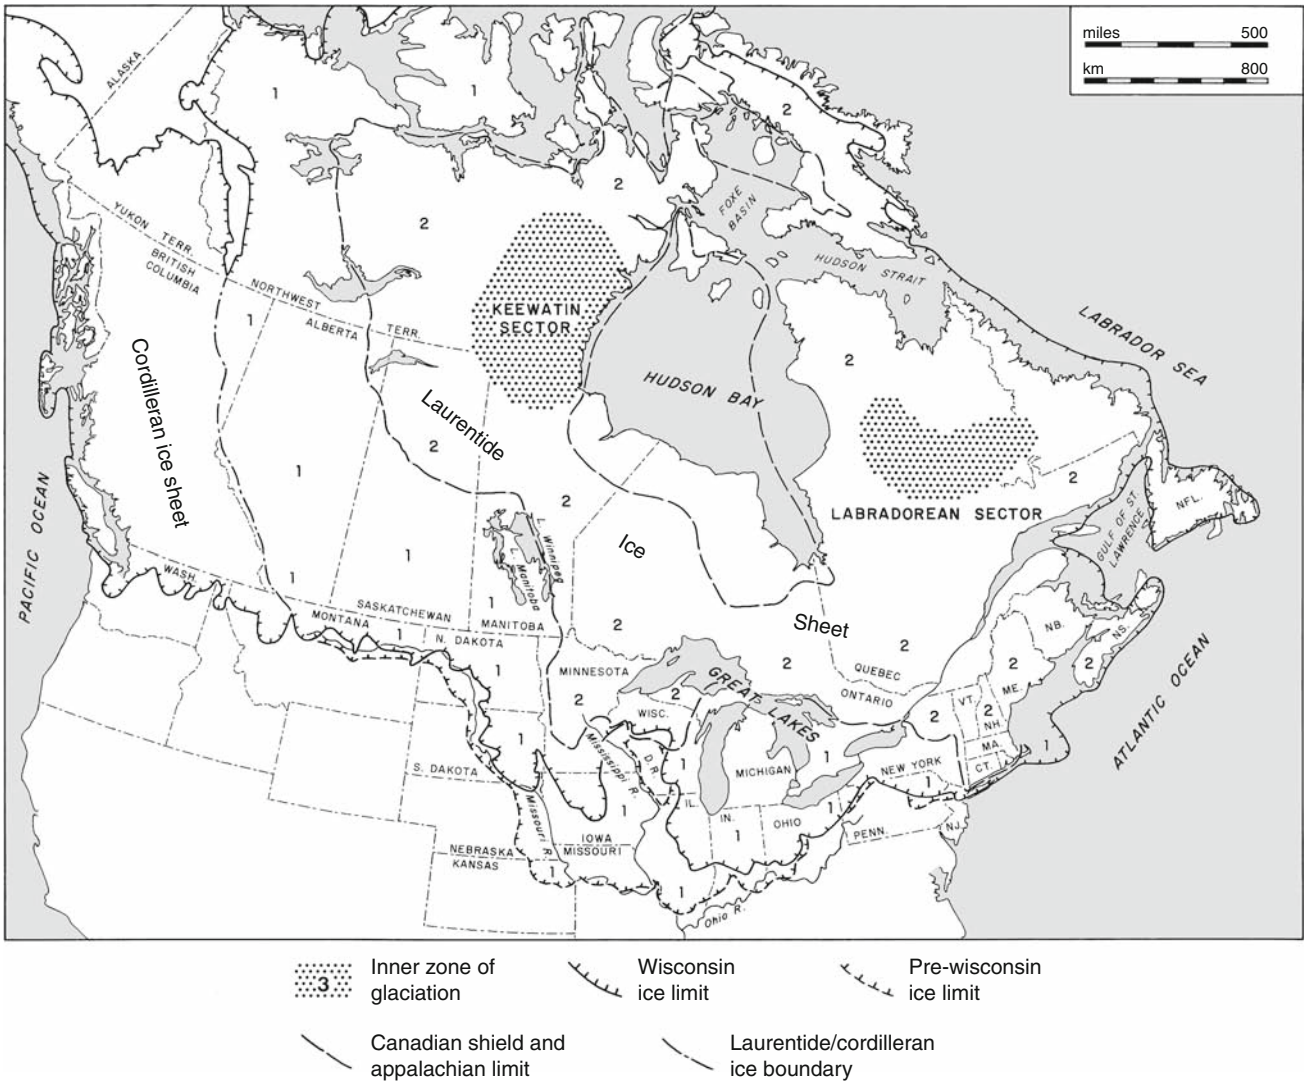
For the outer zone, glaciotectonic features are so abundant that their pattern of distribution may be compared with other glacial phenomena. Two basic regional patterns are recognized for glaciotectonic features.

- Sporatic distribution of megablocks, rafts, diapirs, and other features that have little or no morphologic expressions, along with small cupola hills and drumlins. These features presumably were created in subglacial settings well behind ice margins or were overridden and substantially modified by later glaciation.
- Ice-marginal position of morphologically prominent hill-hole pairs, composite ridges, and large cupola hills. These features were created at or near active ice margins, and their locations are closely related to development of ice lobes or tongues. Associated melt-water features include tunnel valleys, eskers, spillways, and outwash plains.

The Muskau Arc in eastern Germany and southwestern Poland is a particularly good example of glacier shoving around the margin of an ice lobe (Figure 19). Thrust slices of Neogene strata, including brown coal, form the primary core of the structure along with overturned folds and dikes. Highest ridges exceed +140 m elevation, and the basal décollement may reach −50 m. Deformation took place in multiple stages at the maximum advance of the Neiße ice lobe during the Elsterian glaciation, ~350,000 years ago (Kupetz and Kupetz, 2009). The Muskau Arc resembles other large composite ridges such as the Dirt Hills in Saskatchewan (see Figure 5).

Model for Glaciotectonism

A general model for glaciotectonism is based on observations of structures and landforms from many ancient and

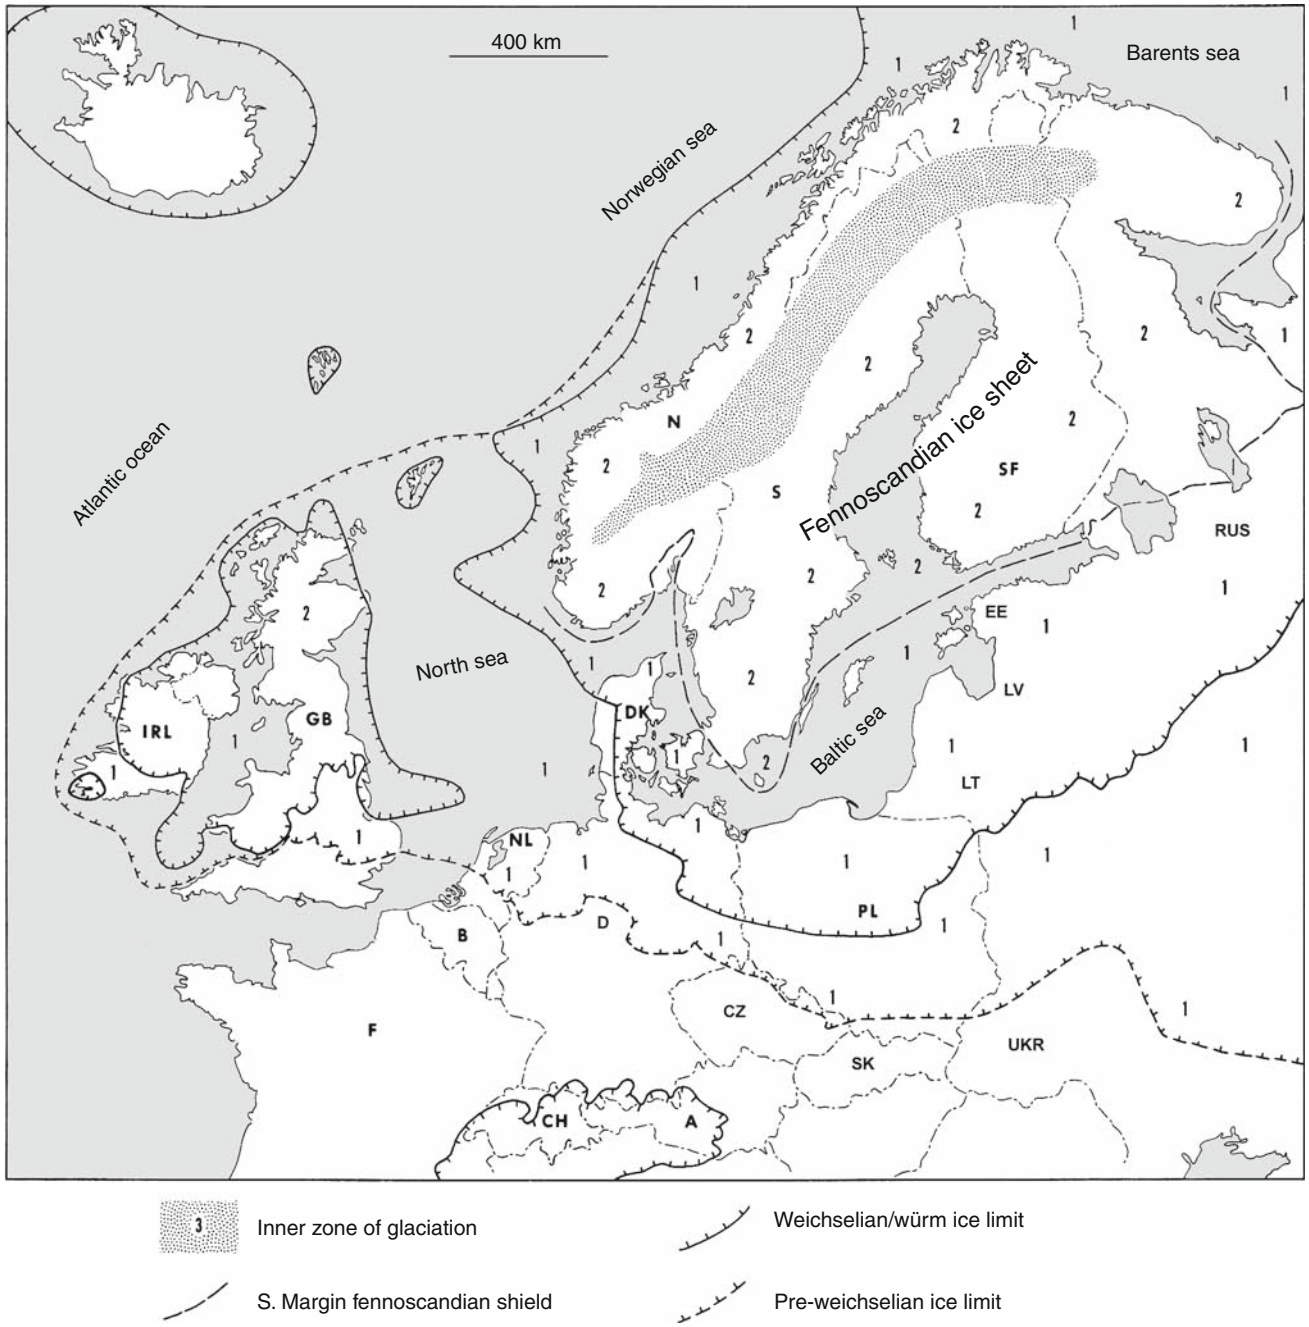


Glaciotectonic Structures, Landforms, and Processes, Figure 16 Major glacial landscape zones of North America: 1 – outer zone of predominant glacial deposition, glaciotectonism, and constructional morphology, 2 – intermediate zone of strong erosion, 3 – inner zones of lesser glacial modification. (Adapted from Aber and Ber, 2007.)

modern ice-shoved hills around the world. The model includes three main phases (Figure 20).

- Initial thrusting and uplift of a composite ridge take place in front of the ice and above a décollement. The décollement may be controlled by several features: lower boundary of permafrost, lithologic contact, position of confined aquifer, or buried hard-rock obstacle. High ground-water pressure is presumably developed along the décollement.
- A prominent ice-shoved hill begins to build up with continued deformation of the substratum at the ice margin. Meanwhile, a source basin is created beneath the glacier by removal of material behind the ice-thrust hill. Glacial deposits and melt-water features also develop simultaneously with continued deformation.
- Continued glacier advance eventually may overrun the ice-shoved hill, at which point a penetrative, highly sheared, metamorphic style of deformation may develop under the ice. Erosion of the hill provides reworked sediment for a discordant till cover, and gradually a cupola-hill morphology develops.

The driving force for these deformations is the pressure or stress difference between the advancing ice margin and the unloaded glacial foreland. The differential pressure



Glaciotectonic Structures, Landforms, and Processes, Figure 17 Major glacial landscape zones of northern Europe. Zone 1 includes the continental shelves, and it extends eastward across northern Russia including continental shelves of the Barents Sea and Kara Sea. (Modified from Aber and Ber, 2007.)

exerted by the ice mass results in shear stress within the substratum. Deformation takes place when the shear stress exceeds the shear strength of soft strata, which may be further weakened by high ground-water pressure. Rapid change in stress during ice-lobe surging over confined aquifers in soft substratum enhances the potential for creating large ice-shoved hills. This mechanism of glacier thrusting is identical, although smaller in scale, to plate-tectonic creation of major thrust mountain systems (Berthelsen, 1979; Figure 21).

Rocks of the Madera Formation are contorted and brecciated in the fault zone, which marks the Culebra Thrust Fault. View from Trinchera Peak looking westward, Sangre de Cristo Mountains, southern Colorado, United States. (Photo by JSA.)

Summary

Glaciotectonic structures and landforms were created throughout zones of former and modern glaciation as a result of glacier loading and movement on the crust. These structures are mostly shallow (<200 m deep), but some extend a kilometer or more below the surface. Distinctive landforms comprise hill-hole pairs, ice-shoved hills, push moraines, cupola hills, and many drumlins. Concealed glaciotectonic structures include megablocks and rafts, diapirs and wedges, and deep-seated deformation of salt, as well as basement faults and seismic zones. On a regional scale, glaciotectonic features are closely related to ice lobes; on a continental basis glaciotectonic phenomena display a distinct distribution within the outer, intermediate, and inner zones of ice-sheet coverage.

GLOBAL CLIMATE MODELING IN CRYOSPHERIC ASSESSMENT

Jeffrey Ridley
Met Office, Hadley Centre, Exeter, UK

Definition

Global climate models (GCMs) are under continuous development. It has now become routine to verify the performance of all sub-models against global datasets, whenever a major change in the GCM is enacted (e.g., McLaren et al., 2006). In addition, sub-models themselves are verified, perhaps against more specialized regional datasets, whenever they undergo a physics upgrade (e.g., Pedersen et al., 2009; Vancoppenollea et al., 2009). Finally, parameterizations within sub-models can be assessed against specialized observations from focused field campaigns (e.g., Pomeroy et al., 1998). The retrieval of observations from measurements involves approximations and assumptions and whenever used to evaluate GCMs an observational uncertainty is required. The GCM component evaluated is deemed satisfactory if it lies within the range of observational uncertainty.

Sea ice

When verifying sea ice characteristics in a GCM, it is essential, due to regional differences in driving mechanisms, to do so separately for each hemisphere. The enclosed nature of the Arctic Ocean means that atmospheric variability plays a major role in sea ice variability. The ocean plays a dominant role in the Antarctic. Most sea ice model components of climate models are thermomechanical models, that is, they include components that simulate both the thermal and dynamical properties of sea ice.

Ice areal coverage

Satellite measurements of microwave radiances, available since 1979, are used to estimate the sea ice coverage. A wide range of instrumental and geophysical corrections and assumptions are needed before a geophysical retrieval can be extracted from the measurements. Estimates of the observational error may be obtained through comparing different methodologies. Such analysis shows that ice area retrievals are not accurate at low or high ice concentrations or during summer months when ice melt ponds are present.

Mean seasonal cycle

The hemispherically integrated monthly ice area fraction identifies if the phase of the GCM seasonal cycle is correct. An early melt may indicate that the GCM sea ice albedo parameterization, often a function of surface temperature and ice thickness, may be in error. Alternatively, it may be that the GCM generates a too high seasonal ocean heat transport.

Spatial distribution

Biases in the spatial patterns of ice area fraction will aid in the diagnoses of GCM mechanisms. For example, distinctive sea ice anomalies may be related to biases in the GCM sea-level pressure systems (North Atlantic Oscillation or Southern Annular Mode).

Interannual variations

A failure of the GCM to reproduce the interannual variations in ice extent may indicate a poor oceanic or atmospheric forcing. Alternatively, the ice may be responding too weakly to wind drag or too strongly to ocean drag.

Ice thickness and volume

Obtaining a good representation of the time-averaged ice thickness in a GCM is the best indicator that the combination of wind-forced dynamics and radiation-forced thermodynamics is well balanced. A further test is to verify the model against the equatorward ice transport. In the Arctic, this is characterized by the Fram Strait export. Changes in ice thickness (and volume) are a more sensitive indicator of climate change than changes in ice area.

Ice thickness

The primary source of thickness data for the Arctic is from the declassified sonar measurements of military submarines. The measurements of ice draft are converted to ice thickness following an assumption of snow depth and density. Submarine measurements, although dense along the submarine track, provide a sparse and incomplete coverage of the Arctic basin. Consequently, an ice thickness climatology requires considerable spatial interpolation (Bourke and Garrett, 1987).

Satellite altimetry can provide measurements of ice freeboard, which is then converted to ice thickness through assumptions about snow depth and density. Altimetry provides a temporally and spatially regular coverage but, because of the inclination of the satellite's polar orbit, coverage of the central Arctic is lacking. Considerable temporal and spatial averaging is required to reduce the measurement "noise." Satellite altimetry (from laser and radar), is a relatively new measurement system and the time series of observations has only been continuous since 1991 (Giles et al., 2008).

A compilation of in situ measurements and estimates from ship-borne observers provides a climatological ice thickness in the Antarctic (Worby et al., 2008). Efforts have been made to reduce systematic biases due to ship navigation practices, but the dataset suffers from poor spatial and temporal sampling.

Ice volume

The storage and release of freshwater in Arctic sea ice has important consequence for North Atlantic oceanography. In GCMs, we see that Arctic ice volume varies on a timescale of order a decade, while ice area varies over 2–3 years. Ice volume is a combination of ice thickness and ice area. The lack of full-hemisphere ice thickness observations in the Arctic, or regular observations in the Antarctic, precludes a validation of GCM ice volume.

Sea ice mass balance

Fixed buoys that continuously monitor the ice surface and basal changes provide a mass balance of sea ice (until the ice melts and the buoys are lost). Data from these buoys provides an assessment of the seasonal cycle of snow and ice melt and growth.

Ice thickness distribution

Many sea ice models include a depiction of the statistical distribution of ice thickness, in each GCM grid cell, through the use of ice thickness categories. The high-resolution spatial sampling of ice thickness by submarines and laser satellite altimetry allow these data to be compared with the modeled thickness distribution. The technique provides an estimate of the seasonal balance of multiyear and first-year ice, complementing mass balance measurements.

Ice drift

Sea ice drift is a balance of wind drag, ocean drag, Coriolis force, internal ice stresses, and ocean surface slope. A verification of ice drift against observations is primarily focused on tuning the sea ice sub-model wind and ocean drag coefficients. A poor GCM depiction of regional atmospheric surface pressure may compromise this process.

Multiple overpasses of a surface imaging satellite can be used to track the motion of features in the ice cover. When optimally merged with buoy drift vectors, a regional map of ice drift may be configured (e.g., Fowler, 2003).

Drift patterns

Ice convergence and divergence are determined by the drift patterns. In the Antarctic, the patterns of drift are

associated with strong ice formation in latent heat polynas at the front of the major ice shelves. Ice is then exported northward and is eventually entrained in the Antarctic Circumpolar Current. Elsewhere around the continent offshore winds and Coriolis force drive the ice westward in a coastal current until it encounters the northward flow from the polynas. In the Arctic, the polar winter atmospheric high-pressure system drives the ice around the Beaufort Gyre. Too strong a GCM gyre will result in a thickening of ice in the Beaufort Sea. Winds off the Russian coast result in strong formation in the East Siberian and Laptev seas driving a transpolar drift. This results in ice export from the Arctic, into the Atlantic, through the Fram Strait.

Fram strait export

The ice export through the Fram Strait is well monitored by fixed upward-looking sonar arrays and satellite observations. Steady-state ice formation in the Arctic will be balanced by in situ melt and export. A GCM that reproduces the annual cycle of ice area and the Fram Strait export will have the correct impact from the Arctic sea ice on the climate system.

Snow

Snow has a high albedo and is a good thermal insulator, thus its presence delays the onset of ice melt during summer and reduces ice thickness growth during winter. In the Antarctic, it is rare for snow to complete its melt in summer, and so progressive accumulation can result in ice thickness growth through snow to ice conversion. Observational data of snow depth on sea ice is available with the most reliable being in situ measurements (Konstantinov and Grachev, 2000; Massom et al., 2001). Reproducing realistic snow behavior in a GCM is partially dependent on the snow precipitation rates, but its accumulation can be controlled by tuning the GCM snow albedo.

Albedo

The annual cycle of sea ice produces changes in albedo. Snowmelts and bare ice develops in summer, followed by the formation of melt-ponds and their eventual refreeze, then more snow in winter. Although satellite observations can be used to derive summer albedo time series, these observations contain some cloud contamination and cannot distinguish between leads and melt ponds, presenting an area mean albedo rather than ice surface albedo. Field campaign measurements of albedo (e.g., Wyser et al., 2008) are the source of data for versification of sea ice albedo schemes (e.g., Pedersen et al., 2009).

Terrestrial snow

A robust feature of the response of climate models to increases in the atmospheric concentration of greenhouse gases is the poleward retreat of terrestrial snow, and the amplification of atmospheric temperature rise in the polar regions.

Many GCMs show biases against the observed seasonal cycle of land snow cover (especially the spring melt). Such biases are closely related to the large variations in GCM snow albedo feedback strength (Hall and Qu, 2006). A new result found independently by Winton (2006) and Qu and Hall (2005) is that surface processes are the main source of divergence in climate simulations of surface albedo feedback, rather than simulated differences in cloud fields in cryospheric regions.

The snow sub-models in GCMs are known to perform poorly, during the melt season, in regions where the snow energy budget is complex, such as under vegetated canopies and in mountainous regions. An additional complexity is that much of the snowmelt season is characterized by a patchy surface, unresolved at GCM scales. Differential heating of the snow and snow-free surfaces results in a significant horizontal transport of energy that affects and contributes to the snowmelt. The calculation of the rate of energy advection requires some knowledge of the behavior of the thermal boundary layer over the patches of snow and snow-free surfaces.

Verification of the snow models themselves occurs at a number of well-instrumented field sites (Pomeroy et al., 1998). Observations of snow cover can be retrieved from satellite, with global coverage and high temporal and spatial resolution. Currently, the most widely used satellite-derived snow cover product for model verification is the Interactive Multisensor Snow and Ice Mapping System (Ramsay, 1998).

Climate models parameterize snow as a water equivalent depth, SWE. The mapping of satellite-derived snow area SWE, requires a functional form that accounts for spatial inhomogeneities in topography and vegetation cover. An example might be

$$\mathrm{SWE} = (-\ln(1 - f_c))/D$$

where f_c is the snow fractional coverage and D is a characteristic masking depth of vegetation ($\sim$0.2 m globally).

Glaciers

There are currently no GCMs that incorporate interactive glaciers. This is partially because glaciers have almost no feedback with the climate system. Consequently, the contribution of glaciers to river runoff can be handled in off-line land surface schemes. The evaluation of GCM river runoff against observed river flow can reveal a missing summer component in some rivers that may be attributed to a lack of glaciers in the GCM.

Ice Sheets

All climate models treat ice sheets as static considering surface mass balance only. Various techniques are employed to ensure that global ocean mass does not drift under preindustrial climatic conditions. The simple expedient of having all snow fall, on ice sheets, instantly runoff to the ocean is commonly used. There are presently no climate models that routinely simulate ice sheet dynamics.

However, several climate models have experimentally coupled high-resolution (~20 km) ice sheet models (dynamics and thermodynamics) to the low-resolution (~200 km) climate components (Huybrechts et al., 2002; Fichefet et al., 2003; Ridley et al., 2005).

Surface mass balance
Estimates of ice sheet surface mass balance are derived from observations of snow accumulation and melt. Accumulation is derived from a combination of ice cores, snow stakes, satellite observations, and synoptic model reanalysis. Surface ablation is derived from empirical relationships between near-surface air temperature and direct runoff of snowmelt. The uncertainty in these methodologies is large, but they provide bounds with which to assess the surface mass balance in GCMs.

Conclusions

The validating of regional processes in climate models requires sources of observational data that are spatially homogeneous, of sufficient duration to incorporate decadal variability (i.e., at least 30 years), and well characterized biases and errors. The cyrosphere is not well provided for with long data series, but recently a wide variety of in situ and remote measurements have become available. A significant effort is required to intercompare the measurements and assess the quality and sampling issues. A recent focus on Arctic sea ice has provided a wealth of measurements to validate specific processes and feedback mechanisms. An example of combined satellite observations is that of sea ice area, drift, and thickness. Since these characteristics are intimately linked in sea ice model physics, the combination is a powerful tool to diagnose the performance of sea ice in climate models.

GLOBAL OUTLOOK OF SNOWCOVER, SEA ICE, AND GLACIERS

Mauri Pelto
Department of Environmental Science, Nichols College, Dudley, MA, USA

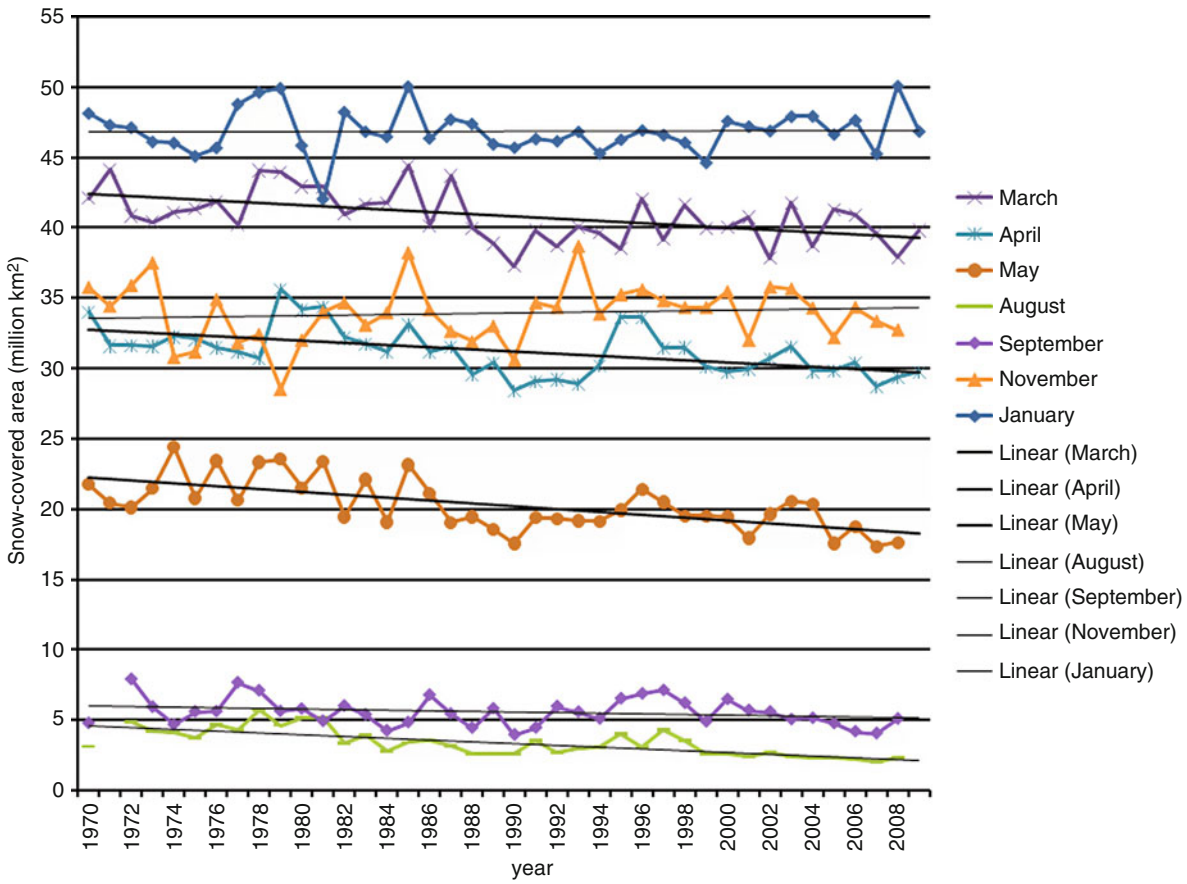
Definition

This article focuses on the broad issue of recent change in the extent of the principal cryospheric earth surface features, snowcover, sea ice, and glaciers.

Snowcover

An examination of Northern Hemisphere snowcover extent monthly anomalies provides a useful overview of recent changes in snowcover. Snowcover extent for the months of December–February as evidenced by the winter season anomaly has had no evident trend during the 2000–2009 period (Rutgers Global Snow, 2009). Of the 30 possible months, positive anomalies of greater than 1 million km^2 have occurred 11 times and negative anomalies of this magnitude three times. The spring season beginning with March is dominated by negative anomalies (Figure 1). In March, 6 of the last 10 years have had a negative anomaly of greater than 1 million km^2, no year had a positive anomaly of greater than 1 million km^2. In both April and May, 8 of the last 10 years have had a negative anomaly of greater than 1 million km^2, no year had a positive anomaly of greater than 1 million km^2. For the summer season, in June 9 of the last 10 years, in July and August all 10 of the years have a negative anomaly of greater than 1 million km^2. The fall season, September–November, as a whole does have an evident decline (Figure 1). This is almost entirely due to seven consecutive years 2002–2008 of negative snow cover anomalies in September. October and November have an equal balance of significant snowcover positive and negative anomalies. The key Northern Hemisphere snowcover change is the substantial spring and summer season negative seasonal trends in snowcovered area. That this has occurred despite winter snowcover extents anomalies tending to be positive from 2000 to 2009, indicates the important role that increased global temperatures are having. It is exclusively the melt season, March–September, snowcover extent that is being negatively impacted.

Examination of mountains snowcover records identifies some similar trends, both temperature and precipitation increases to date have impacted mountain snowpacks simultaneously on the global scale (Stewart, 2008). Warmer temperatures at mid-elevations have decreased snowpack and resulted in earlier melt in spite of precipitation increases, more rain events have also been observed reducing the snow water equivalent snowpack–precipitation ratio (Pelto, 2006). Higher elevations



Global Outlook of Snowcover, Sea Ice, and Glaciers, Figure 1 Northern Hemisphere snowcover extent for selected months from 1970 to early 2009. November and January do not have a negative trend. The rate of decline increases from March through May, the spring melt season. The declining snowcover persists through September. Data source: Rutgers University Global Snow Lab.

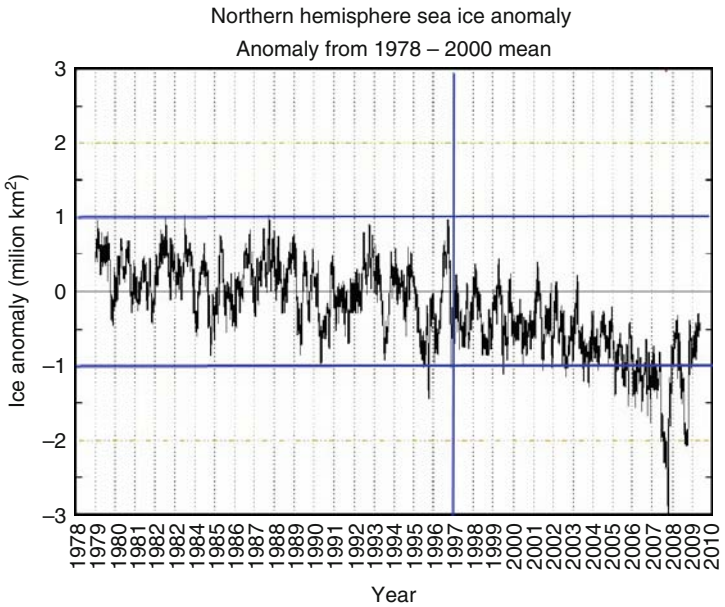
have not been as affected as they remain well below freezing during winter. At high elevations, precipitation increases have resulted in increased snowpack in some cases (Stewart, 2008).

Arctic sea ice

Passive microwave satellite data have been reliably available since 1979. In the Arctic winter, sea ice extent has decreased about 4.2% per decade (Meier et al., 2005) and summer sea ice extent has declined at 8–10% per decade depending on which year is used as the end date from 2004 to 2008 (NSIDC, 2009). That the trend is consistently this large regardless of the end year argues for the robustness of the trend. The observed thinning of the pack is largely an indication of the reduced amount of multiyear ice (Nghiem et al., 2007). Both the 2008 and 2009 winters have recovered to a substantial percentage of normal cover; however, the amount of this cover being first year ice has been at unprecedented levels. The amount of perennial ice in the March ice cover has decreased from approximately 4.2 to 3.0 million km^2 over the period 1998–2007, this loss equals the areal decline from 1957 to 1997 (Nghiem et al., 2007). There has not been a single month since 2003 where Arctic sea ice cover has reached the long-term monthly average (Figure 2). In 2008 and 2009, sea ice older than 2 years comprised less than 10% of the sea ice cover at the end of February. The long-term average, 1981–2000, is older ice comprising 30% of the total sea ice cover at this time of the year (NSIDC, 2009). The thinner young ice is then more prone to summer melting as well as the impact of winds and currents (Maslanik et al., 2007; Serreze et al., 2007). The rapid loss of Arctic sea ice has along with glacier retreat been the most visible impact of global warming to date. The outlook is for continued declines in sea ice extent, with increasing seasonality to sea ice extent, with forecasts for the near-complete loss of summer Arctic Ocean sea ice, ranging from 2015 to 2060. Holland et al. (2006) ran a series of seven CCSM3 climate simulations, each suggested that abrupt increases in the summer Arctic sea ice cover loss are quite likely and are likely to occur early in the twenty-first century. The earliest date was 2015 with 2024 for being the mean date. The result was a nearly ice-free Arctic in September by 2040. The surface albedo feedback is the key factor in sea ice loss acceleration, as more solar radiation is absorbed in the surface ocean, increasing ice melt (Holland et al., 2006). Wang and Overland (2009) used the observed 2007/2008 September sea ice extents as a starting point for 23 simulations of ice extent using six different models. The expected time for a nearly sea ice-free Arctic in September is 2037. The increased open water is influencing climate beyond the melt season, delaying onset of freeze up and impact winter climate (Ford et al., 2009; Serreze et al., 2007).

Antarctic sea ice

The Antarctic Ocean has a much larger annual cycle in sea ice extent, with an average maximum and minimum of 18 million and 3 million km^2, respectively (NSIDC, 2009). The area covered by Antarctic sea ice has shown a small (not statistically significant) increasing trend from 1978 to 2009 of +1% per decade (Cavalieri et al., 2003). In



Global Outlook of Snowcover, Sea Ice, and Glaciers, Figure 2 Sea ice extent anomalies in the Arctic from 1979 to 2009. Beginning in 1997, Arctic sea ice cover does not approach a positive anomaly of 1 million km^2. Since 2003, there has not been a single month with a positive sea ice extent anomaly. Data source: National Snow and Ice Data Center.

the last decade there is no evident trend, mainly as a result of the dramatic annual and seasonal changes in the extent. The greatest minimum extent anomaly interval of the 1990–2009 period was 2002 and 2003 and the maximum period in the Austral summer of 2007–2008, followed by a decline to below normal extent anomalies by the Austral winter 2008 (NSIDC, 2009). There is an asymmetric trend with the largest increase in sea ice being in the Ross Sea region and the largest decrease in the Bellinghausen-Amundsen Sea region. Given the variability in Antarctic sea ice extent temporally and spatially, there is not a clear forecast for near-future sea ice trends around Antarctica.

Alpine glaciers

Glaciers have been studied as sensitive indicators of climate for more than a century and are now part of the Global Climate Observing System (Haeberli et al., 2000). The worldwide retreat of mountain glaciers is one of the clearest signals of ongoing climate change (Oerlemans, 2005; Haeberli and Hoelzle, 1995). The retreat is a reflection of strongly negative mass balances over the last 30 years (WGMS, 2007). Mass balance is the most sensitive climate parameter for glaciers, because it is a direct response to local weather conditions for a year (Pelto and Hedlund, 2001). The change in glacier length is a smoothed and delayed response to the mass balance changes (Haeberli and Hoelzle, 1995). The recent rapid retreat and prolonged negative balances have led to glaciers disappearing (Pelto, 2006).

Glacier mass balance is the difference between accumulation and ablation (melting and sublimation). Climate change may cause variations in temperature and snowfall, altering mass balance. A glacier with a sustained negative balance is out of equilibrium and will retreat. A glacier with sustained positive balance is out of equilibrium, and will advance to reestablish equilibrium. Glacier advance increases the area of a glacier at lower elevations where ablation is highest, offsetting the increase in accumulation. Glacier retreat results in the loss of the low-elevation region of the glacier. Since higher elevations are cooler, the disappearance of the lowest portion of the glacier reduces total ablation, increasing mass balance and potentially reestablishing equilibrium. If a glacier lacks a consistent accumulation zone, it is in disequilibrium, the accumulation zone will thin and the glacier will melt away without a change to a cooler-wetter climate (Pelto, 2010; Paul et al., 2007).

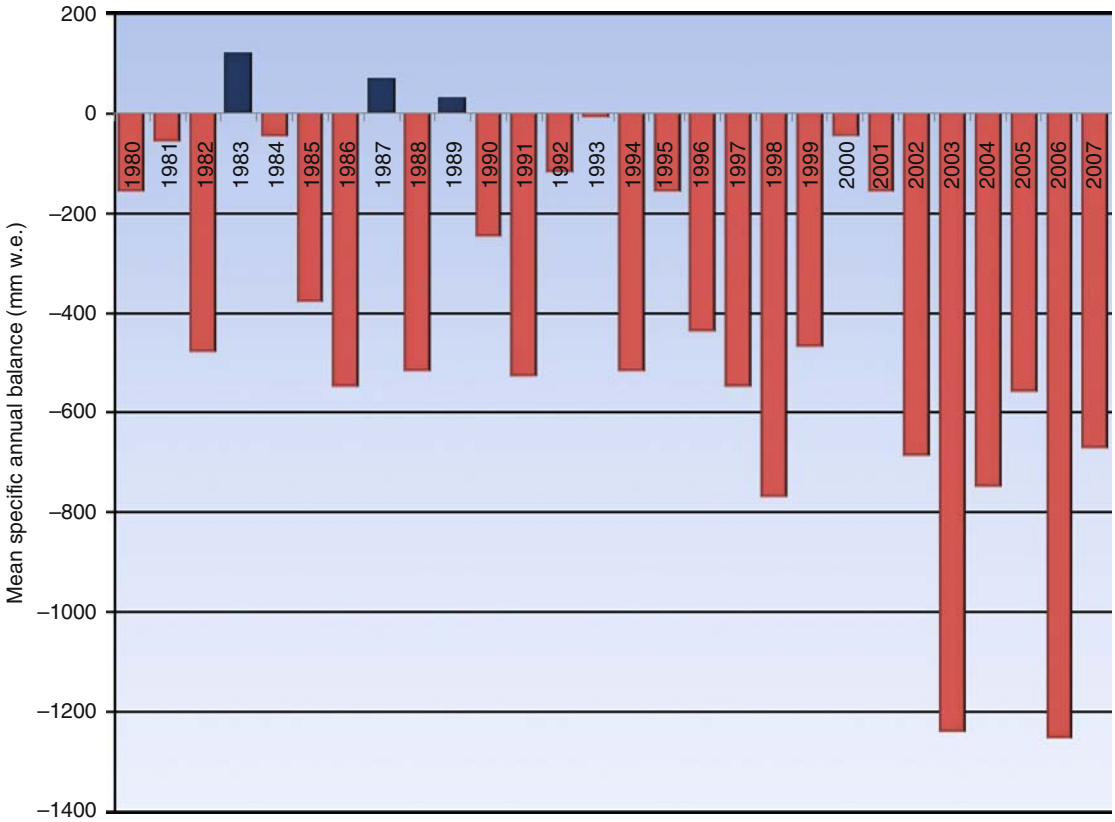
In 2007, mean mass balance of all the WGMS reporting glaciers was -528 mma^{-1}, and -673 mma^{-1} for the 30 reference glaciers, the 17th consecutive year of negative mass balance (Figure 3). WGMS preliminary data from 2008 indicate an 18th consecutive year of negative mass balance. Mass balance is reported in water equivalent thickness changes. A loss of 0.9 m of water equivalent is the same as the loss of 1.0 m of glacier thickness, since ice is less dense than water. The trend of consistent and substantial mass losses demonstrates why alpine glaciers are currently retreating. The cumulative loss of the last 30 years is the equivalent of cutting a 12–14 m thick slice off of the average glacier (Figure 2). The trend is remarkably consistent from region to region (WGMS, 2007).

The second parameter reported by WGMS is terminus behavior. The values are generally for glaciers examined annually. The number of advancing versus retreating glaciers reported to the WGMS shows a 2005 minimum in the percentage of advancing glaciers in Europe, Asia, and North America. In 2005, there were 442 glaciers examined, 26 advancing, 18 stationary, and 398 retreating. That is 90% retreating. Of the 26 advancing glaciers, 15 were in New Zealand. Overall, there has been a substantial volume loss of 11% of New Zealand glaciers from 1975 to 2005 (Chinn et al., 2005). More than 90% of the glaciers reported to the WGMS have retreated each year since 1990 (WGMS, 2008). In 1980, WGMS reported that more than 50% of the glaciers were advancing. This indicates that the ongoing retreat of the last 2 decades is in response to the warming global temperatures of the same time period, not part of a long-term trend of glacier retreat. The trend of negative mass balances indicates that glacier retreat will continue in the short term. The outlook for alpine glaciers is continued retreat and negative mass balances with the continued warm global temperatures.

For some glaciers, the forecast is for disappearance (Pelto, 2010). For a glacier to survive, it must have a persistent accumulation zone. If the upper reaches of a glacier where the accumulation zone becomes a frequent ablation-dominated area, the glacier cannot survive. The occurrence of this is evident by recession of the margin of the glacier in the accumulation zone or emergence of new rock outcrops (Pelto, 2010; Paul et al., 2007). Quantitative simulations of future perspectives for all glaciers in the European Alps are given by Haeberli and Hoelzle (1995). In both, the Swiss Alps and Pacific Northwest, numerous glaciers currently exhibit marginal recession or outcrop emergence in the accumulation zone (Pelto, 2010; Paul et al., 2007). The net result of glacier retreat will be reduced summer-water supply for irrigation, drinking water, aquatic life, and hydropower. The change in glacier extent for the twentieth century is from 25% to 40% in the Tien Shan, Pamir, Rocky Mountains, and Alps (WGMS, 2008), with a sharp increase in the rate noted in several of these areas (Paul et al., 2007; Pelto, 2010; Chinn et al., 2005).

Ice sheets and ice shelves

For the Greenland Ice Sheet, the two recent key changes have been changing melt extent and the acceleration of outlet glaciers. In 2005, melt extent reached a record area of 10.2 million km^2 (Tedesco, 2007). In 2007, the extent and magnitude of the melt was a record in southwest Greenland. In 2008, northern Greenland ice melt lasted 18 days longer than usual leading to 528 km^3 of runoff



Global Outlook of Snowcover, Sea Ice, and Glaciers, Figure 3 Annual glacier mass balance reported to the World Glacier Monitoring Service. The negative mass balance of 2007 is the 17th consecutive year of negative mass balance.

(Tedesco et al., 2008). The record amount of ablation in northern Greenland reflected warm temperatures that led to the breakup of 29 km^2 of the floating terminus lobe of Petermann Glacier.

Two mechanisms have been utilized to explain the change in velocity of the Greenland ice sheets outlet glaciers. The first is the enhanced meltwater effect, which relies on additional surface melting, funneled through moulins reaching the glacier base and reducing the friction through a higher basal water pressure. The continued large extent of ice melt has provided additional meltwater. A brief seasonal acceleration of up to 20% occurred on the Jakobshavn Glacier in 1998 and 1999 at Swiss Camp (Zwally et al., 2002). The acceleration lasted 2–3 months and was less than 10% in 1996 and 1997. The additional meltwater has fueled a limited acceleration from enhanced lubrication from increased meltwater reaching the ice sheet base (Joughin et al., 2008). The acceleration has been short-lived even during the summer melt season and is less than 10%. Examination of recent rapid supraglacial lake drainage documented short-term modest velocity changes due to such events, but they had little significance to the annual flow of the large glaciers outlet glaciers (Joughin et al., 2008).

The second mechanism for Greenland outlet glacier acceleration is due to a force imbalance at the calving front (Thomas, 2004). Thinning causes the glacier to be more buoyant, reducing frictional backstress, which increases calving and velocity as larger areas of the glacier are afloat near the calving front. The reduced friction due to greater buoyancy allows for an increase in velocity. The reduced resistive force at the calving front is then propagated up-glacier via longitudinal extension because of the backstress reduction (Thomas, 2004).

Helheim Glacier, East Greenland had a stable terminus from the 1970s to 2000. In 2001–2005, the glacier retreated 7 km and accelerated from 20 m day^{-1} to 33 m day^{-1}, while thinning up to 130 m in the terminus region. Kangerdlugssuaq Glacier, East Greenland had a stable terminus history from 1960 to 2002. The glacier velocity was 13 m day^{-1} in the 1990s. In 2004–2005, it accelerated to 36 m day^{-1} and thinned by up to 100 m in the lower reach of the glacier. On Jakobshavn, the acceleration began at the calving front and spread up-glacier 20 km in 1997 and up to 55 km inland by 2003 (Joughin et al., 2004). On Helheim, the thinning and velocity propagated up-glacier from the calving front. In each case, the major outlet glaciers accelerated by at least 50%, much

larger than the impact noted due to summer meltwater increase. On each glacier, the acceleration was not restricted to the summer, persisting through the winter when surface meltwater is absent.

An examination of 32 outlet glaciers in southeast Greenland (Howat et al., 2008) indicates that the acceleration is significant only for marine terminating outlet glaciers. That is, glaciers that calve into the ocean. Thinning of the ice sheet is most pronounced for marine terminating outlet glaciers (Rignot and Kanagaratnam, 2006).

As a result of the above, Luckman et al. (2006) and Howat et al. (2008) concluded that the only plausible sequence of events is that increased thinning of the terminus regions, of marine terminating outlet glaciers, ungrounding the glacier tongues and subsequently allowing acceleration, retreat, and further thinning. Enhanced meltwater-induced acceleration does exist, but is of a notably smaller magnitude and duration. If the enhanced meltwater effect is key than since meltwater is a seasonal input, velocity would have a seasonal signal all glaciers would experience this effect, and the acceleration would begin inland and propagate toward the ice sheet margin. The force imbalance effect would be key if the velocity propagated from the terminus up-glacier, there was no seasonal velocity cycle, and the acceleration is focused on calving glaciers. The latter is the case indicating that force imbalance effects are the key to outlet glacier acceleration, not meltwater lubrication.

The primary cause of Greenland ice sheet acceleration has been a change in the balance of forces at the calving front of outlet glaciers. The key factor to Greenland's marine terminating outlet glacier acceleration has been dynamic thinning of the terminus zone of the marine terminating outlet glacier reducing the effective bed pressure, allowing acceleration. Terminus retreat reduces backstress, as does the resulting decrease in glacier thickness. The reduced backstress allows acceleration and increased calving. The acceleration was first reported from Helheim Glacier and Jakobshavn Isbrae. The acceleration began at the ice front and spread inland accompanied by large thinning and retreat. This acceleration has been noted to be present on all outlet glaciers. The widespread nature of this phenomenon indicates its importance and its likelihood of being a consistent and important part of Greenland ice sheet dynamics in a warmer world.

In 2000, six ice shelves remained along the north coast of Ellesmere Island (Mueller et al., 2003). Of the six remaining ice shelves, two have disappeared since 2000: Markham in 2008 and Ayles in 2005 (Copland et al., 2007; Mueller, 2008). Ward Hunt suffered an extensive breakup in 2003 and 2008. Serson experienced extensive breakup in 2008. Petersen has lost 30% of its area since 2005. Only Milne has not experience substantial volume loss in the last decade. On August 2005, almost the entire Ayles Ice Shelf (87.1 km^2) calved off reducing total Arctic Ice Shelf area by 8% (Copland et al., 2007). In 2008, extensive regional warmth that led to record melting in northern Greenland led to the breakup of Arctic ice shelves on the north coast of Ellesmere Island. Ward Hunt lost 22 km^2, Serson Ice Shelf lost 122 km^2, 60% of its area, and Markham lost all 50 km^2 of its area (Mueller, 2008). This system of ice shelves is almost gone.

A similar story has unfolded on the Antarctic Peninsula due to regional warming. The recent collapse of Wordie Ice Shelf, Mueller Ice Shelf, Jones Ice Shelf, and Larsen-A and Larsen-B Ice Shelf on the Antarctic Peninsula has made us aware of how dynamic Antarctic ice shelve systems are (Vaughan et al., 2003). After their loss, the reduced buttressing of feeder glaciers has allowed the expected speedup of inland ice masses after shelf ice breakup (Rignot et al., 2004). In Antarctica, Wilkins Ice Shelf lost 400 km^2 during a rapid February 2008 collapse. Humbert and Braun (2008) noted ongoing thinning preconditioned the ice shelf for collapse, and that existing rifts in February 2008 suggested an additional 2,000 km^2 was in imminent danger of collapse. During the Austral winter an additional 1,350 km^2 has been lost, and in April 2009 the final buttressing connection to Charcot Island failed, which led to additional ice losses.

The other significant change in Antarctica has been the acceleration, thinning, and retreat of Pine Island Glacier (Rignot et al., 2002; Shepherd et al., 2003). This glacier has been considered the weak underbelly of the West Antarctic Ice Sheet since it has only a small buttressing ice shelf and drains 10% of the ice sheet (Shepherd et al., 2003). Thinning and acceleration have reached 200 km behind the calving front and rates of thinning and acceleration increasing velocity from 26% to 42% (Scott et al., 2009). Pine Island Glacier has the largest mass loss of any outlet glacier in the world at present (Scott et al., 2009). This is a similar magnitude as the acceleration of the Greenland outlet glaciers. Wingham et al. (2009) reported that the 5,400 km^2 central trunk of the glacier had experienced a quadrupling in the average rate of volume loss quadrupled from 2.6 km^3 a year in 1995 to 10.1 km^3 a year in 2006. At present, the acceleration has not been noted beyond Pine Island and its neighboring Thwaites Glacier. The cause of the thinning that reduces backstress is thought to be increased basal melting of the floating ice shelf.

Conclusion

We have a consistent theme emerging from long-term records of glaciers, ice sheets, snowcover, ice shelves, and sea ice. The theme is enhanced melting, due to rising temperatures. This has led to: (1) Reduced glacier ice volume with 18 consecutive years of mean negative mass balance for alpine glaciers. (2) A failure of ice shelf systems in the Arctic and Antarctic Peninsula. (3) Substantial acceleration and retreat of marine terminating outlet glaciers in Greenland. (4) Reduced spring and summer snowcover extent in the Northern Hemisphere. (5) A large reduction in Arctic sea ice extent, particularly in summer and fall.

Synonyms

Impact of climate change on the cryosphere

Definition

Global warming. Rising air temperatures on a global scale.
Global warming and its effect on snow/ice/glaciers. Rising air temperatures on a global scale that are modifying components of the cryosphere, including snow, ice, and glaciers.

Introduction

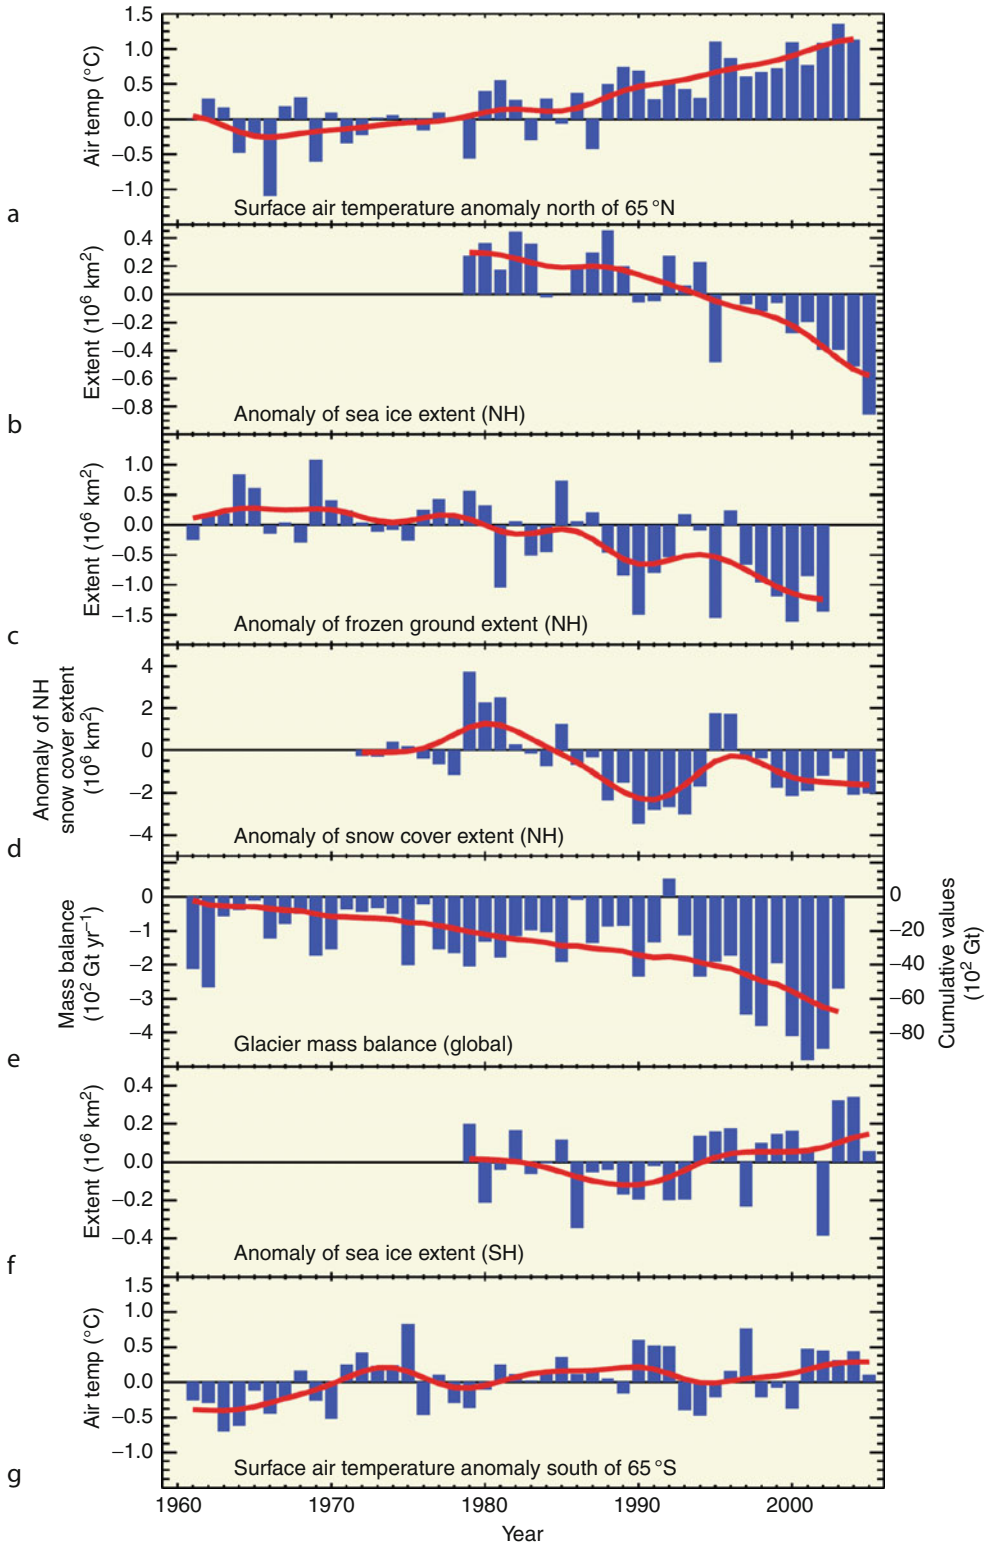
One of the most notable manifestations of global warming is its impact on snow, ice, and glaciers. The cryosphere, defined as the portion of the earth system where water, soils, and other natural materials occur in the frozen form, is a prominent indicator and integrator of climate change as a contraction in its spatial extent, volume, and duration is particularly sensitive to rising air temperatures. Components of the cryosphere such as snow, ice, and glaciers play a major role in the global climate system through their distinct characteristics such as their high albedo values that induce strong positive feedbacks on warming (Déry and Brown, 2007) and their insulating properties that decouple the atmosphere with the underlying land surface or water (Stieglitz et al., 2003). Further, the cryosphere forms important and reliable reservoirs of freshwater, contributing water resources to a large fraction of the global population (Barnett et al., 2005).

Observational evidence of change

There is mounting observational evidence that global warming is leading to modifications in the state of the cryosphere. For instance, Déry and Brown (2007) report a 5% decline in snow cover extent in the Northern Hemisphere between 1972 and 2006 based on satellite measurements. Brown (2000) reconstructs the snow cover extent data prior to the satellite era and finds a decreasing trend in Northern Hemisphere snow cover extent over the period 1915–1997. Brown and Braaten (1998) find declining snow depths across most of Canada during the twentieth century. Mote et al. (2005) document a widespread decline in snow mass in the North American Cordillera from 1925 to 2000 in response to rising surface air temperatures. Ye et al. (1998) report decreasing (increasing) snow depths in the zonal band 50–60°N (60–70°N) in Eurasia from 1936 to 1983. Stone et al. (2002) document a twentieth-century trend toward earlier snowmelt in Alaska whereas Vaganov et al. (1999) observe an opposite trend in northern Eurasia.

Global warming also influences the different forms of ice found in oceans, lakes, or rivers. Observational records point to later freezing (trend of 5.8 days per century) and earlier breakup (trend of 6.5 days per century) of lake and river ice across the Northern Hemisphere from 1846 to 1995 (Magnuson et al., 2000). Sea ice in the Arctic declined in extent by about 3% per decade whereas sea ice in the Antarctic increased spatially by 1.3% per decade over 1978–1996 (Cavalieri et al., 1997). This observed asymmetric response of sea ice extent to global warming is consistent with global climate model (GCM) simulations. The annual minimum in Arctic sea ice extent, typically reached in mid-September, attained an unprecedented low value of 4.2×10^6 km^2 in 2007 (Maslanik et al., 2007). The rapid retreat in Arctic sea ice is outpacing all of the scenarios predicted by GCMs (Stroeve et al., 2007). Submarine measurements reveal a 42% decline in Arctic sea ice draft thickness over a period of 40 years ending in the 1990s (Rothrock et al., 1999).

In response to rising air temperatures and changing precipitation regimes, glaciers worldwide are experiencing a general trend toward negative mass balances (Oerlemans, 2005). Regional declines in glacier extent and volume include the Rockies and Coast Mountains of North America, the Andes of South America, the European Alps, and the Asian Himalayas. Glaciers are particularly sensitive to changes in summertime air temperatures that drive ablation and wintertime precipitation that forms accumulation. Strong modifications in either



Global Warming and its Effect on Snow/Ice/Glaciers, Figure 1 Anomaly time series (departure from the long-term mean) of polar surface air temperature (**a**, **g**), arctic and Antarctic sea ice extent (**b**, **f**), Northern Hemisphere (NH) frozen ground extent (**c**), NH snow cover extent (**d**), and global glacier mass balance (**e**). The solid line in **e** denotes the cumulative global glacier mass balance; in the other panels, it shows decadal variations (Lemke et al., 2007).

of these seasonal quantities may alter the mass budget of glaciers. Discharge of ice from outlet glaciers of Greenland doubled in the period 1996–2005 (Rignot and Kanagaratnam, 2006) while surface melt and ablation expanded to record levels in response to global warming (Tedesco et al., 2008). In the Southern Hemisphere, global warming has not affected the overall mass balance of the Antarctic ice sheet owing in part to its colder environment than the Greenland ice sheet. However, the collapse of the Larsen ice shelf near the Antarctic Peninsula in January 1995 along with the subsequent acceleration of ice discharge and calving provide some evidence of a growing importance of climate change in the area (Rignot et al., 2004).

Future projections

A number of studies have examined the impacts of global warming on the potential future state of the cryosphere. In general, simulations of twenty-first century climate by GCMs project decreases in the spatial extent, volume, and duration of many components of the cryosphere. Déry and Wood (2006) project declines in the extent and duration of the Northern Hemisphere snow cover. They also report potential reductions in the seasonal accumulation of snow, particularly in the mid-latitudes whereas high-Arctic regions may experience increases in seasonal snow mass. Simulations of the future state of the global climate system project abrupt declines in sea ice extent and thickness, with the potential of an ice-free Arctic Ocean by the middle of the twenty-first century (Holland et al., 2006). Rising summertime air temperatures suggest that glaciers may disappear altogether in the Alps by 2100 and contribute substantially to rising sea levels (Zemp et al., 2006). Enhanced melting of the Greenland ice sheet and potentially the Antarctic ice sheet will further advance sea-level rise (Alley et al., 2005). Thus, global warming is anticipated to contribute to a shrinking cryosphere in the coming decades.

Repercussions of change

Changes in the cryosphere have profound environmental, biological, and societal repercussions (Barnett et al., 2005). As an example, mass wasting of glaciers has significant implications on downstream freshwater resources and hydrological processes. Glacier recession in western Canada has led to declines and phase shifts in late summer streamflow (Déry et al., 2009). This has important ramifications for populated downstream areas such as the arid Canadian Prairies that are now subject to an impending water crisis (Schindler and Donahue, 2006). Furthermore, glacier and ice sheet melt contributes to rising sea levels and potential changes in ocean currents (Alley et al., 2005).

Modifications in snowpack characteristics also affect ecological processes such as the duration of the growing season (Vaganov et al., 1999), and on plant productivity, density, and distribution. Changes in snowpack accumulation influence prey–predator relationships (Stenseth et al., 2004) and the feeding habits of mountain caribou and other ungulates (Kinley et al., 2007). The potential collapse in the populations of polar bears in the Arctic (Durner et al., 2009), emperor penguins in Antarctica (Jenouvier et al., 2009), and other species forms another potential consequence of a shrinking cryosphere.

Furthermore, cryospheric changes influence socioeconomic and recreational activities. The potential opening of the Northwest Passage in the Canadian Archipelago may lead to increased shipping activity in the high Arctic. Warmer winters have led to shorter periods with river ice covers in northern Canada, impeding commercial transport on ice roads. Tourism may suffer from the degradation of glaciers in many regions including Waterton National Park in the Canadian Rocky Mountains (Scott et al., 2007). Outdoor recreational activities such as skiing and ice skating may also be curtailed owing to reduced or unreliable snow/ice packs (Elsasser and Bürki, 2002).

Summary

Rising air temperatures are inducing dramatic changes in the state of the cryosphere. Global warming has led to a general decline in the presence of snow, ice, and glaciers over the past decades (Figure 1). Future projections of climate suggest that changes in the cryosphere will intensify and accelerate over the twenty-first century in response to continued global warming. The disappearance of snow, ice, and glaciers will reduce freshwater storage on the land surface, leading to diminishing water resources in many areas. Given the increasing demands for freshwater, changes in the cryosphere driven by global warming may pose serious challenges to humans and ecosystems in the twenty-first century.

GPS IN GLACIOLOGY, APPLICATIONS

Matt A. King
School of Civil Engineering and Geosciences, Newcastle University, Newcastle upon Tyne, UK

Definition

GPS: Global Positioning System (GPS), the now-standard name applied to the NAVSTAR GPS of the U.S. Department of Defense, and used in glaciology to measure ice motion. One of several Global Navigation Satellite Systems (GNSS) in operation today.

Background

Glaciologists adopted GPS as early as the mid-1980s (Hinze and Seeber, 1988; Moller and Ritter, 1988) as it overcame line-of-sight restrictions from traditional survey techniques and reduced or eliminated the time spent in traversing from known locations. Despite the small size of the satellite constellation and complications with receiver signal tracking, memory and power consumption,

positions with precisions of several meters were reported. Completion of the satellite constellation and advances in receiver and power technology now mean that GPS receivers can be deployed year-round without user intervention, and position precisions of several millimeters may be obtained (e.g., Bindschadler et al., 2003).

Geodetic GPS relies on tracking carrier phase signals broadcast by the satellites on both the L1 and L2 frequencies. With a carrier phase tracking precision of ~1 mm, the complexity of obtaining precise positions rests with determining the positions of the GPS satellites and in correcting for signals in the atmosphere, signal multipath, and unwanted solid earth geophysical signal. As an interferometric system, GPS carrier observations suffer from an integer cycle ambiguity (N). A simplified equation for an observation Φ between receiver i and satellite k is

$$\Phi_i^k(t) = \rho_i^k - I_i^k + T_i^k + c\left(\mathrm{d}t_i - \mathrm{d}t^k\right) + \lambda N_i^k - \epsilon_i^k \quad (1)$$

where ρ is the geometric distance, c is the vacuum speed of light, λ is the signal wavelength, and ε are random errors (e.g., signal multipath). Receiver and satellite clock errors ($\mathrm{d}t_i$ and $\mathrm{d}t^k$, respectively) dominate and are double-differenced in relative positioning. Alternatively, previously computed satellite clock errors may be fixed and receiver clock errors treated as unknowns as is done in precise point positioning (*PPP*; Zumberge et al., 1997). A similar equation may be given for the less precise, but unambiguous, pseudo-range observations modulated on each carrier.

Satellite orbit errors are generally regarded as negligible when using precise ephemerides from the International GNSS Service (Dow et al., 2005). Atmospheric errors consist of ionospheric delay (I), essentially reduced to negligible levels by forming an ionosphere-free linear combination of the L1 and L2 carrier observations, and tropospheric delay (T), which cancels over short (<10 km length, <100 m height difference) baselines, but otherwise must be modeled with some imprecision, or the residual treated as an unknown for precise applications. Carrier phase multipath reaches up to 0.25λ (~0.05 m), with its magnitude depending on locations and characteristics of reflectors in the antenna proximity. In coordinate time series, multipath is evident through periodic signal repeating approximately once per sidereal day. Geophysical signals, such as solid earth tides or ocean tide or atmospheric loading displacements, cancel over short baselines, but not over longer baselines or in PPP and must be modeled.

Less-precise positions may be obtained using a subset of the dual frequency observables. The main advantages are the reduced power requirements and observation processing complexity and lower cost of receiver equipment purchase. The principal disadvantage is the much reduced positioning precision. Two such approaches are differential GPS (dGPS) positioning that uses pseudo-range data only or single frequency positioning that uses L1 carrier phase observations only. dGPS positioning is limited to precisions of a few decimeters to meters. Single frequency positioning is limited by ionospheric effects that quickly reach decimeters over baselines of a few tens of kilometers, although for long-term studies the precision may be sufficient (e.g., van de Wal et al., 2008).

Dual frequency carrier phase GPS data processing involves least squares estimation of three-dimensional coordinates, receiver clocks (in PPP), real-valued ambiguities, and possibly zenith-mapped tropospheric delays. In a kinematic environment new coordinates are estimated every observation epoch. For kinematic positioning, it is critical that ambiguities are fixed to correct integers and then removed from the solution. When using a Kalman Filter/Smoother solution it is also possible to retain real-valued, but precisely determined, ambiguity estimates with minor degradation in coordinate precision. Integer ambiguity fixing is a statistical process, and is not always possible to confidently fix ambiguities due to observation noise, such as multipath. Integer ambiguity fixing has only a small effect on static positioning (Blewitt, 1989).

Glaciological applications of derived coordinates or coordinate time series are diverse, with examples below.

Ice velocity and strain rates

Glacier and ice shelf velocities and strain rates were an early glaciological target application of GPS (Hulbe and Whillans, 1994). Velocity measurements were used in obtaining estimates of ice mass balance. In some early cases, GPS was used to determine absolute position, but conventional approaches used to determine strain rate (Determann et al., 1990). Ice shelf rift formation has been studied more recently (Bassis et al., 2005) and GPS velocities are now being used to detect change in ice velocity over many decades (Joughin et al., 2005; King et al., 2007), seasonally (Joughin et al., 2008) or nearly instantaneously (Das et al., 2008).

Tides and tidal modulation of flow

GPS observations have been made of ocean tides on sea ice (Aoki et al., 2000), ice shelves (Riedel et al., 1999), and of subglacial lake tides (Wendt et al., 2005). Measurements of tidal flexure in ice shelf grounding lines have also been made (Vaughan, 1995). Horizontally, tidal modulation of flow has been identified on ice streams (Anandakrishnan et al., 2003; Bindschadler et al., 2003; Gudmundsson, 2006) and ice tongues and shelves (Doake et al., 2002; Legresy et al., 2004). However, the GPS satellite constellation repeat period is not optimal for tidal studies, since it repeats very close to the K1 and K2 tidal frequencies, producing systematic errors of the order of a few millimeters over short baselines and up to ~10 mm using PPP (King et al., 2008).

Mass balance

The difference between the vertical velocity of markers anchored in firn and the long-term rate of snow accumulation reveals the local ice mass balance. Precise vertical

velocities have been determined using GPS to achieve this (Hamilton and Whillans, 2000). Satellite geometry and tropospheric errors, however, mean the vertical coordinate in GPS is less precise than the horizontal, and vertical velocities are subject to reference frame uncertainties and/or bias. Nevertheless, these tend to be too small (<1–2 mm/year) to be relevant to most glaciological studies.

Indirect measurements of ice mass change

GPS mounted adjacent to glaciers is sensitive to contemporaneous ice mass changes through elastic rebound (e.g., Grapenthin et al., 2006; Khan et al., 2007). The Earth's response to ice unloading since the last glacial maximum, known as glacial isostatic adjustment, may also be studied using GPS and therefore provide constraints on ice history and Earth rheology (Milne et al., 2001). Since the velocities of interest are generally small, advanced analysis techniques are required.

Digital elevation models

GPS antenna mounted on snowmobiles or aircraft may be used to determine position for generation of digital elevation models (e.g., Krabill et al., 1995). In airborne applications, GPS positions the LIDAR or photogrammetric camera. Examples of subsequent use include surface elevation change (e.g., King et al., 2009) and satellite calibration/validation (Phillips et al., 1998). Errors and uncertainties can be assessed by designing crossovers into the sampling strategy.

Data analysis

Different GPS data processing software may be divided along lines of their main audiences: the mass-market (commercial) and/or research geodesists. All GPS hardware manufacturers provide high-quality software that is designed to produce robust solutions over generally short (<30–80 km) baselines. Scientific software allows greater flexibility in parameterization, such as in the estimation of tropospheric parameters, or in solution control, such as site motion constraints via process noise settings in a Kalman Filter.

Incorrect processing of GPS data in glaciological environments may yield substantial spurious signal that could be interpreted as real (King, 2004). In particular, processing data from a moving site as if it were static, even for short periods, will likely produce erroneous results.

Several online services now exist, allowing open access to research quality software. Caution should be exercised, however, as to which observation level model options have been applied, including, for example, loading displacements and antenna phase centers. Except for almost stagnant ice, kinematic processing should be adopted.

GPS coordinate formal errors produced by all current GPS processing software do not reflect the true formal error, and are typically overoptimistic as they are based on somewhat arbitrary observation uncertainties and neglect between-epoch and between-observation correlations, which can be substantial. While receiver sampling at least every 30 s is vital, coordinate time series will be correlated over several minutes, especially for a slow-moving site. Scale factors for the reported formal errors may be obtained by examining coordinate time series repeatability (see King, 2004). For kinematic surveys, an examination of crossovers yields useful information (Borsa et al., 2007).

For long baseline or PPP studies of slowly moving ice, the present-day state-of-the-art is likely to yield epoch-to-epoch repeatability in the range 0.01–0.02 m for horizontal positions and 0.03–0.05 m for vertical positions. Multipath effects may be reduced through sidereal filtering (Choi et al., 2004). Errors relating to mounting the GPS antenna robustly in the ice may now dominate the GPS positioning error in many cases.

Conclusions

The GPS has revolutionized point-wise measurements in glaciology, complementing the wide spatial sampling available from interferometric SAR. As precision has improved and as observations switched from campaign style to continuous, new insights have been gained. In the near future multiple GNSS will be available, reducing both random and systematic errors in coordinate time series. Surveys in kinematic environments, such as in glaciology, will be among the greatest beneficiaries.

GRACE IN GLACIOLOGY

John Wahr
Department of Physics and CIRES, University of Colorado, Boulder, CO, USA

Definition

GRACE: The Gravity Recovery and Climate Experiment. A satellite mission launched in March, 2002 by NASA and the German Space Agency that maps out the Earth's global gravity field every month.

GIA: Glacial Isostatic Adjustment. The viscoelastic response of the Earth to past changes in ice mass; especially those associated with the disappearance of ice since the last glacial maximum, ~20,000 years ago.

Introduction

The long-term evolution of an ice sheet or glacier is largely determined by its mass balance: the difference between the mass added through precipitation, and the mass removed through, for example, sublimation, melting, and ice discharge into the ocean. But monitoring mass balance is not easy. Measurements of ice velocities, of changes in surface elevations, and of precipitation and other meteorological variables can all help. But they can provide only part of the mass balance picture, and must

ultimately be combined with models and assumptions of various types to obtain a complete estimate.

But there is now a satellite mission, called GRACE (The Gravity Recovery and Climate Experiment) that is capable of directly monitoring the total mass balance of the polar ice sheets and of large glacier systems, on a month-to-month basis. GRACE was launched in March, 2002 by NASA and DLR (the German Space Agency). As of this writing, the mission is expected to last through ~2014. Every month, GRACE provides a global map of the Earth's gravity field at scales of a few hundred kilometers and more. The gravity field changes from one month to the next because the Earth's mass distribution is constantly varying. The GRACE data allow users to learn about those mass variations and the processes that cause them. Results from GRACE have been used to study changes in the volume of groundwater stored in large aquifers, regional fluctuations in sea-floor pressure (sea-floor pressure is proportional to the amount of mass in the overlying ocean/atmosphere column), and glacial isostatic adjustment (GIA) in the Earth's interior (see below). But arguably, the most important results to come out of GRACE to-date have been estimates of mass loss from polar ice sheets and continental glacier systems.

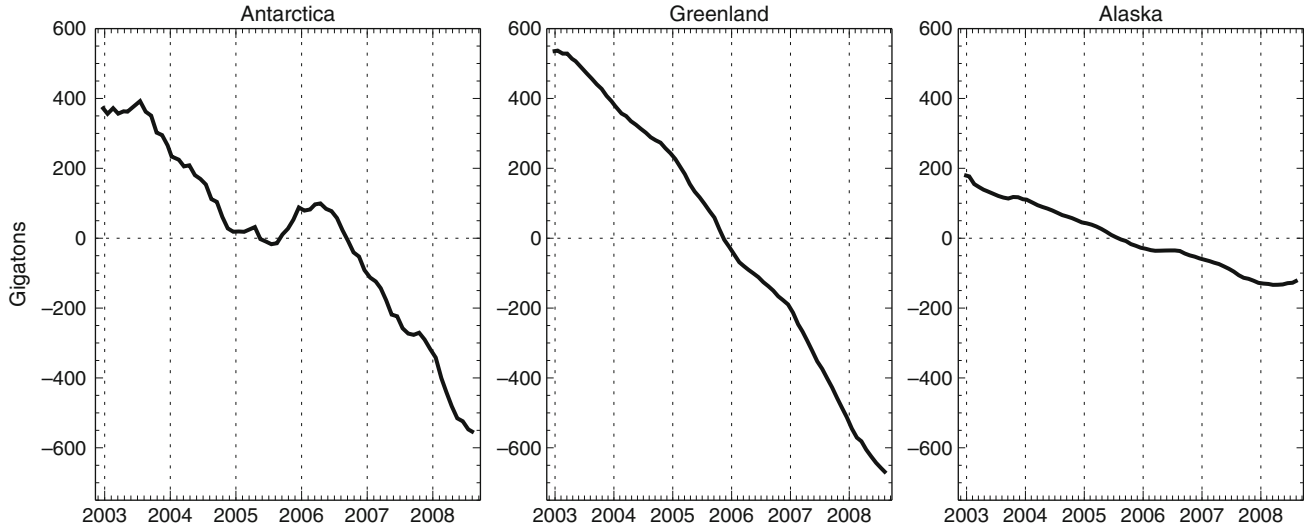
Grace

GRACE consists of two satellites in identical near-polar orbits (89° inclination) about the Earth (an altitude of ~500 km), one satellite following the other at a distance of ~220 km (Tapley et al., 2004). As they orbit, they use microwaves to monitor their separation distance. That distance is constantly changing as they move through gravity highs and lows, and measurements of those changes can be used to determine the gravity field. Accelerometers on-board each spacecraft are used to detect nongravitational accelerations caused, for example, by atmospheric drag; and the results are used to remove those nongravitational effects from the satellite-to-satellite distance measurements before solving for the gravity field.

The monthly gravity solutions are typically represented as a set of spherical harmonic global expansion coefficients, determined by fitting to all the available GRACE data for that month. Those coefficients can be combined to obtain monthly estimates of mass variability averaged across specific regions of the Earth's surface, including over the ice sheets. Because the satellites are at 500 km altitude, they can provide accurate results only over regions with scales of a few hundred kilometers or greater. The resolution at higher latitudes is better than at lower latitudes, because the satellites' ground tracks are denser at high latitudes. The strengths of GRACE for mass recovery are that (1) it provides what are basically direct estimates of mass; no supplementary data or models are required (strictly speaking, GRACE measures gravity rather than mass, but mass variability can be inferred by a straightforward application of Newton's Law of Gravity); and (2) it inherently averages over an entire region; it does not miss small sub-regions, and does not require interpolation or extrapolation of point measurements. The weaknesses of GRACE are (1) it cannot resolve small-scale spatial variability; and (2) it has no vertical resolution. That is, a gravity signal across a region can be used to determine the total mass integrated vertically below that region; but it cannot determine the depth-dependence of that mass distribution. This latter point is important for the ice sheets, primarily because of the GIA process. At the last glacial maximum, some 20,000 years ago, large ice sheets covered northern Canada and Scandinavia, and the Greenland and Antarctic ice sheets were much larger than they are at present. That additional ice has since melted, but because the Earth is viscous it is still uplifting in response to the removal of that load. The resulting mass transport within the Earth's interior contributes to the mass estimate recovered by GRACE. And so, it is necessary to model and remove this GIA contribution before interpreting the GRACE results in terms of present-day ice sheet mass variability. The GIA signal appears as a linear trend, and so an error in the GIA model would cause secular errors in the apparent ice sheet mass.

A number of GRACE-based estimates of mass loss have been published for Antarctica (e.g., Velicogna and Wahr, 2006a; Chen et al., 2006a), Greenland (e.g., Luthcke et al., 2006; Chen et al., 2006b; Velicogna and Wahr, 2006b), and the Alaskan coastal glacier system (e.g., Tamisiea et al., 2005; Luthcke et al., 2008). Each of these published estimates shows significant mass loss, with the exact numerical values depending on the time span considered in the analysis. For instance, the mass loss rates for Antarctica and Greenland appear to have increased over the last few years; whereas the rate for the Alaskan coastal glaciers appears to have decreased. Figure 1 shows smoothed time series for the mass changes of Antarctica, Greenland, and coastal Alaskan glaciers as inferred from monthly GRACE gravity fields produced at the Center for Space Research at the University of Texas (results computed as described by Velicogna and Wahr, 2006a, b). Steady mass loss is apparent in the results for each region. To put these results in perspective, a 100 Gton mass loss causes a ~0.28 mm rise in global sea level.

The results shown in Figure 1 have been corrected for GIA, using model results based on the ICE-5G ice deglaciation history and VM2 viscosity profile of Peltier (2004). The Greenland and Alaskan results are not significantly changed by removing the GIA model. For example, applying the GIA correction has increased the Greenland mass loss estimate by only 5 Gton/year; an insignificant fraction of the Greenland trend evident in Figure 1. But the Antarctic numbers are critically dependent on the GIA correction. Applying the GIA correction has increased the mass loss estimate by an amount in excess of 180 Gtons/year, which is of the same order as the trend evident in the Antarctic figure. In fact, if no GIA correction had been made, the GRACE results would show virtually no trend at all. This implies that errors in the GIA model could have a significant impact on the



GRACE in Glaciology, Figure 1 Time series showing mass variability (in Gigatons) for the Antarctic and Greenland ice sheets, and for the coastal Alaskan glacier system, as inferred from monthly GRACE gravity fields produced by the Center for Space Research at the University of Texas. The method of analysis is as described in Velicogna and Wahr (2006a, b). Contributions from glacial isostatic adjustment, the ongoing viscoelastic response of the earth to the removal of ice loads after the last glacial maximum, have been removed using a model based on the ICE-5G ice deglaciation history (Peltier, 2004). The results shown in these figures have been smoothed to remove the seasonal cycle and other short-period variability. For reference, a 100 Gton mass loss causes a ∼0.28 mm rise in global sea level.

GRACE Antarctic estimates. GIA model results for different plausible viscosity profiles and for two Antarctic deglaciation histories (ICE-5G from Peltier, 2004; and IJ05 from Ivins and James, 2005) give GIA corrections for Antarctica that vary from 100 to 220 Gton/year, suggesting that until knowledge of the GIA process has improved, the uncertainty in GRACE Antarctic trends is on the order of ±60 Gton/year.

Summary

The recently launched GRACE satellite gravity mission is providing glaciologists with a powerful technique for estimating the mass balance of polar ice sheets and continental glacier systems. Results from GRACE show that the combined mass loss of Greenland, Antarctica, and the coastal Alaskan glacier system was probably in excess of 2,000 Gtons between 2003 and 2009.

GRANULOMETRY

Amit Kumar
Department of Geology, Centre of Advanced Study in Geology, Panjab University, Chandigarh, India

It is defined as the measurement of sediment grain size in a granular material as a proportion by weight of particles of different sizes. Granulometric analysis involves the sieving of material and subsequent weighing of individual fractions as combined into mainly three groups. The smallest fraction, clay, has a diameter of less than 75 μm. The sand fraction contains all grains with diameters between 75 μm and 2 mm, and the gravel fraction consists of all grains with a diameter greater than 2mm. It should be noted that the names of these three groups do not correspond with the international geological classification of unconsolidated sediments, which includes all particles with diameters up to 200 μm in the clay fraction.

The grain size is only one of several parameters used to classify unconsolidated sediments. Methodology by Folk and Ward (1957) is mostly used for granulometry study. Parameters such as mean, standard deviation, skewness, and kurtosis are calculated for the sediment samples.

GRAVEL SHEET

Amit Kumar
Department of Geology, Centre of Advanced Study in Geology, Panjab University, Chandigarh, India

Gravel sheets deposits are the Pleistocene meltwater deposits that originated during the Quaternary period (1.8 million years). Except of the erosion, transportation, and deposition by glaciers, glaciers lose ice to melting at lower reaches and produce meltwater, which becomes an important component of the glacial system. Meltwater produces several distinctive landforms and sediments from boulder to clay sizes. These widespread deposits of silt and sand and material were subsequently either scoured out by the advancing ice or covered with gravels. Usually gravel sheet covers a large extent of area to define it as sheet.

GRAVITATIONAL MASS MOVEMENT DEPOSITS

D. P. Dobhal
Wadia Institute of Himalayan Geology, Dehradun, Uttarakhand, India

"Gravitational mass movement" is a geologic term that encompasses the rapid downhill movement of rocks and fine particles due to the force of gravity. One of the most common and generic types of mass movement features on Earth are landslides, but there are many others such as rock falls, debris flows, soil creep, and snow/ice avalanches. The topographic factor such slope and type of terrain play a vital role in gravitational mass movement deposits.

GRAVITY FLOW (MASS FLOW)

Rajesh Kumar
Remote Sensing Division, Birla Institute of Technology, Extension Centre Jaipur, Jaipur, Rajasthan, India

The original form of Bernoulli's equation valid at any point along a streamline flow is

$$\frac{v^2}{2} + gz + \frac{p}{\rho} = \text{Constant}$$

v is the fluid flow speed at a point on streamline.
g is the acceleration due to gravity.
z is the elevation of the point above a reference plan, with the positive Z direction upward.
p is the pressure at the point.
ρ is the density of fluid at all points in the fluid.

If the pressure term is omitted from the above equation, it shows a balance between the velocity and gravity force and such type of flows are termed as gravity flow.

Hence, any material that flows due to the forces of gravity alone and not to an applied pressure will be under the gravity flow. A glacier flow also obeys this principle as the glacier is an accumulation of ice, air, water, and rock debris or sediment in a terrain of differential slope or the slope is created by the differential accumulation of ice mass over a region. Once the mass of compressed ice reaches a critical thickness, it becomes so heavy that it begins to deform and move downward. The sheer restraint of the ice, combined with gravity's influence, causes glaciers to flow downward very slowly due to its extraordinary weight.

GRAY-WHITE ICE

Chelamallu Hariprasad
Centre for Studies in Resource Engineering, IITB, Powai, Mumbai, India

Gray-white ice is a category of young ice (15–30 m thick). Young ice is an ice in the transition stage between nilas and first-year ice. The depth of the young ice varies between 10 and 30 cm. Based on its color, young ice classifies into two types namely, gray ice and gray-white ice (Figure 1).

GREENLAND GLACIERS OUTSIDE THE ICE SHEET

Jacob C. Yde
Center for Geomicrobiology, University of Aarhus, Aarhus C, Denmark

Synonyms

Local glaciers

Definition

Greenland Ice Sheet. The continental ice sheet occupying the central area of Greenland. It is often referred to as the Inland Ice or abbreviated as GIS.
Local glaciers. A term used to address all peripheral glaciers outside a continental ice sheet. In the context of Greenland, the term covers all glaciers in Greenland except the Greenland Ice Sheet.

Introduction

The local glaciers in Greenland can easily be overlooked in the presence of the vast Greenland Ice Sheet (GIS) (see entry *Greenland Ice Sheet*). This is probably the main reason why relatively limited research has been conducted on these glaciers; despite they cover about 5–10% of the total ice cap and minor glacier area of the world (Weidick and Morris, 1998). Another reason for the lack of research may be the remoteness of many local glaciers, which can be logistically and economically challenging for small research operations.

Gray-White Ice, Figure 1 Thingray-white ice showing the effects of ridging and rafting. (Photo courtesy of the Antarctic Sea-Ice Processes and Climate program (ASPeCt).)

The definition of a local glacier is not equivocal because some local glaciers merge with an ice sheet along a large distance of their margins and their ice dynamics may be strongly dependent on the ice dynamics of the adjacent ice sheet. According to Weidick and Morris (1998), three types of local glaciers can be identified: (1) local coastal glaciers, which exist independent from GIS or merge with GIS along a short distance up to about 50 km; (2) local fringing glaciers, which largely merge with GIS along a considerable distance; and (3) local glaciers within the ice sheet zone (e.g., marginal ice domes or glaciers on nunataks). Type 1 local glaciers are traditionally considered as "true" local glaciers, whereas Type 2 and 3 local glaciers often are formed as a consequence of ice thinning and deglaciation along the ice sheet margins. This gradual transition from being part of the ice sheet to become a local glacier is most obvious in East Greenland (termed the Blosseville Ice Cap) and Southeast Greenland (termed the Ammassalik Ice Cap) (Weidick and Morris, 1998). Attempts to delineate these transitional types are still lacking, and these local glaciers are therefore generally included in the GIS.

Very little is known about the number, size, and volume of the local glaciers. Estimations of the area covered by local glaciers range from 48,599 km^2 (Weng, 1995) to 76,000 km^2 (Holtzscherer and Bauer, 1954), but these figures must be considered as minimums as they are based on large-scale mapping and omit most minor glaciers and ice caps that merge with the GIS. Higher and more speculative estimates up to 163,200 km^2 have been presented by Sharp (1956) and references herein.

The most detailed glacier inventory (Weidick et al., 1992) covers the area from Kap Farvel (South Greenland) to Nuussuaq Peninsula (West Greenland) and comprises about 5,000 local glaciers (14,574 km^2). It is primarily based upon relatively old aerial photographs from between 1948 and 1964, and the local glaciers are classified according to a glacier identification code (Müller et al., 1977) based upon a hydrological basin code (Weidick and Olesen, 1980). The identification code system has been extended to cover parts of North Greenland (Weidick, 2001). Although not yet fully implemented to cover the entire Greenland, this glacier identification system provides very useful references as only a small proportion of the local glaciers have been given official names. However, due to the general glacier recession throughout the twentieth century some tributary glaciers have separated from their main glacier, while other glaciers have relocated their drainage routing to neighboring hydrological basins, causing discrepancies to the original inventory system.

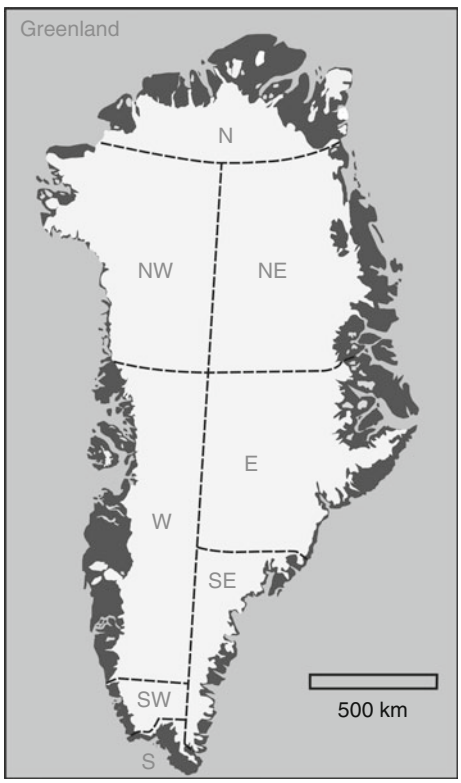
The research on local glaciers in Greenland has generally focused on: (1) Pleistocene and Holocene glacier fluctuations, (2) mass balance and glacier velocity, (3) glacier surging, and (4) glacier hydrology and hydrochemistry.

Glacier distribution

Local glaciers occur in all regions surrounding the GIS, and they exist in all glacier morphological types from ice caps to glacierets and snow fields. Here follows an overview of local glacier extent in different regions of Greenland (Figure 1).

South Greenland

The landscape in South Greenland is alpine and constitutes of many islands and cross-cutting fjords. The second-largest ice cap in Greenland, Julianehåb Ice Cap (6,500 km^2), is confluent with the southern part of the GIS. The delineation between Julianehåb Ice Cap and the GIS is generally defined by the ice stream Qorqup Sermia draining westward and an ice stream draining eastward to the fjord Anoritup Kangerlua. Along the western and southern part of Julianehåb Ice Cap many minor ice caps, valley glaciers, and cirque glaciers exist, and especially the peninsula between Lindenows Fjord (Kangerlussuatsiaq) and Prins Christian Sund (Ikerasassuaq) is heavily glacierized.



Greenland Glaciers Outside the Ice Sheet, Figure 1 Map showing the regions of Greenland.

Southwest Greenland

Cirque glaciers and glacierets occur on the highest mountains in the southern part of Southwest Greenland and in the alpine region between the GIS outlet glaciers Sermiligarssuk Bræ and Sermilik Bræ (Ukassorssuaq Sermia).

West Greenland

In southern West Greenland, there are primarily three glacierized regions: (1) the alpine region between Frederikshåb Isblink and Godthåbsfjorden containing ice caps such as Isortuarssuk Ice Cap (177 km^2) and Sermilik Ice Cap (117 km^2) and many valley and cirque glaciers (Figure 2); (2) the high plateau region between the village Kangamiut and the GIS, which comprises ice caps such as Qarajugtoq Ice Cap (2,010 km^2; Figure 3), Sukkertoppen Ice Cap (1,983 km^2), Perserajoq Ice Cap (692 km^2), Amitsuloq Ice Cap (193 km^2), and Qapiarfiup Sermia Ice Cap (116 km^2); and (3) the coastal alpine region near the fjord Nordre Isortoq. Along a 430 km section from Amitsuloq Ice Cap to Nuussuaq Peninsula, there are no local glaciers close to the GIS. In central West Greenland, Disko Island is 19% glacierized and contains about 1,070 glaciers and snow fields including Sermersuaq Ice Cap (918 km^2) and Bræpasset Ice Cap (254 km^2). On Nuussuaq Peninsula, there are about 600 glaciers and snow fields including Makitarigssagaq Ice Cap (379 km^2) and Qilertinguit Ice Cap (116 km^2). Further north, alpine islands and peninsulas such as Upernavik Ø and Svartenhuk Peninsula are relatively heavily glacierized with minor ice caps, valley glaciers, and cirque glaciers.

Northwest Greenland

Along the coast from Svartenhuk Peninsula to Melville Bugt, only a narrow fringe of land is ice-free. Minor ice caps, valley glaciers, and cirque glaciers occur on the larger islands and peninsulas. The area from Melville Bugt to Humboldt Gletscher is characterized by several ice caps.

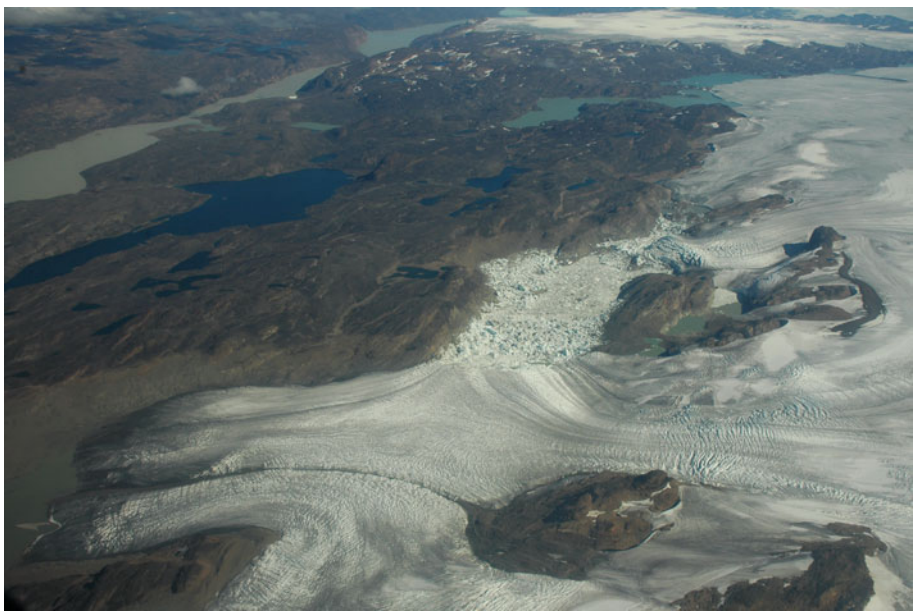
North Greenland

This dry, sparsely vegetated plateau landscape features many ice caps such as Flade Isblink (c. 9,000 km^2) and Hans Tausen Ice Cap (4,208 km^2). The northernmost area, Johannes V. Jensen Land, has a more alpine landscape with valley glaciers and cirque glaciers.

Northeast Greenland

The low coastal plains are mainly ice-free (e.g., on Shannon Island and Hochstetters Forland). Further inland the landscape becomes alpine with outlet glaciers from ice caps and valley glaciers terminating in generally ice-free U-shaped valleys.

Greenland Glaciers Outside the Ice Sheet, Figure 2 Degrading cirque glaciers near Nuuk, southern West Greenland (photo: Jacob Yde, August 2008).



Greenland Glaciers Outside the Ice Sheet, Figure 3 Outlet glaciers descending from the northern margin of Qarajugtoq Ice Cap, West Greenland, looking east. A recent jökulhlaup from an ice-dammed lake (*c.* 6 km^2) caused calving by pressure-release and distribution of ice blocks over the lake floor (see entry *Glacier Lake Outburst Floods*). Amitsuloq Ice Cap is seen in the background, and Lake Tasersiaq, the largest lake in Greenland, is seen in the *upper left corner* (photo: Jacob Yde, August 2008).

East Greenland

In central East Greenland, north of Scoresby Sund, the alpine landscapes on Liverpool Land and Stauning Alper are characterized by valley glaciers and minor ice caps, whereas the intervening terrain on Jameson Land is mainly deglaciated. Closer to the GIS major ice caps dominate Nathorsts Land, Renland, Milne Land, and Gåseland, and adjacent to the GIS other ice caps merge with the GIS. South of Scoresby Sund the ice-free area is restricted to nunataks and both GIS outlet glaciers and

Greenland Glaciers Outside the Ice Sheet, Figure 4 Characteristic landscape along the Blosseville Coast, East Greenland, with large tidewater outlet glaciers receiving ice from ice-filled valleys (photo: Jacob Yde, July 2008).

local glaciers calve into the sea and fjords (Figure 4). The distinction between the GIS and confluent local ice caps is transitional and difficult to delineate (Weidick et al., 1992).

Southeast Greenland

North of the Sermilik Fjord the landscape consists of ice-filled valleys separated by mountain ridges with tributary cirque glaciers. On Ammassalik Island and nearby coastal islands minor ice caps and cirque glaciers dominate. Further south the landscape is characterized by fjords with calving glaciers emanating from the GIS and the eastern sector of Julianehåb Ice Cap and intervening glacierized peninsulas and islands.

Glacier fluctuations and mass balances

As argued by Weidick (1985), the Late Pleistocene and Early Holocene history of glacier variations in Greenland is nearly identical to our current knowledge of the deglaciation of the GIS margins. There is only sporadic information on deglaciation and rebuilding of coastal local glaciers and on detachment from and re-coupling to the GIS of local glaciers (see review by Kelly and Lowell, 2009). Radiocarbon datings from ice caps such as Hans Tausen Ice Cap, North Greenland (Landvik et al., 2001), and Mittivakkat Gletscher, Southeast Greenland (Figure 5; Knudsen et al., 2008), indicate that many local glaciers disappeared during the Holocene Climatic Optimum (8,500–6,000 BP), reformed as the temperature gradually declined and reached their Holocene maximum extent at the end of the Little Ice Age (1150–1920 AD).

Observations and measurements of glacier velocities and frontal fluctuations received significant attention in the pioneering years of systematic glaciological research on local glaciers. The most detailed information is from outlet glaciers descending from Lyngmarksbræ Ice Cap, Disko Island (e.g., Chamberlin, 1894; Steenstrup, 1901), and reports on local glacier fluctuations from other parts of Greenland are abundant (see review by Weidick, 1968).

Mass balance measurements based on stake networks and snow accumulation probing are scarce in Greenland and generally restricted to cover short periods (Weidick, 1984a). The longest record is from Mittivakkat Gletscher (formerly Mitdluagkat Gletscher), Southeast Greenland, where mass balance measurements have been conducted in 1986/1987 and from 1995/1996 onwards (Hasholt, 1988; Knudsen and Hasholt, 2004). Except for 1995/1996 (equilibrium) and 2002/2003 (positive mass balance), the annual net balance has been negative (N. Tvis Knudsen, pers. comm. 2009). Short-term mass balance records obtained at other local glaciers show both positive and negative mass balances for Qapiarfiup Sermia and Amitsuloq Ice Cap, West Greenland, during the period 1981–1985 (Olesen, 1986), and a slightly negative trend in 1994/1995 for Hare Glacier, an outlet glacier from Hans Tausen Ice Cap, North Greenland (Reeh et al., 2001).

Surge-type glaciers

In Greenland, there are two recognized surge clusters (see entry *Glacier Surging*), the Disko-Nuussuaq surge cluster (Weidick, 1988; Yde and Knudsen, 2007, 2009) and the

Greenland Glaciers Outside the Ice Sheet, Figure 5 Mittivakkat Gletscher, Southeast Greenland, is the most examined local glacier in Greenland. It has experienced recession since the end of the Little Ice Cap (photo: Jacob Yde, August 2007).

East Greenland surge cluster (Weidick, 1988; Jiskoot et al., 2003). In addition, confirmed or indicative surge activity has been reported from tidewater-terminating outlet glaciers from the GIS such as Harald Moltke Bræ, Northwest Greenland (Mock, 1966; Rignot and Kanagaratnam, 2006); Brikkerne Gletscher and Ryder Gletscher, North Greenland (Higgins and Weidick, 1988; Joughin et al., 1996); Storstrømmen, Northeast Greenland (Reeh et al., 1994); and Eqalorutsit Kitdlît Sermiat, South Greenland (Weidick, 1984b). Surge activity in Greenland is characterized by some of the longest frontal advances even recorded (about 10 km) and relatively long surge periodicities (i.e. the time interval between active surge events) compared to other surge clusters in the world (at least 100 years). There are indications of a decline in the frequency in surge events throughout since the termination of the LIA. Both Greenlandic surge clusters are primarily located in Tertiary basalt provinces with widespread occurrence of homothermal springs, indicating that the geothermal heat flux may be enhanced in these regions.

The Disko-Nuussuaq surge cluster comprises an estimated number of 75 surge-type glaciers on Disko Island (Yde and Knudsen, 2007, 2009) and two surge-type glaciers on Nuussuaq Peninsula (Weidick, 1988). In addition, there are signs of surge activity on at least two glaciers on Svartenhuk Peninsula (Yde, unpublished data). Most research has been focused on the 1995–1998 surge event of Kuannersuit Glacier, central Disko Island, which advanced 10.5 km down-valley with a maximum velocity of at least 70 m/day (Gilbert et al., 2002; Yde and Knudsen, 2005a; Yde et al., 2005a; Roberts et al., 2009).

The estimated number of surge-type glaciers included in the East Greenland surge cluster range from 71 (Jiskoot et al., 2003) to about 200 (Weidick, 2000). Particular in the Stauning Alper, surge-type glaciers are very common and include glaciers such as Løberen, Bjørnbo Gletscher, Roslin Gletscher, Schuchert Gletscher, Sirius Gletscher, and Østre Gletscher. On the Blosseville Kyst, the best-documented surge event is the 1992–1995 surge of Sortebræ, which advanced 10 km (e.g., Jiskoot et al., 2001; Murray et al., 2002).

Glacier hydrology and hydrochemistry

Measurements of runoff, sediment, and solute transport from local glaciers in Greenland are relatively sporadic (see entries *Glacier Hydrology*; *Sediment Yield* and *Solute in Glacial Meltwaters*).

The most intensive studies on glacier hydrology and suspended sediment transport are from the forefield of Mittivakkat Gletscher. In this coastal granitic-gneissic catchment, frequent runoff measurements have been conducted since 1958 (Larsen, 1959) and combined with sediment sampling, indicating a specific transport rate of about 1,000 $t\,km^{-2}\ year^{-1}$ (e.g., Hasholt, 1976). The solute yield has been estimated to 18 $t\,km^{-2}\ year^{-1}$ (Yde, unpublished data) and 32 $t\,km^{-2}\ year^{-1}$ (Hagedorn and Hasholt, 2004).

At the surge-type glacier Skelbræ, East Greenland, large irregular fluctuations in runoff have been related to precipitation events and ice-block damming events

(Stott and Grove, 2001). The suspended sediment yield has been estimated to 732 t km^{-2} year^{-1}.

At Zackenberg, Northeast Greenland, runoff, sediment, and solute monitoring has been conducted since 1996–1997 (Rasch et al., 2000). The distance from the hydrometric station to the local glaciers in A. P. Olsen Land is more than 30 km, suggesting that the periglacial area has a significant influence on water quality. The suspended sediment yield varies between 29 and 255 t km^{-2} year^{-1}, whereas the solute yield ranged between 5 and 22 t km^{-2} year^{-1} (Hasholt et al., 2008).

The 1995–1998 surge event of Kuannersuit Glacier, Disko Island, West Greenland, caused evacuation of extreme amounts of sediment from the overridden area. The sediment yield in 1999 has been estimated to 49,100 t km^{-2} year^{-1}, and it gradually decreased to about 7,700–13,400 t km^{-2} year^{-1} in 2001 (Knudsen et al., 2007). The solute yield and atmospheric CO_2 drawdown in 2001 was 76–98 t km^{-2} year^{-1} and 8,500–13,700 kg C km^{-2} year^{-1} (Yde et al., 2005b). Surge events on Disko Island have been related to the formation and occurrence of glacier-derived naled assemblages (Yde and Knudsen, 2005b).

In front of Kitdlerssuaq Gletscher, an outlet glacier from Amitsuloq Ice Cap, West Greenland, water level and conductivity measurements were conducted in 1982, showing that conductivity varied inversely with water level and ablation (Andreasen, 1984).

Summary

The local glaciers surrounding the GIS constitute a significant proportion (5–10%) of the global ice masses besides ice sheets. Nevertheless, they have not yet received much attention. The actual size of local glaciers in Greenland is difficult to determine because there is a gradual transition from dynamically dependence to independence from the GIS. This interrelationship along parts of the GIS margin may have fluctuated throughout the Holocene. Many coastal local glaciers diminished or disappeared during the Holocene Climatic Optimum (8,500–6,000 BP) and reformed to have a maximal Holocene extent at the end of the Little Ice Age (1150–1920 AD). Current mass balance measurements are in concordance with the global negative trend. Two areas with widespread surge activity exist in Greenland: the East Greenland surge cluster and the Disko-Nuussuaq surge cluster. Both clusters are mainly located on Tertiary basaltic rocks and have surge cycle periodicity of more than 100 years. The contribution from local Greenlandic glaciers to global sea-level rise derives mainly from meltwater runoff rather than marine calving, but a total contribution has not been thoroughly estimated due to the problems with the definition of local glaciers. The specific contribution of suspended sediments and solutes from glacierized areas is highest from the basaltic regions in West and East Greenland.

Introduction

The Greenland Ice Sheet covers 80% of the Greenland land surface area of 2.2 million km^2. The volume of ice in the ice sheet is 2.8 million km^3. The geographical position of the ice sheet ranges from 59° to 83° North and from 73° to 110° West. Each year, snow accumulation provides the equivalent of 680 km^3 of ice and if the ice sheet was in a steady state it would lose the same amount by surface meltwater runoff and iceberg discharge.

The Greenland Ice Sheet is thought to have formed approximately 3 million years ago when glaciations in the northern hemisphere became extensive. The cause of

Northern hemisphere glaciations is not fully established. It is possible that tectonic processes such as the uplift of Tibet and closure of the Panama sea way caused global cooling (e.g., Haug and Tiedemann, 1998), but Earth system modeling shows that a decline in atmospheric carbon dioxide could have triggered the most recent era of glaciations in Greenland (Lunt et al., 2008).

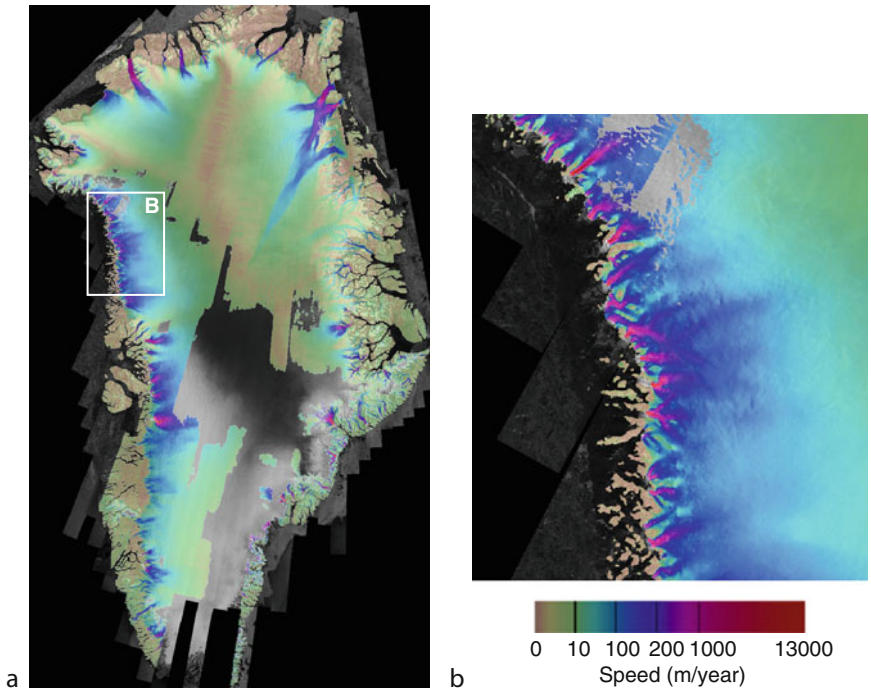
Ice cores and paleoclimate

Paleo-environmental records of a very high quality have been established from ice cores drilled on the Greenland Ice Sheet (Andersen et al., 2004; Dansgaard et al., 1993; Grootes et al., 1993). These records are established from the composition of stable isotopes and various types of gasses trapped in air bubbles that formed when snow transformed into firn and ice. Ice cores also contain atmospheric dust, which yields information about storminess. Salt is an indicator of the distance to open ocean and ash layers can be traced to known volcanic eruptions. The Greenland ice cores have shown that Earth's climate can change abruptly (e.g., Dansgaard et al., 1993). During the last glacial period temperatures rose by more than 10°C in recurring warm periods known as Dansgaard-Oeschgar events.

The first ice core to reach the base of the Greenland Ice Sheet was drilled at Camp Century in 1966. Additional deep ice cores were subsequently collected through the Greenland Ice Sheet Project (GISP), the Greenland Ice-Core Project (GRIP), and the North Greenland Ice Core Project (NGRIP). The North Greenland Eemian Ice Drilling Project (NEEM), which aims to determine the paleoclimate of the last interglacial period, began in 2008.

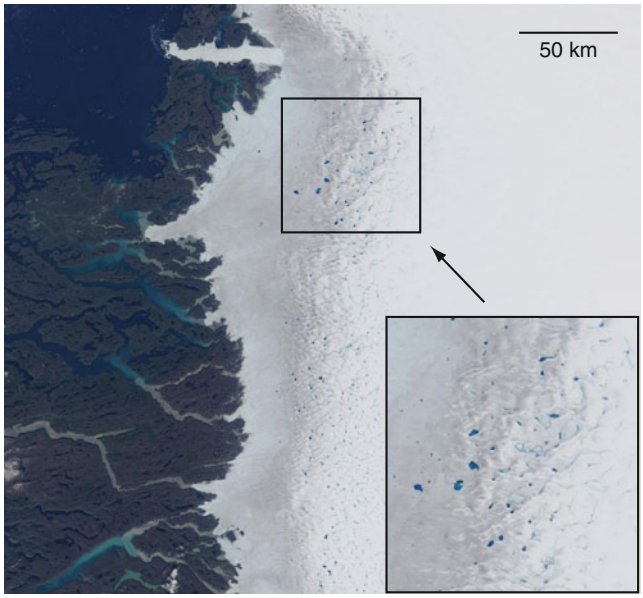
Ice sheet mass balance

The mass balance of ice sheets is the difference between the net accumulation of snow and the combined loss of snow and ice by melt processes, sublimation and iceberg discharge. Measuring the mass balance of the Greenland Ice Sheet is a scientific challenge because of its large size and remote position, but estimates can be made in a number of different ways. In the mass budget approach, snow accumulation rates are typically inferred from ice cores or meteorological models while surface meltwater runoff is assessed in energy balance models (e.g., Bougamont et al., 2007). Estimates of the discharge of ice into fjords and other coastal environments require knowledge of the speed and thickness of marine-terminating outlet glaciers (Figure 1). Speeds can be determined from surface displacements measured in situ using global positioning systems (van de Wal et al., 2008) or from satellite remote sensing methods such as radar interferometry and repeat pass tracking of surface features (e.g., Howat et al., 2007; Joughin et al., 2004; Luckman et al., 2006). The thickness of ice is measured by radio-echo sounding at the surface or from aircraft (Gogineni et al., 2001). Using the mass budget approach, Rignot et al. (2008) estimate the mass balance of



Greenland Ice Sheet, Figure 1 Velocity map of the Greenland Ice Sheet for winter 2006 derived from synthetic aperture radar imagery. The color scale illustrates surface speed, which is particularly high for marine-terminating outlet glaciers. (Courtesy of I. Joughin, Applied Physics Laboratory, University of Washington.)

the Greenland Ice Sheet to have deteriorated from a steady state in the 1970s to a state of rapid and sustained ice-mass loss of several hundred gigaton per year in the 2000s. Other approaches to measuring ice sheet mass balance include altimetry from satellites and aircraft (e.g., Krabill et al., 2000). Satellites in the Gravity Recovery and Climate Experiment (GRACE) can detect changes in gravitational attraction and this method also gives valuable information about short-term changes in ice sheet mass (e.g., Velicogna and Wahr, 2006). The various approaches used to measure ice sheet mass balance have different strengths and weaknesses and mass loss estimates are not always identical (Shepherd and Wingham, 2007). The relatively short timescale of satellite observations makes it difficult to accurately determine the magnitude of decadal variability in snowfall, surface ablation, and iceberg calving. This uncertainty is becoming less significant because mass-balance measurements are becoming longer and supported by new and complementary investigative techniques. Today, there is a clear consensus that the Greenland Ice Sheet is losing mass at a pace of at least a hundred gigaton of ice per year.



Greenland Ice Sheet, Figure 2 MODIS satellite image showing large and abundant supraglacial lakes on the surface of the western margin of the Greenland Ice Sheet.

Atmospheric or oceanic forcing?

The rapid loss of ice from the Greenland Ice Sheet since the mid-1990s coincides with a period where atmospheric temperatures were high. The seasonal extent of surface meltwater, which has been monitored by satellites since 1979, shows a variable, but progressive increase culminating with record high ablation in 2002, 2005, and 2007. Hanna et al. (2008) use meteorological observations and a surface energy–balance model to estimate meltwater runoff from the Greenland Ice Sheet during summers in the period 1958–2006. According to this model, the five record years were 1993, 1995, 1998, 2002 and 2006. Expanding the simulations by one more year showed that 2007 was yet another record year in terms of the magnitude of surface meltwater runoff (Rignot et al., 2008). The year 2010 was yet another year with record melt extent in Greenland.

Zwally et al. (2002) measured surface displacements with global positioning systems installed 35 km inland of the western margin of the ice sheet and over 1,175 m of ice. They identified possible relationships between changes in surface velocity and the timings and intensities of surface melting. It was proposed that short-term changes in surface velocity occur because surface meltwater drains to the bed and lubricates the basal motion of the ice sheet. The proposed link between ice flow and seasonal production of surface meltwater has been examined closely because satellite remote imagery show that glacial lakes on the surface of the Greenland Ice Sheet are numerous and widespread in the ablation zone (Figure 2). A direct response of the Greenland Ice Sheet to atmospheric forcing is of crucial significance because it may influence contemporary rates of sea-level change. If surface lowering occurs in response to surface-melt-induced ice-flow perturbations, it may trigger a precarious positive feedback mechanism whereby an increase in surface meltwater production increases the surface melt extent, which lead to yet more surface meltwater and so forth. Atmospherically coupled hydrological systems in ice sheets may accelerate the pace of ice moving from the interior toward lower and warmer elevations and this effect can potentially cause a fast demise of the ice sheet.

Recent studies have confirmed the occurrence of short-term velocity fluctuations in response to penetration of surface meltwater to the bed of the Greenland Ice Sheet (e.g., Das et al., 2008; Shepherd et al., 2009). However, the impact of the mechanism remains uncertain (van de Wal et al., 2008) and its influence seems restricted to the relatively slow-moving, land-terminating part of the ice sheet (Joughin et al., 2008). Surface-melt-induced basal lubrication does not appear to be an important driver of the fast flow of marine-terminating outlet glaciers, which exert a key control on the mass balance through discharge of icebergs to fjords and other coastal environments (Figure 3). Land-terminating glaciers have not changed significantly in recent years, at least not compared to the widespread and synchronous retreat reported for outlet glaciers terminating in seawater (Moon and Joughin, 2008). This suggests that the cause of recent rapid change may be oceanic. The exact nature of the oceanic forcing is not yet known, but it has been suggested that warm subsurface waters has triggered glacial recession of marine-terminating outlet glaciers because oceanic warming increases rates of submarine melting, thereby increasing rates of iceberg calving (Holland et al., 2008). It is possible that warming of subsurface waters occurs from

Greenland Ice Sheet, Figure 3 Aerial photograph of the marine-terminating Daugaard-Jensen Glacier in East Greenland. (From Christoffersen and Hambrey, 2006.)

air–ocean exchange of heat within the fjords or because warm Atlantic water enter fjords via coastal currents.

Fast-flowing outlet glaciers

Outlet glaciers in Greenland are steep and fast and they contribute to sea-level rise in a significant way despite their modest widths of approximately 5 km or less (Figure 3). Dynamic processes associated with fast glacier flow and iceberg discharge may have caused about two-thirds of the current rate of ice-mass loss (Rignot and Kanagaratnam, 2006). Approximately half of the icebergs discharged from the Greenland Ice Sheet in 2005 came from a dozen glaciers. Of their collective discharge, almost half came from the largest three. These glaciers are Jakobshavn Isbræ on the West Coast and Kangerdlugssuaq and Helheim glaciers on the East Coast.

Jakobshavn Isbræ was one of the first glaciers where major contemporary changes in flow dynamics were detected. The calving front of the glacier was in a relatively stable position from the 1950s to the 1990s. In 1998, the front retreated by 5 km and this caused flow speeds to increase from 5 km/year to 9 km/year. More dramatic changes followed between 2001 and 2003 as the majority of a floating ice tongue collapsed and caused the calving ice front to retreat several kilometers. This caused speeds to increase to 13 km/year (Joughin et al., 2004). Similar, although not identical events occurred in Kangerdlugssuaq and Sermilik fjords on the eastern side of the ice sheet. The front of Helheim Glacier retreated 7 km between 2001 and 2005. Subsequently, the speed of the glacier increased from 7 km/year to 11 km/year. Kangerdlugssuaq Glacier experienced an abrupt retreat of 5 km between 2004 and 2005 and its flow speed almost doubled from 7 km/year to about 13 km/year (Howat et al., 2007).

Jakobshavn Isbræ is currently capable of maintaining the accelerated pace set by the near-total disintegration of its floating ice tongue (Joughin et al., 2008). The response of Kangerdlugssuaq and Helheim Glaciers has been different. Both glaciers stopped retreating in 2005 and they have subsequently slowed down. The excess discharge caused by the speed-up events was about 30–50 Gt per glacier (Howat et al., 2007). The cumulative ice loss associated with excess discharge from numerous outlet glaciers experiencing retreat and flow acceleration in the early 2000s account for a considerable part of the volume loss identified across the ice sheet as a whole (e.g., Velicogna and Wahr, 2006).

Climate change

The Greenland Ice Sheet was in the past perceived to be in a relatively stable position and its demise was thought to require thousands of years of melting under warm climatic conditions. This premise has been questioned in light of the recent abrupt changes. Assessing the sensitivity and response of the Greenland Ice Sheet to the current warming of Earth's oceans and atmosphere is today an issue of tremendous scientific, societal, and political significance. The Greenland Ice Sheet contains enough ice to raise global sea levels by approximately 7 m. Gregory et al. (2004) forced an ice sheet model with outputs from a global climate model and the results suggest that global warming of 3°C is a critical threshold that could lead to a complete demise of the ice sheet. This threshold will

most likely be exceeded before 2100 unless emissions of carbon dioxide and other greenhouse gasses are stabilized and reduced to the level of year 2000 before 2050 (IPCC, 2007). This level of greenhouse gas reduction will require an economic outlook consistent with greenhouse gas emissions scenario with a global emphasis on resource-efficient technologies and global solutions to economic, social, and environmental sustainability. The alternative is less rapid economic development with emphasis on local solutions and environmental protection. So far, global economic growth remains fossil-fuel intensive, and this economic outlook is not consistent with a sustainable long-term presence of an ice sheet in Greenland.

The onset of a demise of the Greenland Ice Sheet may be tied to a predictable magnitude of global warming, but there is currently no consensus about the rate of demise. A demise controlled by surface melting mainly could take several thousand years (e.g., Ridley et al., 2005), but this scenario has been questioned on the basis of recent rapid change of the flow of outlet glaciers (Pfeffer et al., 2008). The main reason for this crucial lack of information is problems associated with the representation of dynamical processes in ice sheet models. Whereas assessments of surface mass balance are in good agreement with observational constraints, there are still major uncertainties associated with retention and runoff of surface meltwater in snow pack and on icy surfaces. The greatest problem, however, is the sheer lack of representation of outlet glaciers in ice sheet models. The available computational power currently limits the size of grid cells in ice sheet models to 5 km or more. This is obviously a major limitation because the widths of outlet glaciers are less than a single grid cell. Even with fast progress in the computer development industry, accurate quantitative predictions of sea-level rise from ice sheet models will require precise understanding of dynamic processes and representation of fast-flowing outlets in high spatial resolution.

Summary

The Greenland Ice Sheet is not in balance; it is losing mass at a rapid rate. The mass loss in some recent years was as high as 200 gigaton. This rate of ice-mass loss is equivalent to global sea-level rise of 0.6 mm per year. Approximately a third of this ice loss was in 2005 caused by runoff from increased surface melt. Two-thirds were attributed increased discharge from accelerated flow in outlet glaciers (Rignot and Kanagaratnam, 2006), although the dynamic contribution to the net mass loss is less (~50%) when losses are averaged over the period 2003–2008 (van den Broeke et al., 2009). Flow dynamics are thus a key control on ice-sheet and sea-level changes. It is well known that snowfall and surface melting in Greenland vary from year to year. Superimposed on these annual variations are seasonal as well as interannual variations in the speed and discharge of outlet glaciers. As a consequence, it is difficult to measure and understand variations in the mass of the Greenland Ice Sheet. However, new techniques and longer records have improved the understanding of the variability and decadal trends of ice sheet mass balance.

Rapid ice loss caused by increased discharge from outlet glaciers is likely to influence future rates of sea-level rise. The dynamic processes associated with fast glacier flow are nonetheless excluded from the projections in the IPCC Fourth Assessment Report (IPCC, 2007) because their potential magnitude is highly uncertain. The serious nature of dynamic contributions to sea-level rise is clearly demonstrated by rapid and widespread glacial recession followed by speed-up, thinning, and enhanced discharge. In recent years a dozen glaciers were responsible for approximately half of the ice that was discharged to the Greenland seas. Retreat and speed-up of the three largest glaciers, i.e., Jakobshavn, Kangerdlugssuaq, and Helheim, was associated with ice losses of around 60 gigaton per year. The three large glaciers have responded similarly to retreats of their calving ice fronts, but whereas Jakobshavn Isbræ is maintaining the accelerated pace of 13 km/year, the enhanced speeds of Kangerdlugssuaq and Helheim have dropped to levels more or less consistent with the state of flow prior to retreat.

The fact that recent abrupt changes occurred on glaciers terminating in fjords suggests an oceanic cause, but this does not exclude potentially significant impacts from atmospheric warming, which occurs at a faster rate in the Arctic than the global mean. These implications may include expansion of atmospherically coupled hydrological systems inside and beneath the Greenland Ice Sheet. Scientific focus is nonetheless also directed toward a better understanding of variations in the intensity and direction of ocean currents in the Arctic and the North Atlantic. It is well known that discharge of ice from the northern hemisphere ice sheets reduced the intensity of thermohaline circulation during the last glacial period (e.g., Dokken and Jansen, 1999), but it is possible that currents in the Arctic Ocean and the sub-Arctic seas in turn also influence the discharge of ice from the Greenland Ice Sheet.

Ice Sheet Mass Balance

GROUND ICE

D. P. Dobhal
Wadia Institute of Himalayan Geology, Dehradun, India

At temperatures below 0°C almost all soil moisture remains in the form of ground ice. In permafrost regions, ground ice is one of the most important attributes of the terrain. Ground ice occurs in two main forms: (1) a structure-forming ice and (2) a large body of more or less pure ice. The structure-forming ice comprises segregated ice, intrusive ice, reticulate vein ice, ice crystals, and icy coatings on soil particles. The large bodies of more or less pure ice exist mainly in the upper part of the ground representing massive icy beds and ice wedges.

GROUND PENETRATING RADAR MEASUREMENTS OVER GLACIERS

David C. Nobes
Department of Geological Sciences, University of Canterbury, Christchurch, New Zealand

Synonyms

Georadar (primarily in Europe; géoradar in France); GPR; Ground probing radar; Subsurface interface radar (SIR)

Definition

Ground penetrating radar. GPR is a near-surface geophysical technique that uses the propagation of a shaped pulse or wavelet of radio-frequency electromagnetic energy (radar) into the subsurface and measures the radar echoes returned to yield *radargrams* or profiles of the physical property variations in the subsurface.

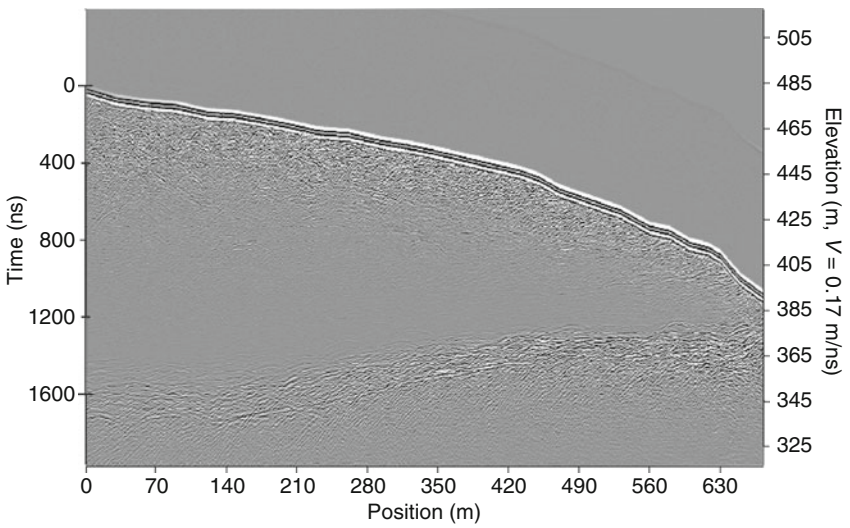
Radargram. A plot of individual GPR traces, one next to the other, to yield a cross-section of the subsurface structure and stratigraphy as expressed in the subsurface physical property variations.

Radar. An acronym for radio detection and ranging, the term RADAR has become so widespread and well known that the standard acronym capitalization long ago disappeared.

Ground penetrating radar

Ground penetrating radar (GPR) has been in widespread use for only a matter of decades, but its origins extend back much further (Leimbach and Löwy, 1910a, b, cited in Lampe, 2003). By the middle of the twentieth century, radar was being proposed as a means for determining glacier ice thickness (Steenson, 1951, cited in Evans, 1963, and in Daniels, 1996). In what may be an apocryphal story, it was reported that flights over Greenland and Antarctica during and immediately after World War II recorded errors in their radar altimetry, errors attributed to the radar transparency of ice (Waite and Schmidt, 1962; Evans, 1963; see *Antarctica*; *Greenland Ice Sheet*; *Radar Application in Snow, Ice, and Glaciers*). Subsequent experiments confirmed that radar could be used to determine glacier and ice sheet thicknesses (Evans, 1963; Waite, 1966; Rinker and Mock, 1967; Walker et al., 1968; Evans, 1969 and the accompanying papers). A P38 fighter bomber that crashed on the Greenland ice was found using radar (Fildes and Williams, 2001). The reasons for the crash are not mentioned, however.

Thus radar, specifically ground penetrating radar (GPR), can successfully provide images of ice sheets and glaciers, as shown by the example from the Garwood Glacier, a cold-based glacier (Figure 1, and see *Antarctica*; *Cold-Based Glaciers*). What distinguishes GPR from other radio-frequency techniques, such as radio echo sounding (RES), is that GPR antennas are constructed as an array of impedance-balanced wires that generate short-duration pulses (e.g., Annan, 1973; Arcone et al., 1995) that have better and more direct resolution of both englacial and basal glacial features. A more recent term has come into use – ice penetrating radar (IPR) – but IPR can mean either RES or GPR specifically applied to glacier measurements, and thus caution should be exercised in the use of the term IPR.



Ground Penetrating Radar Measurements Over Glaciers, Figure 1 GPR profile of the Garwood Glacier. An example of a ground penetrating radar profile of a glacier, in this case the cold-based Garwood Glacier in Antarctica. (Profile courtesy of Sean Fitzsimons, University of Otago.)

Basic GPR principles

Introduction

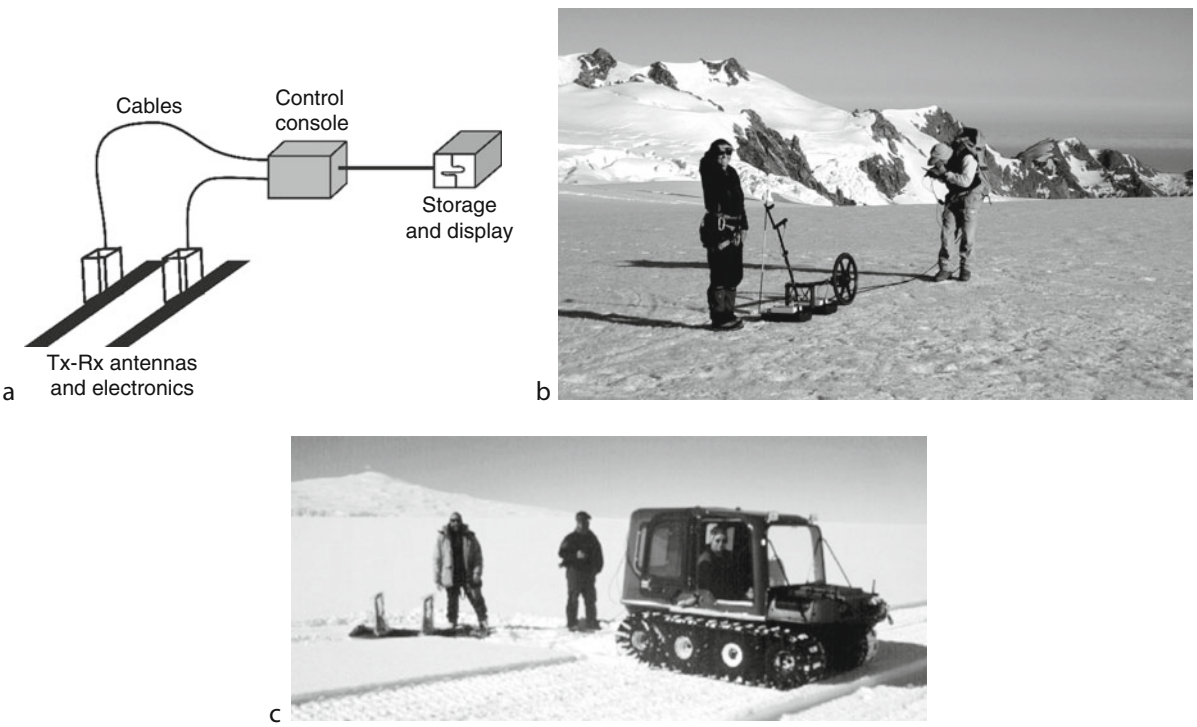
A GPR system usually comprises a set of two antennas, one an antenna that transmits a pulse of radio-frequency electromagnetic energy into the ground and the other a receiving antenna that detects the subsequent echoes that return from subsurface layers and structures (Figure 2a). The time it takes for an echo to return can be converted to the depth or distance to the reflecting surface if, and only if, the average radar velocity is known. The signal is then transferred through a console into a visual display and recording device. Sometimes the console and visual display and recording unit are one; sometimes the display and recording unit is a laptop. The record of voltage in the receiving antenna is stored and displayed; the record at each location – the trace – is typically plotted beside the previous trace so that time is on the vertical (down) axis and the position scrolls across the top of the display. Then any echoes that are spatially and temporally coherent are aligned, and the resulting radargram is a cross-section representation of the subsurface physical properties. These physical property changes frequently, but not always, correlate with the underlying geological and glaciological structure and stratigraphy (e.g., Davis and Annan, 1989; Annan and Cosway, 1992; Jol and Bristow, 2003).

The antennas are moved to cover the survey site: by shifting the individual antennas by hand – if for example the surface is rough as when there is significant debris cover; using a hand-towed sled (Figure 2b) for detailed imaging of a small area (e.g., Jol et al., 2004); or by towing an antenna sled using a vehicle such as a snowmobile or a tracked vehicle (Figure 2c).

Electromagnetic radiation pattern

GPR works because of an interesting effect. The electric and dielectric properties of a given material vary with frequency, except within the frequency range from about 1 to 1,000 megahertz (MHz). In this "radar range," the propagation of radio-frequency electromagnetic energy is dominated by the polarization properties of the material; the dielectric permittivity, ε, is a measure of how easily a material is polarized by the passage of a pulse of electromagnetic energy (Davis and Annan, 1989; Daniels, 1996).

A GPR antenna is composed of a set of regularly-spaced wires that have regularly-spaced resistors that, when properly constructed, yield a symmetrical oblate



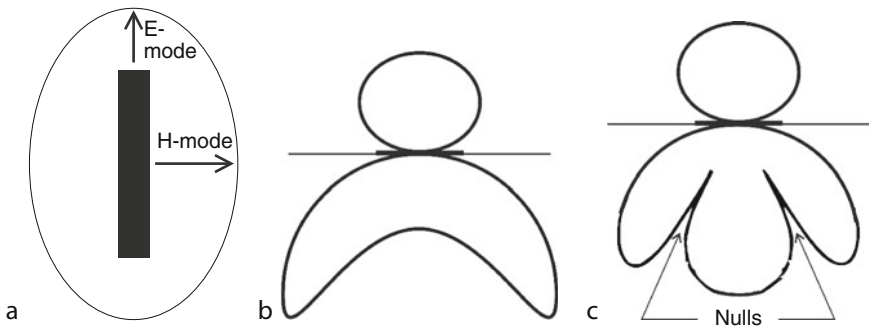
Ground Penetrating Radar Measurements Over Glaciers, Figure 2 GPR system schematic. (**a**) Schematic representation of a "typical" GPR system, showing: the transmitting–receiving antenna pair (Tx–Rx at lower left) with the electronics used to generate and measure the signal and its echoes; the cables connecting the Tx–Rx to the control console (center), where the cables may instead be an infrared remote communications system; and the storage and display unit, which may be incorporated into the main control console. (**b**) A hand-towed sled with high-frequency antennas was used for detailed imaging of the snowpack on the névé of the Franz Josef Glacier (Jol et al., 2004). (**c**) A vehicle towed sled with lower frequency antennas was used for imaging of the McMurdo Ice Shelf (Davis, 2003). (Photographs by the author.)

radiation pattern (Annan, 1973; Olsson et al., 1987; Annan and Cosway, 1992; Arcone, 1995). The energy radiates primarily in a direction perpendicular to the long axis of the antenna (Figure 3a) in what is called the H-mode (Arcone, 1995; Daniels, 1996). This has also been called the "broadside" mode in the applied literature (e.g., Nobes and Annan, 2000), but this terminology differs from that used in the electrical engineering literature. Conversely, the energy off the ends of the antenna (Figure 3a) is called the E-mode (Arcone, 1995; Daniels, 1996), or, in the applied literature, the "end-fire" mode. When in contact with the ground, the radiation pattern is bow-shaped (Figure 3b) from the long-edge of the GPR antenna when it is in contact with a material surface, such as the ground or the surface of a glacier. The pattern is different from the ends of the antenna (Figure 3c), where "nulls" or areas of little or no energy occur.

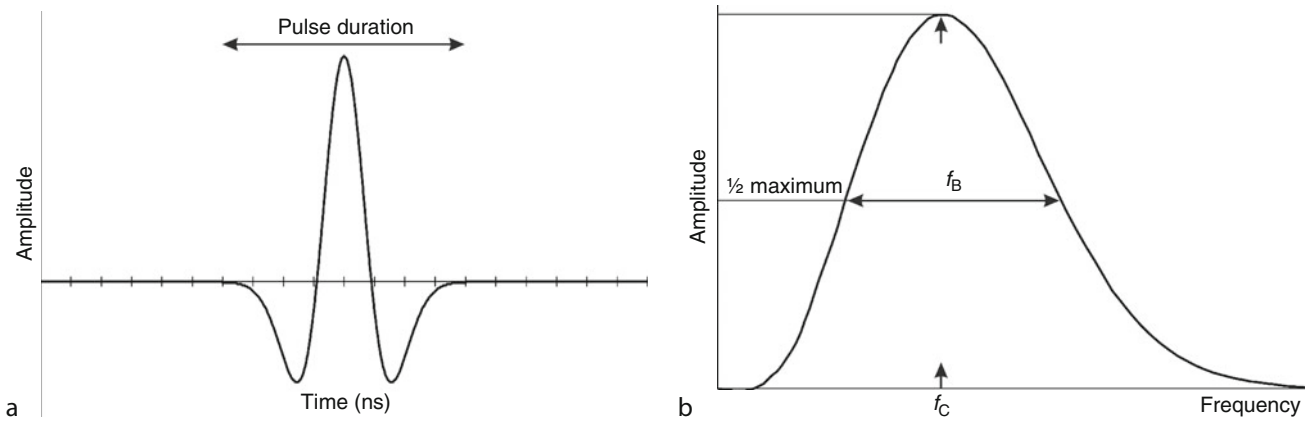
The radar pulse has a compact shape in time (Figure 4a). The length of the pulse or wavelet depends on the frequency content of the signal (Figure 4b). GPR antennas are in general characterized by their central frequencies, f_C, e.g., 50, 100, or 200 MHz, which usually has the peak amplitude. In many if not most cases, the bandwidth, f_B, is equal to the central frequency, so that the 100 MHz antenna has a 100 MHz bandwidth, from 50 to 150 MHz. The bandwidth determines how compact the pulse will be, and thus the resolution of the pulse in time and depth. The relationship between frequency, resolution, and depth of penetration will be discussed in more detail later.

GPR velocity and the dielectric permittivity

The velocity at which radar energy travels depends on the dielectric properties, ε, of the medium in which it is travelling. In particular, the velocity is determined by the relative dielectric permittivity, ε_r, which is frequently called the dielectric constant, a misnomer as it is not a constant.



Ground Penetrating Radar Measurements Over Glaciers, Figure 3 GPR radiation pattern. Schematic diagram showing the radar radiation pattern for a GPR antenna in contact with the ground. In plan view (**a**), the radiation has two modes: the H-mode which is often in field applications called the broadside (BD) mode, and the E-mode which is sometimes called the end-fire (EF) mode. (**b**) The radiation pattern from the H-mode has a clearly lobate pattern with most of the energy directed into the ground. (**c**) In contrast, the E-mode has "nulls" which are at discrete angles dependent on the material properties of the subsurface.



Ground Penetrating Radar Measurements Over Glaciers, Figure 4 GPR pulse. The GPR pulse or wavelet is relatively compact (**a**). The pulse duration depends on the frequency content (**b**), which is defined by the center frequency (f_C) and the bandwidth (f_B), that is the width of the amplitude versus frequency at half of the maximum amplitude.

In the absence of any significant amounts of magnetic material, the radar velocity, v, is equal to:

$$v = c/\sqrt{\varepsilon_r}, \quad (1)$$

where c is the speed of light in air, 300 metres per microsecond (m/μs). Table 1 lists the relative dielectric permittivities and radar velocities for some common materials, in particular water, snow, and ice. Note that these material velocities are those for "pure" materials. In the field, the velocity is rarely "pure," and is in general an average of the all of the materials between the antenna pair at the surface and the reflecting boundary at depth.

A quick glance at Table 1 shows that the presence or absence of water dominates the radar velocity. If water is present in any material to any extent, then the radar velocity of that material will be less, often significantly less, than it would be if it were dry or frozen. The way the dielectric properties, and hence the velocity, depend on various parameters, such as the water content, has been widely studied, and numerous relationships have been proposed, such as effective medium theories and the empirical Topp equation (Topp et al., 1980) which is still one of the more commonly used and robust equations for estimating the effect of the water content on the dielectric properties.

Because of the significant influence of water on the dielectric properties, and thus the radar velocity, then the thermal and hydrological state of a glacier can be estimated using the variations in the velocity (e.g., Macheret et al., 1993; Moorman and Michel, 2000; Copland and Sharp, 2001; Irvine-Fynn et al., 2006; Barrett et al., 2007; Murray et al., 2007; and see *Polythermal Glaciers*; *Subglacial Drainage System*; *Temperate Glaciers*). Similarly the imaging of internal structures can be related to changes in the radar velocities that in turn are related to changes in water content (e.g., Stevens et al., 2008; Watanabe et al., 2008; and see *Englacial Conduit*; *Englacial Processes*; *Meltwater Channels*; *Meltwater Conduit*; *Subglacial Drainage System*).

Ground Penetrating Radar Measurements Over Glaciers, Table 1 Dielectric properties and radar velocities for some common materials

Material	Relative dielectric permittivity, ε_r	Velocity (m/μs)
Air	1	300
Water	~80[a]	~33
Snow	2–3	200
Ice	3–4	160
Dry sand	3–5	150
Wet sand	20–30	60
Dry salt	5–6	130
Granite	4–6	130

[a]The dielectric properties, particularly for water, are temperature-dependent.

In the absence of water, the dielectric permittivity is related to the density of the material (Keller, 1982), and in particular the change in density from snow to firn to ice (Pearce and Walker, 1967; Tiuri et al., 1984; and see *Firn*; *Ice*; *Physical Properties of Snow*; *Snow Density* and *Transformations of Snow at the Earth's Surface and its Climatic and Environmental Consequences*) which gives rise to a corresponding increase in ε, the dielectric permittivity, and an associated decrease in the velocity (Equation 1). When the radar pulse encounters a boundary between layers with different dielectric properties, between firn and ice, for example, the velocity changes as well, and part of the signal is reflected back towards the surface. The reflection coefficient, r, is:

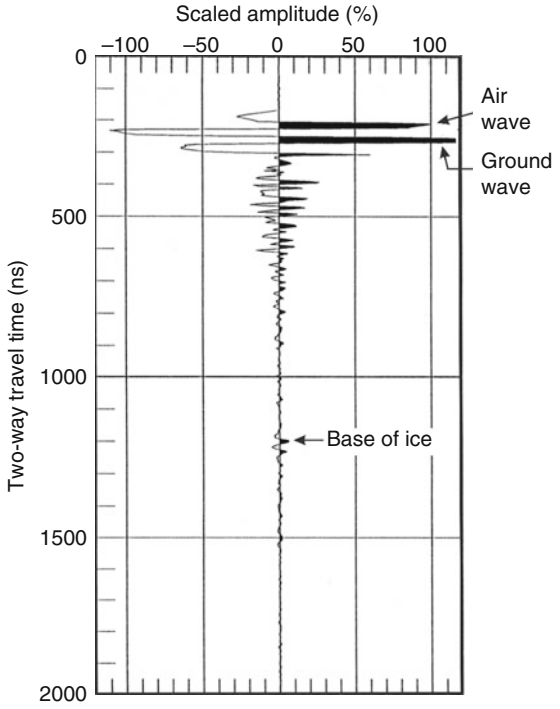
$$\begin{aligned} r &= (v_2 - v_1)/(v_2 + v_1) \\ &= (\sqrt{\varepsilon_1} - \sqrt{\varepsilon_2})/(\sqrt{\varepsilon_1} + \sqrt{\varepsilon_2}). \end{aligned} \quad (2)$$

where p_1 is the value of the parameter (velocity, v, or dielectric permittivity, ε) for layer 1, i.e., above the boundary, and p_2 is the value for layer 2, i.e., below the reflecting boundary. The amount of energy reflected is r^2, and the amount of energy that is transmitted through the boundary is:

$$t^2 = 1 - r^2. \quad (3)$$

The strength of the radar echo depends on the contrast in the dielectric properties between the layers; alternatively, it can be thought of as the contrast in the radar velocities. A velocity increase generates a positive radar echo, whereas a velocity decrease, as occurs at the water table, yields a negative radar echo. A single trace (Figure 5) will have a direct air wave arrival which serves as a time reference, a direct ground wave arrival which serves as a ground surface reference, and any reflection echoes.

The reflectivity associated with changes in density can be used to obtain a radar stratigraphy of snow and ice, especially high-resolution stratigraphy (e.g., Arcone, 1996; Jol et al., 2004; Kanagaratnam et al., 2004; Jacobel and Welch, 2005; see *Layering of Snow*; *Mapping of Internal Glacial Layers*; *Stratigraphy of Snowpacks*), determination of snow accumulation rates (Kohler et al., 1997; Pälli et al., 2002; Spikes et al., 2005; Machguth et al., 2006; Dunse et al., 2008; see *Scandinavian Glaciers*, *Snow Depth*; *Snow Drift*), near-surface structures in ice-rich permafrost (Hinkel et al., 2001; Munroe et al., 2007; Godfrey et al., 2008; Stevens et al., 2008; Watanabe et al., 2008; see *Alaskan Glaciers*; *Antarctica*; *Permafrost*), and processes at glacier margins (e.g., Fitzsimons, 2008). Seasonal freeze and thaw cycles will of course cause temporal changes in the reflectivity as well, specifically in polythermal glaciers (Irvine-Fynn et al., 2006; see *Climate Change and Glaciers*; *Polythermal Glaciers*), and in the Antarctic Dry Valleys permafrost (Godfrey et al., 2008; see *Antarctica*; *Permafrost*; *Permafrost and Climate Interactions*).

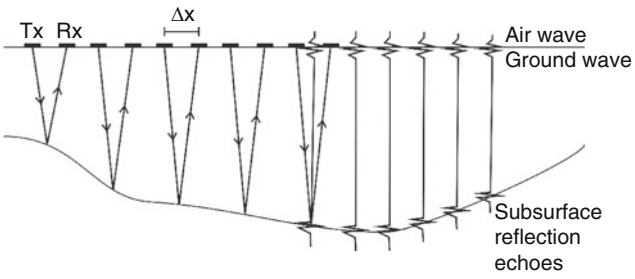


Ground Penetrating Radar Measurements Over Glaciers, Figure 5 Sample GPR trace. An example raw radar trace, without any gains (amplification), showing the relative amplitudes of the air wave, the ground wave and the reflection from the base of the ice. The air wave arrives first, and serves as a time reference for alignment of successive traces. The ground wave arrives immediately after the air wave, and represents a ground level reference. The basal reflection appears to be small, but is large when corrected for geometrical spreading. (Adapted and modified from Leary, 1993, and from Nobes et al., 1994.)

Monostatic versus bistatic GPR systems and survey design

The radar pulse is sent from a transmitting antenna. The receiving antenna can either be the same antenna as was used as the transmitter (a monostatic GPR system), or a separate and independent receiving antenna (a bistatic system). In a monostatic system, the pulse is transmitted and then the antenna is turned into a receiving antenna, listening for the radar echoes to return from reflecting boundaries and objects. The advantage of a monostatic system is that only one antenna is required. However, there are more advantages to bistatic systems, and so bistatic systems are the norm whereas monostatic systems are the exception. A separate receiving antenna allows the researcher to record the character of the transmitted signal as it appears entering the ground. A bistatic system also allows us to determine the subsurface velocity, v, which is needed for: (1) conversion of the two-way travel time, T, to depth, d:

$$d \cong vT/2, \tag{4}$$



Ground Penetrating Radar Measurements Over Glaciers, Figure 6 Common offset geometry. The common offset mode of GPR data acquisition is illustrated. On the left, the transmitter–receiver (Tx–Rx) pair is shown stepped along at constant step sizes (offsets), Δx. At each location, a record of the radar echoes is recorded (shown on the *right*). The first arrival is the direct air wave, which serves as a time reference, followed by the direct ground wave, and at later times the subsurface reflection echoes (*bottom right*). Each successive trace (radar echo record) is plotted beside previous traces to form a radar profile or radargram that has the appearance of a subsurface cross-section.

which is valid when d is much greater than the antenna separation and (2) estimating the subsurface physical properties. The velocity is also needed for one of the final steps in the prevalent processing protocols, migration, which will be discussed later.

GPR surveys are normally conducted in what is called common offset mode (Figure 6). The antennas are separated by a constant distance, which will depend on the antenna frequency, and then stepped along at regular spatial increments, Δx. Those increments should be less than or equal to the minimum resolution required to "see" an object of a size Δx or greater (e.g., Annan and Cosway, 1992; Jol and Bristow, 2003). Alternatively, Δx is set equal to the resolution, R, at the ground surface for a given antenna, which is a function of the velocity of the material, v, and the antenna frequency, f:

$$R \approx \lambda/4 = v/4f, \tag{5}$$

where λ is the wavelength, which equals v/f. Equation 5 is the limiting case as the depth approaches zero for the first Fresnel scattering zone (Sheriff, 2002), which is that portion of a subsurface reflector that constructively scatters energy back to the receiving antenna. The size of the Fresnel scattering zone as a function of the wavelength, λ, and the depth, h, is:

$$R^2 = \lambda^2/16 + h\lambda/2 \tag{6}$$

Thus the design of a survey, including the step size and antenna frequency, can be based on the size of object the researcher wishes to target; alternatively the researcher designs the survey for the optimal step size as determined by the antenna frequency and the ground conditions. Frequently, the determining factor in survey design is not the

desired resolution but rather the depth of penetration needed to detect, for example, bedrock beneath a glacier (see *Bed (Bottom) Topography*). In general, as the antenna frequency is lowered, the depth of penetration increases.

The alternative survey mode is the wide-angle reflection and refraction (WARR) survey (e.g., Davis and Annan, 1989), which is commonly conducted in common mid-point (CMP) mode (Figure 7). The CMP involves stepping the transmitting and receiving antennas in equal steps out from a central survey point. The travel paths in the air and in the uppermost layer of the ground increase linearly with increasing antenna separation, and so therefore does the travel time for the signal to travel between antennas. The path of the signal that travels to and from a buried reflective surface, however, increases as the square root of the squares of the depth and separation, and thus so too does the two-way travel time (TWT), i.e., the travel time to and from the reflective boundary, T, depends on the depth, h, and antenna separation, s, as:

$$h^2 = x^2 + d^2 = s^2/4 + d^2 = V^2(T/2)^2 = V^2T^2/4, \quad (7)$$

where V is the velocity of the radar signal. By rearranging terms, we find that the travel time depends on depth and separation as:

$$T^2 = s^2/V^2 + 4d^2/V^2 = ms^2 + T_0^2. \quad (8)$$

The relationship between the TWT and the separation defines a parabola, whose curvature (shape), represented by the parameter m in equation (8), depends on the velocity of the radar wave in the subsurface above the reflective boundary, or conversely given the plot of T^2 versus s^2, then $V = \sqrt{m}$. Thus the curvature of the reflection parabola determines the subsurface velocity above the reflecting boundary. The time intercept, T_0, in turn depends on the depth and the velocity as:

$$T_0 = 2d/V. \quad (9)$$

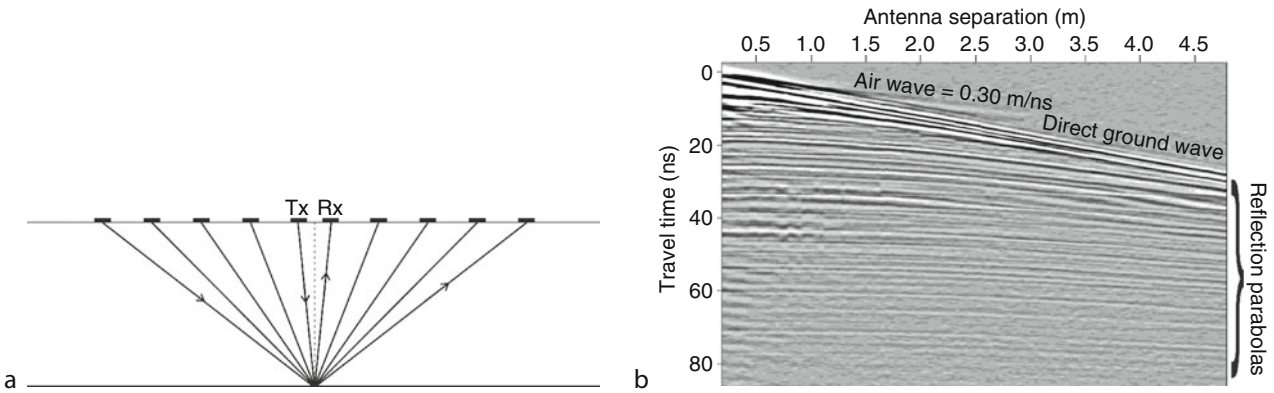
The CMP survey thus yields the velocity structure and the depth to the reflecting boundary. The WARR style of survey cannot be done using a monostatic system, only with a bistatic system where the antennas can be operated independently.

The CMP geometry yields velocity information that allows us to construct a model of the dielectric layering (see *Mapping of Internal Glacial Layers* and *Stratigraphy of Snowpacks*) and to convert travel time to depth, as well as provide some information about water content (Murray et al., 2007). However, CMP acquisition must be carefully done, as even small errors in the survey geometry can cause errors in the calculated velocities and thus in the subsequent ice water content estimates (Barrett et al., 2007). It should also be noted that the velocity to a given reflector is the root-mean-square *weighted average* of the velocities of all of the overlying layers (e.g., Reynolds, 1997; Sheriff, 2002). The weights are the travel times spent in each layer. Hence although the radar velocity in ice is 160 m/ms, the observed field velocity is often greater due to the overlying layers of firn and snow, which have faster radar velocities (Table 1).

Advanced GPR principles and specific aspects of glacier GPR

WARR variants

A variation of the CMP is where one of the antennas, either the transmitter or receiver, is placed at the central point and the other antenna is systematically stepped out first to one side and then to the other. The result, once merged, yields a curve similar to that in Figure 7, but double-sided.

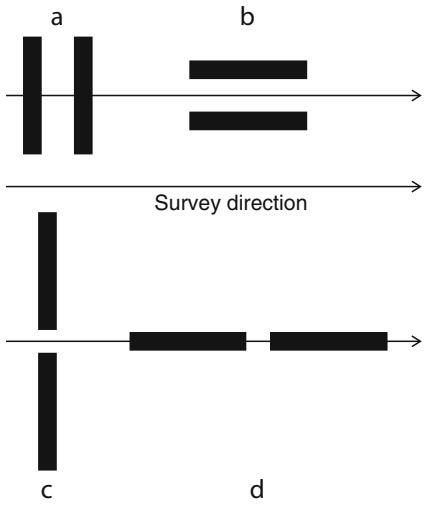


Ground Penetrating Radar Measurements Over Glaciers, Figure 7 CMP geometry. (**a**) The common mid-point (CMP) geometry uses a Tx–Rx pair stepped out from a common central point (*dashed vertical line*). (**b**) A CMP from the Franz Josef névé (Jol et al., 2004) illustrates the CMP concepts. The air wave is the first arrival, travelling at 0.30 m/ns (300 m/μs), followed by the direct ground wave which travels along the top surface of the ground. The reflections from subsurface reflective boundaries yield a set of parabolas, as the travel time squared is a function of the square of the antenna separation. The curvature is then used to determine the subsurface radar velocity down to the reflective boundary.

This is sometimes called a common depth point (CDP), because in the case of a flat-lying layer the reflections originate from a common depth. Such surveys are also called by their seismic analogues: If the receiver is the antenna fixed at the central point, then the survey is called a common receiver point or common receiver gather, whereas if the transmitter is fixed, it is called a common shot point or common shot gather. The advantage of a CDP-style survey is that if the reflecting boundary is not horizontal but dipping, then the dip of the layer can be determined in addition to the velocity (Nobes, 1999). Using a CMP geometry yields an apparent velocity that is instead a mix of the real velocity and a correction factor proportional to the sine of the dip of the layer. If the dip is small, then so is the effect of the dip on the velocity determinations.

Directionality and anisotropy

The radar radiation pattern, as shown schematically in Figure 3, leads to an obvious directionality in the radar response in almost all situations, whether structural or textural: schistosity or crystal orientation (Tillard, 1994; Matsuoka et al., 2003; see *Cryogenic Fabric*); sedimentary structures (van Overmeeren, 1994); or glacial structures (Watts and Wright, 1981; Nobes, 1999; Matsuoka et al., 2007; see *Crevasses*; *Englacial Conduit*; *Meltwater Conduit*; *Structural Glaciology*). This directionality is incorporated into the survey design by using different antenna orientations (e.g., Jol and Bristow, 2003; Figure 8). To optimize the overall survey design, in particular the survey line direction and antenna orientation, the overall structural and textural directions and their orientations relative to the antennas should, if possible, be known. The combination of the angle of the nulls in the "end-fire" response (Figure 3) with the dip of structural features can give rise to dramatic differences in the reflection energies; the broadside energy can be much greater, as has been observed on the Franz Josef Glacier in New Zealand (Nobes, 1999; Nobes and Annan, 2000; see *Temperate Glaciers*), in Antarctica (Matsuoka et al., 2003; see *Antarctica*), and in Iceland (Matsuoka et al., 2007; see *Iceland Glaciers*). Nobes (1999) ascribed the change in reflection energy with antenna orientation to structural alignment of glacial features (see *Crevasses* and *Structural Glaciology*), whereas Matsuoka et al. (2003, 2007) ascribe the change in reflection energy to the preferential orientation of ice crystal fabric (see *Cryogenic Fabric*). Thus, in designing a glacier GPR survey, the particular target must be kept clearly in mind. Is the internal structure the target, in particular ring fractures and associated crevasses? In that case, the antennas should be oriented perpendicular to the direction of glacier flow to yield maximum reflection energy from the internal structures. Is the ice–bedrock interface the target? Then the antennas should be parallel to the glacier flow direction so that the energy from the internal structure is minimized and the bedrock surface is the primary reflective boundary.



Ground Penetrating Radar Measurements Over Glaciers, Figure 8 Antenna geometries. Illustration of the most common antenna survey configurations. (**a**) The most commonly used antenna geometry is with the antennas in a broadside mode (i.e., the long edges of the Tx–Rx antennas aligned) and perpendicular to the survey line direction (*long arrow*). (**b**) The second most common geometry has the antennas in broadside mode but parallel to the survey direction. Less common are the "end-fire" geometries (**c**, **d**). As for a and b (*top*), the antennas are either perpendicular (**c**) or parallel (**d**) to the survey line direction. Geometry d is easy for towing large antennas, but at the expense of the maximum coupling of the signal strength between the antennas. That is why geometries a and b are the most commonly used.

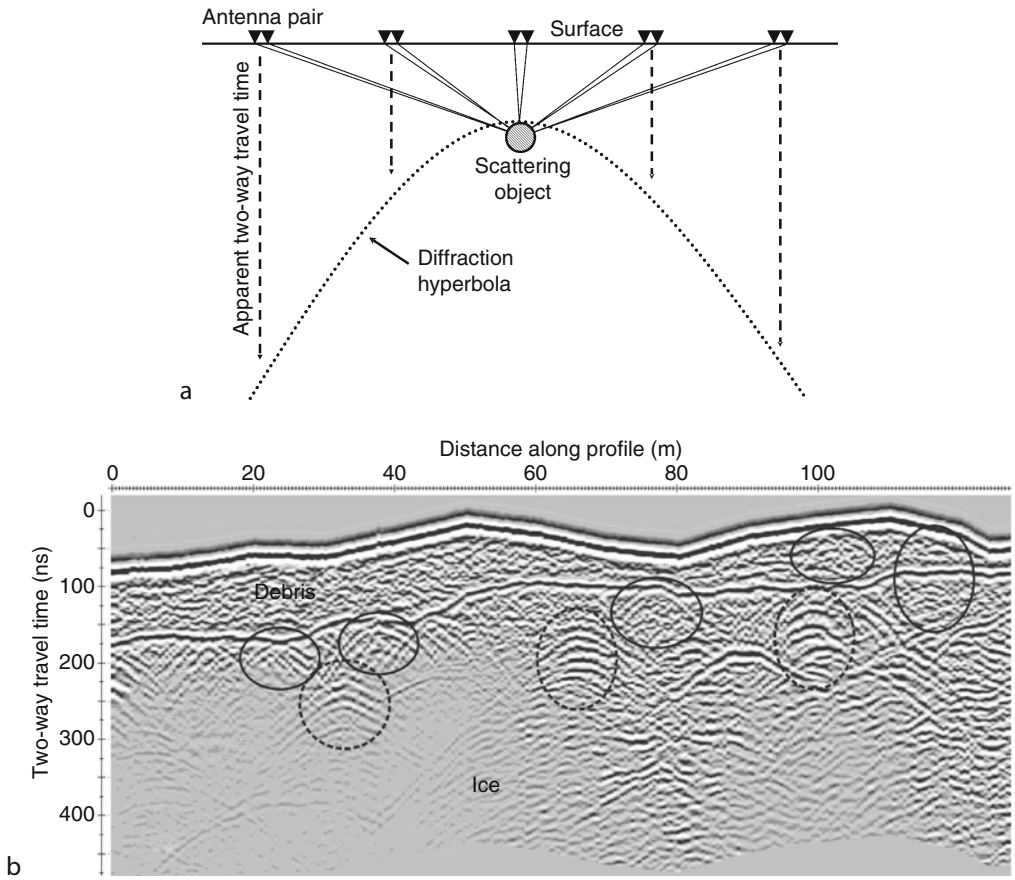
In addition to structural and textural directionality, the GPR velocity can be inherently anisotropic (Rigsby, 1960; Kovacs and Morey, 1978; see *Cryogenic Fabric*). That is, the velocity differs depending on the orientation of the ice crystals. If they are preferentially aligned, as can happen in a flow environment where the forces acting can orient the crystals in the flow direction, then the velocity has maximum and minimum values in the *c*-axis direction (Kovacs and Morey, 1978; Matsuoka et al., 2003). However, while a change in reflection energy is noted, a change in velocity (and thus in travel times) is not always observed.

Larger scale structures, such as crevasses, can be difficult to detect (see *Crevasses* and *Structural Glaciology*). Nearly vertical features rarely generate direct reflections; the energy is not reflected back to the receiving antenna on the surface. However, either a lack of signal return or a disruption or sudden lack of layering, can allow for the detection of crevasses (Glover and Rees, 1992; Delaney et al., 2004). Similarly, features such as englacial and subglacial channels and water flow pathways can be detected (Moorman and Michel, 2000; Copland and Sharp, 2001; Stuart et al., 2003; see *Base Flow/Groundwater Flow*; *Englacial Conduit*; *Glacier Hydrology*; *Meltwater Channels*; *Meltwater Conduit*; *Scandinavian Glaciers*;

Subglacial Drainage System), often because they cause terminations of layers which in turn generate diffractions (e.g., Figure 9).

Diffractions

In addition to obtaining velocity estimates from WARR surveys, the subsurface velocity can be obtained from diffractions (Figure 9). Diffractions are the result of the scattering of the GPR signal by features such as truncated beds, boulders, englacial channels, etc. that have dimensions that are of the order of but smaller than the signal resolution, i.e., of the order of ¼ of the radar signal wavelength in the material. The shape of the diffraction – the steepness of the curvature – depends on the velocity between the surface and the feature causing the diffractions. This alternative way for estimating the velocity provides an independent check on the WARR velocity, if available, and its spatial homogeneity. In many cases, the surface of a glacier may be too rough and rugged for a WARR survey to be completed, especially in the case of debris-covered, debris-laden, and rock glaciers (see *Debris*; *Debris-Covered Glaciers*, and *Rock Glaciers*). In such cases, the diffractions may be the only means available to obtain velocity estimates. An example is shown in Figure 9b. Note the clear diffraction hyperbolas apparent at the base of the surface debris layer, and at depth arising from buried englacial channels (see *Englacial Conduit*; *Meltwater Channels*; *Meltwater Conduit*).



Ground Penetrating Radar Measurements Over Glaciers, Figure 9 Source of diffractions and sample radargram. (**a**) Schematic illustration of the cause of diffraction hyperbolae. A subsurface object or feature such as a boulder, englacial channel, etc., which is of the order of but smaller than 1/4 of a wavelength, will generate scattering as shown. As the antenna Tx–Rx pair approach the object, reflected energy is observed, but is plotted always as if the energy is directly below the antennas. As the antennas get closer to the object, the travel time decreases, reaching a minimum immediately above the object that is causing the scattering of the energy, and then increasing again as the antennas move away. The curvature of the resultant diffraction hyperbola is diagnostic of the velocity between the antennas and the object, and can be used as an alternative means of estimating the velocity. (**b**) Example of a GPR profile targetted at the shallow debris-covered portion of a glacier. Diffractions from boulders beneath and within the debris are clear – a few are circled – as are strong diffractions that appear to be stacked one above the other (*dashed circles*). The latter sets of diffractions are likely due to englacial channels that have small horizontal extent but substantial vertical extent. Vertical profile scale is about 30 m. (Profile courtesy of Natalya Reznichenko.)

Signal loss, attenuation and scattering

In addition to the simple propagation of a pulse of electromagnetic energy that is involved in GPR, we must consider attenuation of the signal (Davis and Annan, 1989; Daniels, 1996). There are many contributions to the loss of signal, the most important of which, for our purposes, are:

- Geometrical spreading: loss of energy as it spreads out across a volume of the subsurface
- Conductive losses (attenuation): loss of energy due to electric current induced to flow in the ground by the radar wave, in which case the attenuation, α, is:

$$\alpha \cong \sigma/\omega\varepsilon \tag{10}$$

where σ is the electrical conductivity, ω is the angular frequency, equal to $2\pi f$, and ε is, as before, the dielectric permittivity and

- Scattering losses or clutter: loss of energy because the high-frequency radar waves are scattered by boulders, fractures, etc. that are of the scale of the resolution of the signal.

As the signal travels through a medium, it spreads out geometrically as the inverse square of the distance. It is straightforward to correct for geometrical spreading, and some radar processing programmes do what is called spreading and exponential compensation (SEC). The signal is also attenuated, that is energy is lost from the pulse at an exponential rate:

$$e^{-\alpha z} \tag{11}$$

where α is the rate of signal loss. In contrast to geometrical spreading, the correction for attenuation is largely empirical, adjusted from an initial informed guess until the profile appears to be balanced between too much and too little amplification of echo strength. This serves to preserve, as much as possible, the relative strengths of the echoes from reflective boundaries, and serves to aid interpretation.

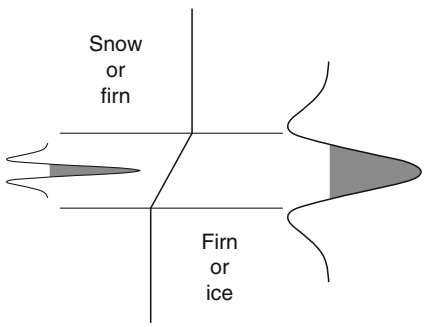
Alternatively, we frequently use automatic gain control (AGC) which amplifies the signal using a gain factor that is in essence equal to the inverse of the signal strength. Thus all echoes are amplified to the point where they are effectively equal. AGC is well suited for showing all of the stratigraphy in the subsurface, even subtle stratigraphy, without regard to how massive a bed might be (Nobes et al., 2001). Disadvantages of AGC are that it also amplifies any noise present, both random and coherent "noise," and also does not preserve the relative strengths of the radar echoes.

The electrical conductivity of almost all snow and ice, and thus of almost all glaciers, is negligible. The exception is sea ice, which can incorporate sea water into pores that gradually freeze and isolate pockets of hypersaline water, and ice shelves, where brine can infiltrate in a layer some kilometers inland from the sea (Heine, 1968; Morse and Waddington, 1984; see *Ice Shelf* and *Sea Ice*). Sea ice and ice shelves are thus special cases. The brine layer has such a large change in the physical properties, especially the electrical conductivity, that it can behave like a mirror that almost completely reflects radar signals (Nobes et al., 2005).

With the exception of sea ice and ice shelf brine layers, then, geometrical spreading, which is well constrained, and clutter or scattering are the most noteworthy contributions to loss of signal in glacier GPR. Clutter will be highly dependent on the degree of breakup of the ice, the nature and amount of debris, both surface debris and that incorporated into the mass of the glacier, especially rock glaciers (see *Debris*; *Debris-Covered Glaciers*; *Rock Glaciers*). The scattering of signals will often yield diffractions (as in Figure 9), and thus an abundance of diffractions will be diagnostic of a high degree of scattering and thus of loss of signal. Higher frequency signals will be more susceptible to clutter, but yield more detail (e.g., Figure 9b); lower frequency signals will suffer less from the effects of clutter, and have greater penetration, but at the expense of detail. Scattering and clutter will have the greatest detrimental effect on GPR across debris-covered, debris-laden, and rock glaciers. Nonetheless, GPR has been shown to work well on all such glaciers (e.g., Nobes et al., 1994; Degenhardt and Giardino, 2003; Degenhardt et al., 2003; Musil et al., 2006; Maurer and Hauck, 2007).

Frequency versus resolution

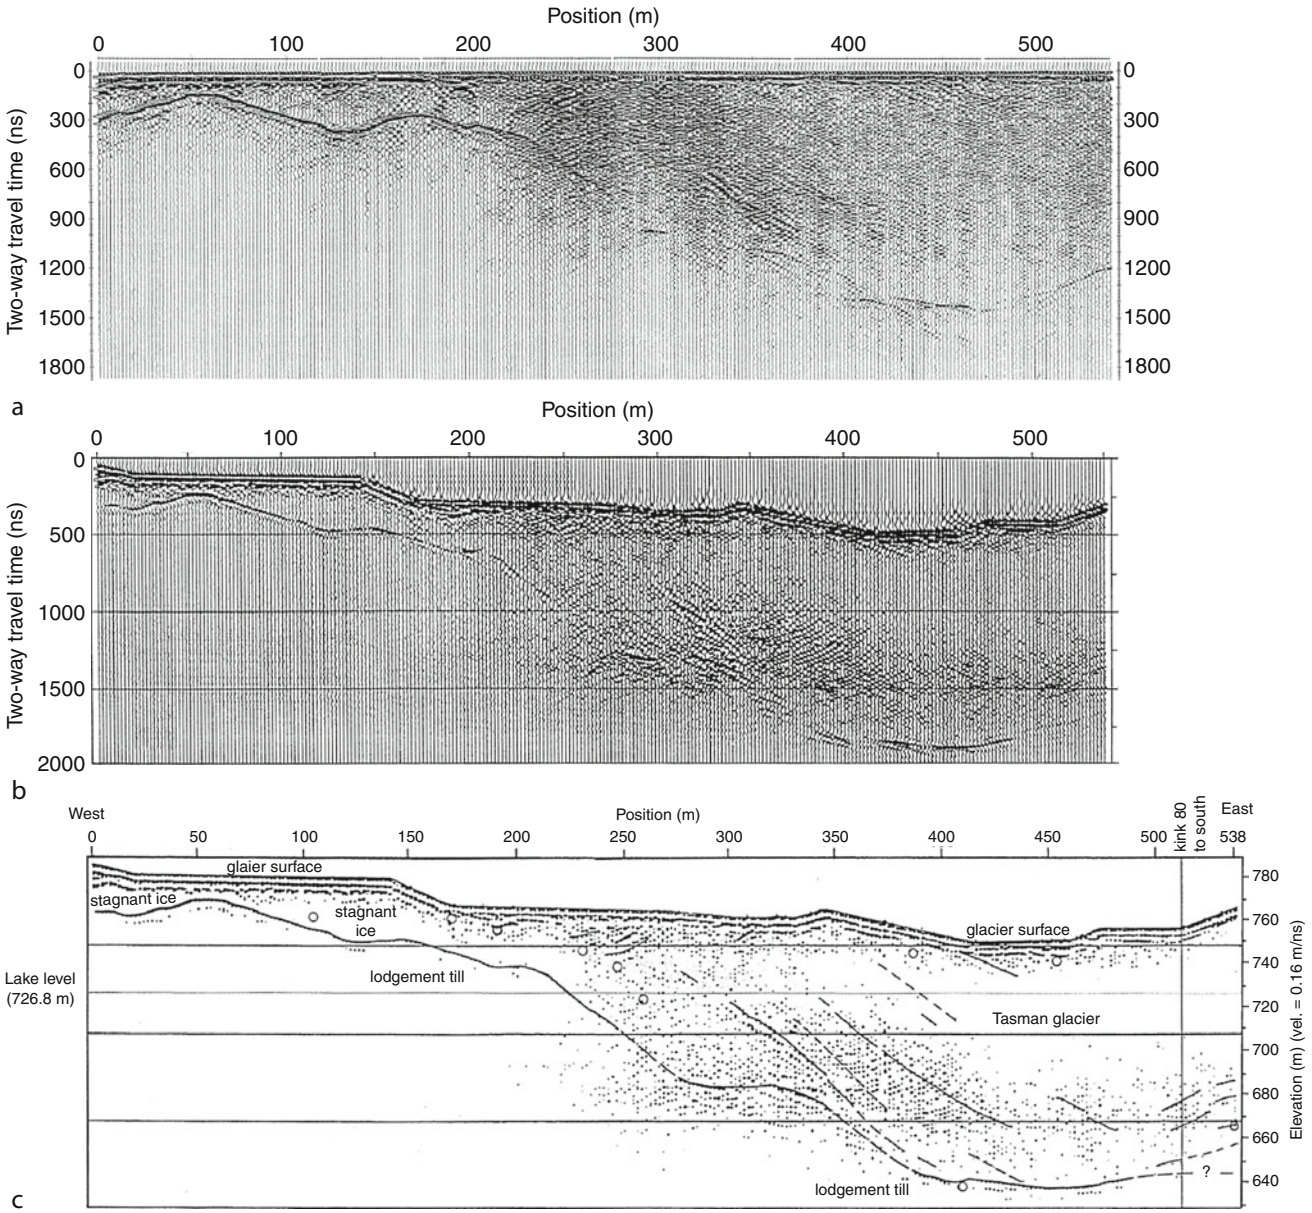
As noted earlier, there is a fundamental trade-off between the frequency and resolution, or to put it another way, depth versus detail. For example, higher frequency antennas will yield greater detail but that does not necessarily equate with greater information. In fact, the greater detail may well obscure the very features that we are trying to detect.



Ground Penetrating Radar Measurements Over Glaciers, Figure 10 A representation of the radar velocity at the boundary between snow and firn, or firn and ice. The change in velocity may be transitional, as shown by the near-vertical line. A sharp, high-frequency pulse (*left*) will see the transition as a separate layer with slowly changing properties, and no reflection will occur. A low-frequency pulse, in contrast, will see the transition as a sharp boundary between the layer above and the layer below.

For observing the base of a glacier, a lower frequency (e.g., 50 MHz or lower) might normally be used (e.g., Nobes et al., 1994, and Hochstein et al., 1995, on the Tasman Glacier terminus; see *Temperate Glaciers*), whereas a high-frequency system (e.g., higher than 200–250 MHz) would be used to provide images of layering in snow and ice (e.g., Jol et al., 2004, on the Franz Josef névé; and Kanagaratnam et al., 2004, in Greenland; see *Greenland Ice Sheet*; *Layering of Snow*; *Mapping of Internal Glacial Layers*). This is a good general rule of thumb, but there are other considerations.

Arcone and Laatsch (2004) observed that high frequency signals (400 MHz) yielded a clearer image of the base of the McMurdo Ice Shelf, whereas low to moderate frequency signals (100 MHz) yielded a clearer image of the stratigraphy (see *Antarctica*; *Ice Shelf*; *Mapping of*



Ground Penetrating Radar Measurements Over Glaciers, Figure 11 Example raw, migrated and interpreted profiles. GPR profiles from the terminus of the Tasman Glacier showing the effects of processing, especially of migration. (**a**) The raw profile has significant energy from diffractions, and the basal reflection appears to be discontinuous. (**b**) When the profile is migrated and corrected for topography, the dipping bed in the centre becomes steeper and deeper. Where the dip shallows, the basal reflection becomes continuous, as it should be. The major diffractions have been collapsed, as they will if the correct velocity is used. (**c**) The migrated profile can then be interpreted. (Adapted and modified from Leary, 1993, and from Nobes et al., 1994.)

Internal Glacial Layers). This is at first glance counter-intuitive. Upon closer examination of the basic principles, this apparent contradiction can be explained.

First of all, the base of the ice shelf is rough (see *Bed Roughness*). The scale of the roughness is of the order of the resolution of the 100 MHz signal at that depth, of the order of 145 m. Thus the basal response appears as a set of diffractions. In contrast the high frequency signal shows a relatively continuous reflection from the ice shelf base. The attenuation of the radar signal in the ice of the McMurdo Ice Shelf is so low that even high-frequency signals are able to penetrate relatively large depths.

The lower frequency signal (100 MHz) showed more information about the layering because the transitions from one layer to the next are not sharp enough to cause high-frequency reflections. The reasons for this are illustrated in Figure 10. The high-frequency pulse simply refracts, or bends, at the boundary between the layers because the physical properties change slowly across a transition zone, whereas the low-frequency pulse "sees" the transition zone as a sharp boundary. Thus, in this case, the low-frequency signal yields more information on the layering. This is not uncommon, and has been observed, for example, in seismic surveys (e.g., Nobes and Schneider, 1996). The conclusion is that every site and the conditions present are unique, and the antennas and survey designs to use must be adapted to each site.

Migration and imaging

One of the last steps in the processing of GPR data is migration. Migration in essence is a mathematical inversion process that uses the velocity obtained from CMP, WARR, and diffraction analyses to collapse diffractions to their sources and place reflecting boundaries in their correct geometric positions (Sheriff, 2002, and Figure 11). Dipping boundaries, in particular, are steeper and deeper than they appear in raw radar profiles (compare Figure 11a and b). The migrated profile can then be properly interpreted, especially when topography is added to the top surface (Figure 11c). The velocity is used to convert the time to depth. However, we cannot always check that the velocities and thus the depths are correct, but when such tests have been done (e.g., Hochstein et al., 1995), the depths have often been confirmed, so long as the velocity determination has been completed correctly.

There are many ways to carry out migration (see Sheriff, 2002), but the traditional methods usually have an implicit assumption that the surface topography is small relative to the depth to the basal layers. This assumption is often false in glacier GPR; the topography can serve to significantly focus and de-focus the signal energy. In such instances, the topography becomes part of the migration process; the result is more effective at imaging layering and properly focussing reflections (Lehmann and Green, 2000).

Reflections of course do not occur in simple two-dimensional planes, but originate from complex three-dimensional (3D) beds and structures (see "*Bed (Bottom) Topography*" and "*Bed Load/Bedrock*"). The migration process, again, needs to take into account such complexities when they are present (Moran et al., 2003).

3D imaging provides additional information on subsurface structures and the continuity of layers and structures, including bedforms and basal hydrology (Moran et al., 2003; see also *Base Flow/Groundwater Flow*; *Bed Roughness*; *Glacier Hydrology*; *Subglacial Drainage System*), accumulation layers, the transition to firn, and englacial hydrological features (Jol et al., 2004; see *Firn*; *Mapping of Internal Glacial Layers*; *Temperate Glaciers*), and Antarctic permafrost polygonal patterned ground (Godfrey et al., 2008; see *Antarctica* and *Permafrost*). The logical extension to time lapse, or 4D (four-dimensional) imaging allows us to see whether the subsurface features we observe are evolving and changing with time, and to what extent (Godfrey et al., 2008; see also *Permafrost* and *Climate Change and Glaciers*).

Mars

No discussion on glacier GPR is complete without mention of Mars. The search for water or water ice on Mars necessarily involves radar methods, especially in permafrost environments on Earth (see *Antarctica* and *Permafrost*). The Antarctic Dry Valleys are a natural terrestrial analogue for the Martian environment, and have thus been a focus or at least a motivation for many such studies (Arcone et al., 2002; Berthelier et al., 2005; Godfrey et al., 2008), all of which show that radar has some promise in determining the presence and extent of Martian permafrost.

Summary

Ground penetrating radar is one of the predominant techniques to determine the thickness and internal structure of glaciers and other ice-rich environments, including layering and snow accumulation. The electric and dielectric properties which govern the propagation of radar signals allow radar to travel easily and far in snow and ice, even when laden with debris as in debris-covered and rock glaciers, or in mixtures of soil and ice as in permafrost. The directionality of the radar response tells us something about the structure and dynamics of the glacier, and the layering apparent in GPR profiles can be tied to accumulation rates and to particular isochrones for studies of paleoclimate. GPR imaging is providing not just 3D views of the subsurface, but time lapse imaging is allowing us to see those subsurface features change and evolve. The successful application of GPR on Earth will allow us to extend it to the search for water and water ice on Mars.

HEAT AND MASS TRANSFER IN SEA ICE

Daniel J. Pringle
Arctic Region Supercomputing Center and Geophysical Institute, University of Alaska, Fairbanks, AK, USA

Definition

Heat and mass transfer in sea ice refers to the transport of, respectively, thermal energy and matter within and through sea ice.

Introduction

Sea ice is a boundary layer that mediates interactions between high-latitude oceans and the overlying atmosphere (Sea Ice). Heat and mass transport in sea ice underpin two well-known effects of sea ice: the ice-albedo feedback (Albedo, Energy Exchange over Snow and Ice Surfaces) and the effect of brine exclusion on thermohaline circulation (Dieckmann and Hellmer, 2003).

We here concentrate on the underlying mechanisms of the heat and mass transfer and the relevant ice properties. This short article is by no means exhaustive; for discussion of the connections with large-scale forcing and impacts, good starting points are the books of Wadhams (2000) and Thomas and Dieckmann (2003). Related processes not discussed here include sediment entrainment and transport by sea ice (e.g., Eicken et al., 2005) and the deposition of particulate matter from melting sea ice (Leventer, 2003).

The transfer of heat in sea ice is relevant to ice formation, persistence and decay, and, through the net surface energy balance, on the response of sea ice to changes in climate forcing (Thinning of Arctic Sea Ice). Mass transfer in sea ice relates mainly to the retention and passage of salts, gases, meltwater, pollutants, and biomass. The transfer of heat and mass are coupled. Sea ice is a porous medium with thermohaline equilibrium between pore-space brine and the surrounding ice. Brine, meltwater, and seawater may all flow through the pore space, transferring both heat and mass, and in the process changing the very properties of the ice that control these flows and transfers (Meltwater Fluxes due to Heat Fluxes, Meltwater Percolation).

Connection with sea ice structure, growth, and melt

The ability of heat and mass flow to flow through sea ice depends strongly on the salinity- and temperature-dependent structure. In general, sea ice is a porous, composite medium composed primarily of brine and gas inclusions within a matrix of pure ice (Sea Ice). Sea ice transport properties depend strongly on the volume fraction of brine and the pore space connectivity, which both depend on salinity and temperature (Weeks and Ackley, 1986; Eicken, 2003; Golden et al., 2007).

Brine motion may transfer both heat and mass. Given a temperature profile in the ice, there is a corresponding profile of equilibrium brine salinity given by the salinity–freezing point relationship. Brine motion due to drainage, flushing, or convective overturning may disturb this equilibrium (Weeks and Ackley, 1986; Eicken, 2003). Heat diffuses much faster than salt, so thermohaline equilibrium is restored as the ice around the inclusions either freezes, which releases latent heat, or melts, which absorbs latent heat.

Such changes to the pore space geometry of brine (and air) inclusions alter the fluid permeability, with feedbacks on fluid flow itself. Additional coupling of heat and mass transfer comes from the temperature-driven changes in the pore space permeability, and from the hydrology of surface melt ponds (Pringle and Ingham, 2009).

During sea ice growth, salts are excluded from the crystal lattice of ice and sea water is incorporated as intra-crystalline

Vijay P. Singh, Pratap Singh & Umesh K. Haritashya (eds.), *Encyclopedia of Snow, Ice and Glaciers*, DOI 10.1007/978-90-481-2642-2,

layers and in-grain boundaries. This brine exclusion makes sea ice less saline than sea water and has strong oceanographic impacts. Ice formation, typically in autumn and winter, therefore constitutes a salt flux into the upper ocean. Likewise, melt in spring and summer represents a flux of fresh water or a negative flux of salt. The overall effect is a delayed mass transfer, with significant effects on physical and biogeochemical aspects of polar oceanography (e.g., Dieckmann and Hellmer, 2003).

The desalination of warming sea ice leads to the important distinction between first year (FY) ice and multi-year (MY) ice. MY ice has undergone at least one melt season during which brine drainage and flushing significantly reduce the bulk sea ice salinity. This process is strongly coupled to the thermal evolution of the ice, and therefore heat transfer. As it warms, sea ice "rots from the inside out." The volume and connectivity of brine inclusions both increase, allowing drainage of internal brine layers, pockets, and channels. This increase in permeability also allows percolation through the ice of surface melt ponds formed from melted snow and ice (e.g., Freitag and Eicken, 2003).

Heat transfer and sea ice thermal properties

Sea ice growth involves the conduction to the atmosphere of latent heat released during freezing. Growth rates and thermal evolution are controlled by oceanic and atmospheric heat fluxes, the thermal conductivity, specific heat, and enthalpy of the ice (Weeks and Ackley, 1986; Eicken, 2003) (Physical Properties of Snow). Heat flow in sea ice is generally dominated by conduction, that is, molecular diffusive heat transfer. As air and brine have lower thermal conductivities than pure ice, effective medium models have been developed for various inclusion geometries to predict the bulk sea ice conductivity as a function of salinity, density, and temperature (Yen, 1981; Pringle et al., 2007). Conductivity measurements are difficult to make but in good general agreement with predictions. Specific heat measurements are in excellent agreement with predictions. The conductivity k (W m^{-1} K^{-1}) and specific heat c (J kg^{-1} K^{-1}) can be calculated by (Pringle et al., 2007).

$$k = \frac{\rho}{\rho_i}\left(2.11 - 0.011\,T + 0.09\frac{S}{T} - 0.01(\rho - \rho_i)\right),$$

$$c = 2113 + 7.5 - 3.4\,S + 0.08ST + 18040\frac{S}{T^2},$$

where ρ is sea ice bulk density (kg m^{-3}), S is sea ice bulk salinity (ppt, i.e., parts per thousand by weight), T is temperature (°C), and the subscript i indicates fresh ice.

The thermal conductivity of snow is an order of magnitude less than ice, meaning 10 cm of snow has an insulating effect of about 1 m of sea ice, and even thin snow cover can strongly reduce conductive heat flow (Sturm et al., 2002). Direct radiative heating of near-surface ice can occur in spring and summer (Eicken, 2003; Ehn et al., 2008).

Heat flow may be enhanced by convective and advective heat transport caused by fluid flow. If down-flowing, cold, saline brine is replaced with lower-salinity brine from below, there is a net transfer of sensible and (through refreezing) latent heat from ocean to atmosphere. The size of this contribution depends on location and ice type. In land-fast FY ice, the convective contribution to the spring/winter heat flux has been estimated as a few percent of the total winter heat flow (Pringle et al., 2007). In cold, low-salinity MY ice, the contribution will be less. Observations in FY Antarctic ice show significant heat flow associated with upwelling sea water when the high snow loading suppresses the ice/snow interface below sea level (Lytle and Ackley, 1996). Surface flooding can here lead to the formation of superimposed ice with the release of latent heat.

Mass transfer, fluid flow, and permeability

In general, mass transfer in sea ice is a by-product of fluid flow. Brine motion in a porous medium like sea ice is described by Darcy's law (e.g., Freitag and Eicken, 2003). The volumetric specific discharge q (m^3 s^{-1} m^{-2}) along a pressure gradient ∇P (Pa m^{-1}) is

$$q = -\frac{\Pi}{\mu}\nabla P,$$

where μ (kg m^{-1} s^{-1} = Pa s) is fluid dynamic viscosity and Π (m^2) is ice permeability. At sufficiently fast flow, turbulence occurs, resulting in energy dissipation and less flow than predicted by Darcy's law. The transition between laminar and turbulent flow occurs for a critical value of the dimensionless Reynolds number: $Re_c = \rho$ U l/μ , were ρ is density, μ dynamic viscosity, U mean fluid velocity, and la characteristic length scale. For complex porous media like sea ice, l is an average pore diameter and Re_C = 1–10 (Freitag and Eicken, 2003). Both laminar and turbulent flows have been observed and analyzed in sea ice permeability measurements (Freitag and Eicken, 2003). The origin of pressure gradients driving fluid flow include the hydraulic head of dense cold brine in ice above the freeboard, surface melt ponds, and density instabilities in brine inclusions and networks.

The fluid permeability depends on the pore-space connectivity and hence, the brine volume fraction, v_b. The permeability spans six orders of magnitude from 10^{-13} to 10^{-6} m^2, nearly half the range of all geological materials. Various parameterizations of permeability are presented in Petrich et al. (2006), Golden et al. (2007), and Pringle and Ingham (2009). Sea ice exhibits threshold behavior, being essentially impermeable for $v_b < 5\%$ (e.g., Freitag and Eicken, 2003; Petrich et al., 2006). For typical FY ice with S = 5 ppt, this threshold corresponds to about −5°C, easily remembered as the "rule of fives" (Golden et al., 1998).

Percolation theory has been applied to both the bulk permeability and connectivity of intracrystalline brine inclusions (Golden et al., 2007; Pringle et al., 2009).

The wide range in permeability is due to permeability scaling with the radius squared of restrictions in the flow path. Drainage of surface melt ponds can be greatly accelerated by seal breathing holes (up to a meter in diameter), or inhibited by impermeable "superimposed ice" formed early in the melt season by refreezing snowmelt (Refreezing of Meltwater). The detailed heat and mass budgets of melt ponds remains an area of active research.

Outlook: ecological and environmental aspects

Sea ice supports large communities of microorganisms in the thin, high-porosity skeletal layer at the ice base (Thomas and Papadimitriou, 2003). For these communities, there are beneficial and harmful mass transfers. First, they rely on the ongoing delivery of nutrients from the ocean. Modeling shows the advective volume flux F_V through the skeletal layer (the volume of water per time and interface area) to be 1–100 times the ice growth rate dh/dt, and to scale as $F_V \propto (dh/dt)^{1/2}$ (Chris Petrich, personal communication, 2008).

Second, under-ice pollutants may also enter through the skeletal layer (Pfirman et al., 1995). Recent renewed interest in Arctic oil development raises the potential for the under-ice spills. With a density of about 800 kg m^{-3}, crude oil is buoyant in water and ice, and will migrate up into sea ice as allowed by pore-space connectivity and surface tension constraints.

HIGH ELEVATION GLACIO-CLIMATOLOGY

Vladimir Aizen
College of Science, University of Idaho, Moscow, ID, USA

Definition

Scientific study of the complex processes of climate and cryosphere interaction at high elevation (HE) mountains over a period of time ranging from months to thousands or millions of years. Reconstruction of past and modeling of modern and future climate variations are generally based on isotope-geochemistry and micro-biological analysis of HE ice-cores, borehole ice temperatures, modern meteorological observations, and remote sensing information.

Introduction

The HE glacio-climatology emphasizes on the statistical description in terms of the mean and variability of numerous glacio-meteorological and actinometrical elements and detail studies of the processes of interaction between snow/ice land-surface and atmosphere at HE environment and its feedback to climate and atmosphere circulation. The results of HE glacio-climatological investigations improve the regional and local energy balance/atmosphere circulation models and assist in study of the modern and past climate variability and water resources changes. The information from HE glacio-meteorological observations (Figure 1) delivers essential contribution to study alpine climate, alpine hydrology, and to estimate precisely the freshwater resources in regions where water demand has been projected to continuously rise, but where seasonal snow cover, glaciers, and permafrost cannot continue indefinitely to waste away. Our knowledge of HE glacio-climatology at alpine environment is limited by both difficulties to access HE areas and the paucity of observations, short records that seldom span lesser than 100 years, and a sparse station network and insufficient scientific attention given to the complex interaction of spatial scales in weather and climate phenomena in HE mountains.

Climate

Climate controls the cryosphere processes in HE area, that is, surface energy balance, snow and glacier ice accumulation and ablation, extension of seasonal snow covered areas, glacier mass balance and glacier dynamics, depth of permafrost active layer, permafrost dynamics, and land surface geomorphic activity. Glaciers grow and shrink in response to climatic changes and, therefore, glaciers are considered as sensitive indicators of climate change. The rise of global air temperature (IPCC, 2001) for the last century caused the mountain glaciers around the world to generally decrease in area and volume. From the standpoint of geographical determination, there are three factors that control the HE glacier climate, that is, latitude, topography, and level of continentality. There is a wide range of glacio-climate conditions that exist over the glaciers of Alaska to subtropical/tropical Himalayas to equatorial Andes' to Scandinavian marine areas to Central Asian/Tibetan areas.

Atmosphere is sensitive to physical changes at its low boundary, that is, at the earth surface. Snow cover and extended glacierized massive/caps are recognized as important factors influencing the climate both at the regional and local scales. The large HE glacier massifs deform air masses flows, barometric waves, and pressure field. There is a jump in energy/radiation balance, air temperature, and relative humidity between glacial/snow and non-glacial/non-snow surfaces. At HE, where there is snow/glacier cover, the sharp increased albedo (up to 85% of fresh snow; Gray and Male, 1981) causes reduction in absorbed short wave radiation and, consequently, net radiation decreases (20–30%; Barry, 1992). During ablation season, the amount of energy used to melt snow is of the same order as the combination of other components of the heat budget (e.g., heat associated with atmospheric advection, radiation balance, and turbulent heat exchange) (Aizen et al., 2000). The difference in air temperature between glacier and non-glacier surfaces is about 1–2°C (Krenke, 1982) in summer at the equilibrium line altitude. The cooling of atmosphere over glacier depends on glacier size, albedo, air temperature, latitude, and cloudiness. For example, the air balloon meteorological observations over one of the world's largest Fedchenko Glacier (Pamir) exhibits 1.5°C summer air temperature lower than at 5,000 m a.s.l. over the Pamir plains (Djodjio et al., 1962).

High Elevation Glacio-Climatology, Figure 1 High elevation glacio-climatological monitoring, Gongga Glacier, South-Eastern Tibet (photo by V. Aizen, 1990).

Over the glaciers, the radiation contributes more energy in the heat balance than the turbulent heat. Evaporation process is typical for the ablation zone of glaciers, while the condensation is a prevailing process over the accumulation field of glaciers. In regions with dry climate, glaciers evaporate moisture and wet the atmosphere, while in regions with humid climate, glaciers condensate moisture on their surface. HE glaciers catch the solid precipitation for decades, sometimes for thousands of years from global water cycle.

Cooling of atmosphere from extended glaciers develop continuous cold katabatic winds over the large glacierized massif that could decrease turbulent exchange, which results in minor contribution from sensible heat transfer in the heat balance of glaciers. Strong katabatic winds suppress precipitation, but favor evaporation reducing glacier melt even in the ablation zone. Human life and society are strongly depending on the heterogeneous precipitation distribution and weather changes due to this water and energy cycle processes.

Snow

Snow cover in HE mountains is the most important source of meltwater and heat exchange between surface and near surface atmosphere in HE areas. Seasonal snow contributes up to 60% of snowmelt runoff in non-glacial catchments (Aizen et al., 1996). Over the Tien Shan HE mountains, energy used for snowmelt amounted to 3×10^{13} MJ year^{-1} with a maximum from the end of spring to the middle of summer. The annual air volume cooled 5°C by snowmelt amounted, on average, to 10^7 km^3 year^{-1}. Heating of the air would have been three times higher if snowmelt had not occurred. Over the mountains, energy used for snowmelt amounted to about one third of heat loss in the continental plains. The difference in the proportions occurred as a result of lesser air thickness in mountains than over plains that allowed cooling a larger air volume in mountains under the same amounts of heat losses. The process of snow ablation and atmospheric cooling in mountains due to snowmelt occurs more slowly and without abrupt changes observed on the plains, and energy losses in mountains smooth the general processes of atmospheric cooling prolonging it until the beginning of autumn, that is, appearing new snow (Aizen et al., 2000). The feedback of the spring and summer snow ablation can explain the long-term rise in air temperatures, which is more pronounced from June to August (Aizen et al., 1997) when maximum energy losses from snowmelt occurs over the mountainous areas. The study of seasonal snow cover extension and the energy spent during the snowmelt are important in developing the regional and global climatic models.

Glaciers

Glacier ice at HE mountains presently covers approximately 3% of the Earth's total land surface or 500,000 km^2 and stores about 180,000 km^3 of the world's freshwater (Benn and Evans, 1998). Large HE glacierized areas, such as the Fedchenko Glacier in Pamir, Inylchek Glacier in Tien Shan, or Siachen Glacier in Karakoram are supplying water and generating river flow, which is vital not only for the millions of people living downstream, but also for forestry, agriculture, industry, and urban areas in adjacent lowlands. The glacier meltwater is particularly important when the lower courses flow through semi-arid and arid regions with high evaporation rates and high demands for irrigation water during the vegetation period in many mid-latitude areas adjacent to mountain systems, such as Alps, Andes, the mountains of central Asia and western China. Rapid glacier recession in mid- low-latitude mountain regions is a major concern in assuring freshwater resources for the future. A decrease in glacial and seasonal snow-covered areas reduces the portions of water in total river runoff, increasing the proportion of precipitation runoff. Although it has been demonstrated that total water quantity from glacier wastage is relatively small, the timing of release of those waters are critical. It is in years of generally low flow that glacier wastage contributes most and it is in late summer (when evaporation rates are high and when demand for water is also high) that glaciers make their biggest contributions to stream flow. Changes in seasonal precipitation, snow cover, and glacier melt regimes in HE mountains are already causing concern for water supply, agriculture, and hydropower in central Asian countries. Furthermore, study of high elevation glaciers allow to integrate climate variations over a wide range of time scales, making them natural sensors of climate variability and providing a visible expression of climate changes preserving climatic signatures, which can be used to reconstruct past climatic and environmental records in mid- low-latitudes through the glacier deep ice-cores isotope-geochemical analyses. The ice-coring research, paleo-climatic and environmental reconstructions at mid- low- latitudes, is the important part of high elevation glacio-climatology.

Conclusion

Glacio-climatological studies are an important part of geoscience that links global system involving global energy sources, the hydrological cycle, the atmospheric circulation, climate and physics of snow, glaciers, and permafrost.

HIMALAYA

John F. Shroder
Department of Geography and Geology, University of Nebraska at Omaha, Omaha, NE, USA

Introduction

The term "Himalaya" is a Sanskrit word that means "abode of snow." As the highest mountains in the world, the Himalaya are the so-called water towers of Asia whose snow and ice meltwaters provide essential irrigation, hydroelectricity, potable water, and other uses to billions of people downstream. The Himalaya are the product of plate tectonic collision of an Indian plate that broke from the Southern Hemisphere supercontinent of Gondwanaland in Mesozoic time, to eventually push inexorably north into the Asian plate during the Cenozoic. The mountain uplift of the Himalaya resulted from this slow upward thrusting of the mighty ranges as the two plates became progressively sutured together. The ongoing collision, which continues today at about the rate that fingernails grow, has resulted in more >7,000 and >8,000 m high peaks than anywhere else in the world. Where these peaks effectively trap moisture from the wintertime westerly winds and the summertime monsoon, the precipitation at such altitudes accumulates as snow and ice, with the result that the Himalaya host glacier stores of accumulated frozen water that is released later when it melts.

Himalayan orography is complex because of the long history of uplift and the diversity of geological mountain-building mechanisms that have occurred there. The result is a vast sweep of ranges from the so-called Pamir knot on the west to the complex of approximately north–south-trending, parallel ranges and rivers in south China, some 2,600 km to the east. In general, the Himalaya are marked at both the west and east ends by geological syntaxial bends in rock structures wherein the tight, fault-bounded, "trapdoor" or "pop-up" uplifts of Nanga Parbat on the west and Namche Barwa on the east have occurred in the past few million years. In the most modern *tectonic aneurysm model* of these uplifts (Zeitler et al., 2001a, b), the geomorphic diversion of the great Indus River and the Tsangpo-Brahmaputra by headward erosion of small rivers that undercut and captured these huge river discharges is thought to have so rapidly eroded the upper surfaces of the rocks that the crust of the Earth was thereby weakened at those locations and rose rapidly upward in a highly localized fashion. But in spite of the syntaxial uplifts that more or less mark the ends of the Himalaya, especially on the wider west end, a number of other ranges also occur somewhat further away that are included in Table 1.

In fact if one observes a map of the overall planimetric shape of the Himalaya without including the Tibetan Plateau as well, it is immediately apparent that the mountain range is wider on its western end than it is on the east. This is in large part an accident of the geometry of the way the crustal plates of the Earth became sutured together, with more crustal plate fragments being incorporated on the west over a longer time than on the east. Thus, the simplest organization of the geography of the Himalaya is one of the older subdivisions by Burrard and Hayden (1907–1908). This was done at the time, for example, wherein the main points for consideration of subdivision of the mountain range were done only in a weak topographic sense (river locations and general peak altitudes), and not in any true topographic or geologic sense. In some cases mountain range names were carried erroneously from the west (Ladakh Range) far into the east where clearly few would use that terminology.

In addition certain unusual regions at the east and west ends of the Himalaya came to be what is now known as the western syntaxis in Pakistan where the Indus River gorge incises into the Nanga Parbat – Haramosh massif uplift, and the eastern syntaxis in China where the Tsangpo-Brahmaputra cuts through the Namche Barwah – Gyala Pelri massif uplift. This division by syntaxes as to what constitutes the Himalaya may make some limited sense, especially at the wetter and more forest covered east end in China where less is known geologically, but not at the drier and more exposed west end in Pakistan. Here ending the Himalaya at the syntaxial bend is a topographic and geologic oversimplification because it entirely neglects directly contiguous and connecting ranges that are genetically linked to the main Himalaya. A further problem arises in that the topographic and geologic complexities at both ends of the Himalaya are of quite high altitude as well,

Himalaya, Table 1 Physical divisions of the Himalaya mountains (*sensu lato*), extending from Pakistan on the west, through northwest India, Nepal, and Chinese Tibet in the middle to northeast India and China on the east, with emphasis on mountains high enough to support past glaciation or present-day glacierization (after Burrard and Hayden, 1907–1908; Mason, 1955; Grötzbach, 1990; Neate, 1978; Neate, 1989; Bolinder et al., 1990; Bhutan, 2006; Bhutan Himalaya, 1996; Bossart, 1981; Karan, 1969; National Atlas of India, 1964; Verlag, 2008). Individual mountain massifs >7,000 m are named (after Neate, 1989). A number of directly peripheral ranges in Chinese Tibet are included in this table, although they are not considered further as part of the Himalaya

Western (Punjab) Himalaya (Pakistan, India, China)

1.0 Hindu Raj — Can be considered a part of a Lesser Himalaya of the west, although that term generally is not used in this region.
2.0 Kohistan ranges
- 2.1 Dir Kohistan
- 2.2 Swat Kohistan
- 2.3 Indus Kohistan

3.0 Pir Panjal — Occurs in both the western and central Himalaya.
4.0 Great Himalaya
- 4.1 Nanga Parbat massif
  - Nanga Parbat (8,126 m)
  - Raikot (7,070 m)
  - Mazeno
- 4.2 Pangi range
- 4.3 Nun Kun massif
  - Nun (7,135 m)
  - Kun (7,086 m)

5.0 Inner Himalaya
- 5.1 Deosai mountains
- 5.2 Zanskar range — Occurs in both western and central Himalaya.
- 5.3 Ladakh range — Occurs in both western and central Himalaya.

6.0 Lesser (South) Karakoram Himalaya of the trans-Himalaya
- 6.1 Naltar range
- 6.2 Rakaposhi range-Haramosh range (including Spantik-Sosbun Mtns)
  - Rakaposhi (7,788 m)
  - Diran (Minapin) (7,257 m)
  - Malubiting (7,458 m)
  - Haramosh (7,409 m)
  - Spantik (Ghenish Chhish, Pyramid peak, Golden Parri) (7,027 m)
- 6.3 Masherbrum (7,821 m) range
  - Baltistan peak (K6) (7,821 m)
  - Link Sar (7,041 m)
  - Chogolisa (Bride peak) (7,665 m)
  - Baltoro Kangri (Golden Throne) (7,240 m)
  - Yermanendi Kangri (7,260 m)
- 6.4 Saltoro range
  - Saltoro Kangri (7,742 m)
  - Sherpi Kangri (7,380 m)
  - Depak (7,150 m)
  - K12 (7,428 m)

7.0 Greater Karakoram Himalaya of the trans-Himalaya
- 7.1 Lupghar mountains
- 7.2 Batura Muztagh
  - Batura (7,795)
  - Kampire Dior (Karambar Sar) (7,143 m)
  - Muchu Chhish (7,453 m)
  - Pasu (7,284 m)
  - Shispare (7,611 m)
  - Bojohagur Duanasir (Ultar) (7,329 m)
- 7.3 Hispar Muztagh
  - Lupghar Sar (7,200 m)
  - Momhil Sar (7,343 m)
  - Trivor (7,728 m)
  - Malangutti Sar (7,025 m)
  - Disteghil Sar (7,885 m)
  - Bularung Sar (7,200 m)
  - Yazghil (7,559 m)
  - Khunyang Chhish (7,852 m)
  - Pumari Chhish (7,492 m)
  - Yukshin Gardan Sar (7,530 m)
  - Yutmaru Sar (7,330 m)
  - Kanjut Sar (7,760 m)
- 7.4 Panmah Muztagh
  - Baintha Braak (Ogre) (7,285 m)
  - Latok (7,145 m)
  - Changtok (Chiring) (7,091 m)
- 7.5 Baltoro Muztagh
  - Muztagh tower (7,273 m)
  - Chongtar (7,370 m)
  - Skil Brum (7,360 m)
  - K2 (8,611 m)
  - Skyang Kangri (Staircase peak) (7,544 m)
  - Broad peak (8,047 m)
  - Gasherbrum (Hidden peak) (8,068 m)
  - Urdok (7,300 m)
- 7.6 Siachen Muztagh
  - Sia Kangri (7,422 m)
  - Singhi Kangri (7,202 m)
  - Teram Kangri (7,462 m)
  - Apsarasas (7,245 m)
- 7.7 Rimo (7,385 m) Muztagh
  - Chong Kumdan (7,069 m)
  - Mamostong Kangri (7,516 m)
- 7.8 Saser Muztagh
  - Saser Kangri (7,672 m)

8.0 Lesser (North) Karakoram Himalaya of the trans-Himalaya
- 8.1 North Ghujerab mountains
- 8.2 South Ghujerab mountains
  - Karun Kuh (7,350 m)
- 8.3 Wesm mountains
  - Crown (Huang Guan Shan) (7,265 m)
- 8.4 Aghil range
- 8.5 Mushin-Ta-Ko-Shan
- 8.6 Mustagh Ata range (not on map)

9.0 Pangong range (Tibetan highlands of China)
10.0 Chang Chenmo range (Tibetan highlands of China)
11.0 Kailas range (Gangdise Shan) (Tibetan highlands of China – not on map)

Central (Garhwal or Kumaun [Kumaon], and Nepal) Himalaya (India, China, Nepal)

12.0 Lesser Himalaya (Garhwal and Nepal)
- 12.1 Dhauladhar range
- 12.2 Nag Tibba range
- 12.3 Mahabharat range

13.0 Great Himalaya (Garhwal)
- 13.1 Gangotri group
  - Chaukamba (7,138 m)
  - Satopanth (7,075 m)

Himalaya, Table 1 (Continued)

- 13.2 Kamet group
  - Abi Gamin (7,355 m)
  - Kamet (7,756 m)
  - Mana (7,272 m)
  - Makut Parbat (7,242 m)
- 13.3 Nanda Devi group
  - Dunagiri (7,066 m)
  - Hardeol (Tirisuli South) (7,151 m)
  - Tirisuli (East) (7,074 m)
  - Nandi Devi (7,816 m)
  - Trisul (7,120 m)

14.0 Great Himalaya (Nepal)

- 14.1 Karnali section
  - 14.1.1 Kubi Kangri
  - 14.1.2 Nalakankar Himal
    - Gurla Mandhata (7,728 m)
    - Api (7,132 m)
    - Saipal (7,031 m)
  - 14.1.3 Byasrikh Himal
  - 14.1.4 Changla Himal
  - 14.1.5 Punga Range
  - 14.1.6 Sisne Himal
  - 14.1.7 Kanji Roba Himal
  - 14.1.8 Dhaulagiri Himal
    - Churen Himal (7,371 m)
    - Dhaulagiri (8,167 m)
    - Gurja Himal (Sauwala) (7,193 m)
- 14.2 Gandaki section
  - 14.2.1 Annapurna Lamjung
    - Annapurna (8,091 m)
    - Gangapurna (7,455 m)
    - Khangsar Kang (7,485 m)
  - 14.2.2 Nilgiri North (7,061 m)
    - Tarke Kang (7,193 m)
    - Tilitso (7,134 m)
    - Varah Shikar (7,647 m)
  - 14.2.3 Peri Himal
    - Himlung (7,126 m)
    - Ratna Chuli (7,035 m)
    - Kang Guru (7,010 m)
  - 14.2.4 Larkya Himal
    - Manaslu (8,163 m)
    - Himal Chuli (7,893 m)
  - 14.2.3 Kutang Himal
  - 14.2.4 Ganesh Himal
    - Ganesh (7,406 m)
- 14.3 Kosi section
  - 14.3.1 Langtang Himal
    - Gang Benchen (Kangpenqing) (7,211 m)
    - Langtang Lirung (Ganchen Ledrub) (7,234 m)
  - 14.3.2 Jugal Himal
    - Lonpo Gang (7,080 m)
    - Risum (7,050 m)
  - 14.3.3 Lapche Kang
  - 14.3.4 Rolwaling Himal
    - Gaurishankar (7,134 m)
    - Menlungtse (7,181 m)
    - Nyanang Ri (7,071 m)
    - Phola Gangchen (7,661 m)
    - Porong Ri (7,284 m)
  - 14.3.5 Mahalungur Himal (Barun section)
    - Baruntse (7,129 m)
    - Chamlang (7,319 m)

Himalaya, Table 1 (Continued)

  - 14.3.6 Mahalungur Himal (Makalu section)
    - Kangchungtse (7,678 m)
    - Chomolönzo (7,790 m)
  - 14.3.7 Mahalungur Himal (Khumbu section, or Kumbhakarna Himal)
    - Pumori (7,161 m)
    - Cho Oyu (8,201 m)
    - Everest (8,848 m)
    - Nuptse (7,855 m)
    - Makalu (8,462 m)
    - Pumori (7,161 m)
    - Cho Aui (Nangpai Gosum II) (7,350 m)
    - Jasamba (7,351 m)
    - Nangpai Gosum III (7,110 m)
    - Gyachung Kang (7,952 m)
    - Hungchi (7,036 m)
    - Ngojumba Kang I (7,916 m)
    - Kharta Changri (7,056 m)
    - Khartaphu (7,227 m)
    - Palung Ri (7,013 m)
  - 14.3.8 Umbak Himal

Eastern Himalaya (India, Bhutan, China)

15.0 Lesser Himalaya (Sikkim)

16.0 Great Himalaya (Sikkim)

- 16.1 Kangchenjunga Himal (Singalila range)
  - Pathibara (Pyramid peak) (7,123 m)
  - Kanchenjunga (8,586 m)
  - Kabru (7,353 m)
  - Talung (7,349 m)
  - Zemu (7,780 m)
  - Dome Kang (7,442 m)
  - Janak (7,035 m)
  - Jongsong peak (7,483 m)
- 16.2 Chorten Nyima range
- 16.3 Janak Himal (Dongkya ridge)

17.0 Bhutan Himalaya

- 17.1 Lesser Himalaya (<∼4,000 m)
- 17.2 Chomolhari-Laya group (>∼4,000 m)
  - Chomolhari (Jomolhari) (7,315 m)
  - Gangchen Tag (Kangcheta) (7,000 m)
  - Matsa Gang (Masa Gang, Masang Gang) (7,200 m)
- 17.3 Luana group (>∼4,000 m)
  - Tsenda (7,100 m)
  - Teri Kang (7,000 m)
  - Jeje Khangphu (7,300 m)
  - Kangphu Gang (7,200 m)
  - Zongophu Gang (Table Mountain) (7,000 m)
  - Gang Chen (Kang Chen) (7,200 m)
  - Chomolhari Gang (Chomolhari Kangri) (7,000 m)
- 17.4 Bumthang group (>∼4,000 m)
  - Gangkar Puensum (Kangkar Pünzum Rinchita) (7,541 m)
  - Kula Kangri (Künla Kangri, Gula Kangri) (7,554 m)
  - Karjiang (7,221 m)
  - Melunghi Kang (7,000 m)
  - Chumhari Gang (7,000 m)
  - Chura Gang (7,000 m)
- 17.5 Trashi Yangtse Himalaya

18.0 Assam Himalaya

- 18.1 Lesser Himalaya (<∼4,000 m)
  - 18.1.1 Dafla hills
  - 18.1.2 Arbor hills
  - 18.1.3 Miri hills
  - 18.1.4 Mishmi hills

Himalaya, Table 1 (Continued)

18.2 Great Himalaya (>∼4,000 m)
Kangtö (7,090 m)
Nyegyi Kangsang (7,047 m)
Namche Barwa (Namjag Barwa Feng) (7,782 m)
Nai Peng (7,043 m)
Gyala Peri (Jialabiali Feng) (7,150 m)
19.0 Hengduan Shan (Tibetan highlands of China – not on map)
20.0 Nyenchen Tangla Shan (north of Lhasa) (Tibetan highlands of China – not on map)
Nyenchen Tangla (Nyingêntangla Feng) (7,162 m)

which requires sorting them out as much as possible in this classification.

Nonetheless then, with a careful ordering of all these ranges, and a reasonable subdivision of the Himalaya into its constituent parts, some semblance of order can be assigned to the widespread and complex region. In general only some of the ranges of the Tibetan Plateau were included if they were reasonably close to the main ranges of the Himalaya. Thus overall, we can subdivide the Himalaya into the Western or Punjab Himalaya, the Central Himalaya, and the Eastern Himalaya (Mason, 1955). These three master divisions are then further subdivided into subsections. The Western (Punjab) Himalaya is therefore mapped most easily into a series of as many as six northwest–southeast-trending subparallel ranges extending from Tibet across the main range axis and south into the foothills of the Himalaya. Fewer known or named separate ranges occur to the east, however. This reduction in number of ranges eastward occurs in part because several ranges join together successively in areas of the Central Himalaya in what Burrard and Hayden (1907–1908) termed as "bifurcations." Furthermore, the subdivision of the less extensive Central and Eastern parts of the Himalaya has also been done somewhat arbitrarily by drawing it into sections drawn transverse or perpendicularly to the main range axis, and even using somewhat random political boundaries (Mason, 1955). The resulting sections tend to be of rather arbitrary width, generally named for political boundaries coinciding in some cases with accessibility of drainage basins from the south, which is not an ideal situation but must suffice for now.

There are many ways to organize, subdivide, and classify mountain areas so that physical aspects of geology, geomorphology, orography, hydrology, or topography are featured, or so that cultural, political, and other such human-related aspects are also part of the consideration if that is desired. In the course of doing this work, we have become aware of certain assumptions, inconsistencies, lack of knowledge, out-of-date usages, and differences of opinion as to exactly where certain areas or mountain groups are located. In addition, a further complication occurs where various mountain ranges have been designated or named differently by different ethnic groups or nationalities, and on different sides of mountains. Accordingly it is the intention here to investigate what has been written and mapped in the past, with an eye toward reconciling where possible and reordering where necessary. With pervasive satellite imagery at all scales now so readily available, it would seem timely therefore to make a new map of the entire area from the Hindu Kush on the west to the farthest Himalaya on the east in order to bring some order to the apparent miscellany of ranges and peaks. We concentrated our efforts on the areas of the Himalaya of direct interest, but generally not on the more northern ranges of central Asia radiating out from the so-called Pamir Knot, an orographic designation that intrigued many 19th and early 20th century geographers. We did, however, incorporate a few of the trans-Himalayan ranges in Tibet because in many cases they had been ignored by scientists in the British Raj who were more or less unaware of them, or who had an imperfect understanding of their attributes in the early days of exploration and mapping, and because some or all of them have been directly involved in the geologically recent Himalayan uplift.

This map of the Himalaya was made with an ASTER-satellite-image-derived digital elevation model (DEM), with an emphasis on mountains high enough to support past glaciation or present-day glacierization, but some lower mountains have been included where continuity of classification was enhanced. Burrard and Hayden (1907–1908) classified the mountains of Asia according to an altitude hierarchy of first through a seventh order. First-order peaks are those >∼7,600 m, second-order >∼6,700 m, third-order >∼5,800 m, fourth-order >∼4,600 m, fifth-order >∼3,300 m, sixth-order >∼2,100 m, and seventh-order >∼910 m. These designations are used in a few cases herein where such designations were deemed useful. In several cases in the eastern Himalaya (Sikkim, Bhutan, Assam) DEM altitudes were used to crudely define the division between the Greater and Lesser Himalaya.

In general we tried to maintain all the existing and mutually compatible classifications of which we were aware, although in a few cases we had to change prior designations for various reasons having mostly to do with issues dealing with past or present glaciers. Several problems that emerged have to do with the older techniques of linking high mountain peaks into a geographically designated mountain range even across major river valleys, and a newer desire to designate ranges by circumscribing them in their valley bottoms using the pervasive new satellite imagery and DEMs. A further problem with this can be that large glaciers generally occupy valley bottoms in some places that mark borders between adjacent mountain ranges, so in those cases a glacier can, of course, have source areas in several different places.

One of the most recognized schemes of this sort of mountain range division is the work of Burrard and Hayden (1907), who initially subdivided the Himalaya based mainly upon main drainages to the south, coupled with political boundary delineations based on the government of the British Raj. In some cases they carried

geographic names from the far west to the far eastern parts of the Himalaya, which was not valid and is suppressed herein. Mason (1955) maintained these east-to-west designations of the Punjab Himalaya in the west, then the Karakoram, Kumaun Himalaya, and Nepal Himalaya with its Karnali, Gandaki, and Kosi sections, as well as the Sikkim and Assam Himalaya to the east. In a number of cases, Mason's designations of mountain divisions followed political boundaries set along river bottoms (India–Nepal border along the Kali River), which was convenient, but in other cases the division was at the ridge line (Sikkim Himalaya), which was not. Neate (1989) also followed these basic prior subdivision plans in her assessment of the 7,000 m peaks in the region. Statistics on names, heights, locations, and climbing histories are kept by a variety of people and organizations, but Neate's (1978) book is one of the more succinct versions up to the time of its publication. With these primary sources we have established our subdivisions of high south Asia, as well as the general locations of all the fourteen >8,000 m peaks, and many of the >400 examples of the >7,000 m ones as well. Where a great many peaks of similar height were too close together to plot separately, we did not consider them all (Table 1). In several cases in Nepal we listed large numbers of named "Himal" that occurred on a number of maps (United Kingdom Ministry of Defense, 1967, 1969; Nelles Maps, 2008) but were discussed in no other texts.

Western (Punjab) Himalaya

The Western Himalaya (Figure 1), considered as the Punjab Himalaya by Mason (1955), begins somewhat arbitrarily in western Pakistan close to the border with Afghanistan, and extends well into India where it terminates approximately along the Sutlej River and the old summer capital of Simla (now "Shimla") of the British Raj. The Western Himalaya is the widest in latitude of the Himalayan chains, extending >500 km north to south, if the Aghil and Kun Lun of Tibet are included, together with the Lesser and Greater Karakoram, and the Great and Lesser Himalaya.

Hindu Raj

These mountains in northern Pakistan between Chitral and Gilgit occur just south of the Wakhan Pamir and east of the East Hindu Kush of Afghanistan and the Pakistan border, and west of the Karakoram and Great Himalaya of Pakistan. The mountains of the Hindu Raj have no 7,000 m peaks but instead consist mainly of 5,000–6,000 m peaks so they are mountains primarily only of the third and fourth magnitudes (Burrad and Hayden, 1907–1908). The highest peak, Koyo Zom, is 6,872 m, and is near the head of the Yarkand River valley where the Baroghil Pass leads into Pakistan from the Wakhan Corridor of Afghanistan. The Chiantar Glacier is the largest ice mass in this area of the Hindu Raj.

Kohistan ranges

South of the Hindu Raj in Pakistan, the ranges of Dir, Swat, and the Indus Kohistan extend from northeast of the Kunar River at the Afghanistan–Pakistan border, across the Swat Valley area, to both sides of the Indus River valley and the Kaghan Valley where they meet the Great Himalaya at Nanga Parbat and the Pir Panjal of the Kashmir–Indian border. Although a very few peaks in the Kohistan Ranges make it over 6,000 m, most are only 4,000–5,000 m and the glaciers are all small. The mountains of the Lesser Himalaya here are even less consequential.

Punjab lesser Himalaya

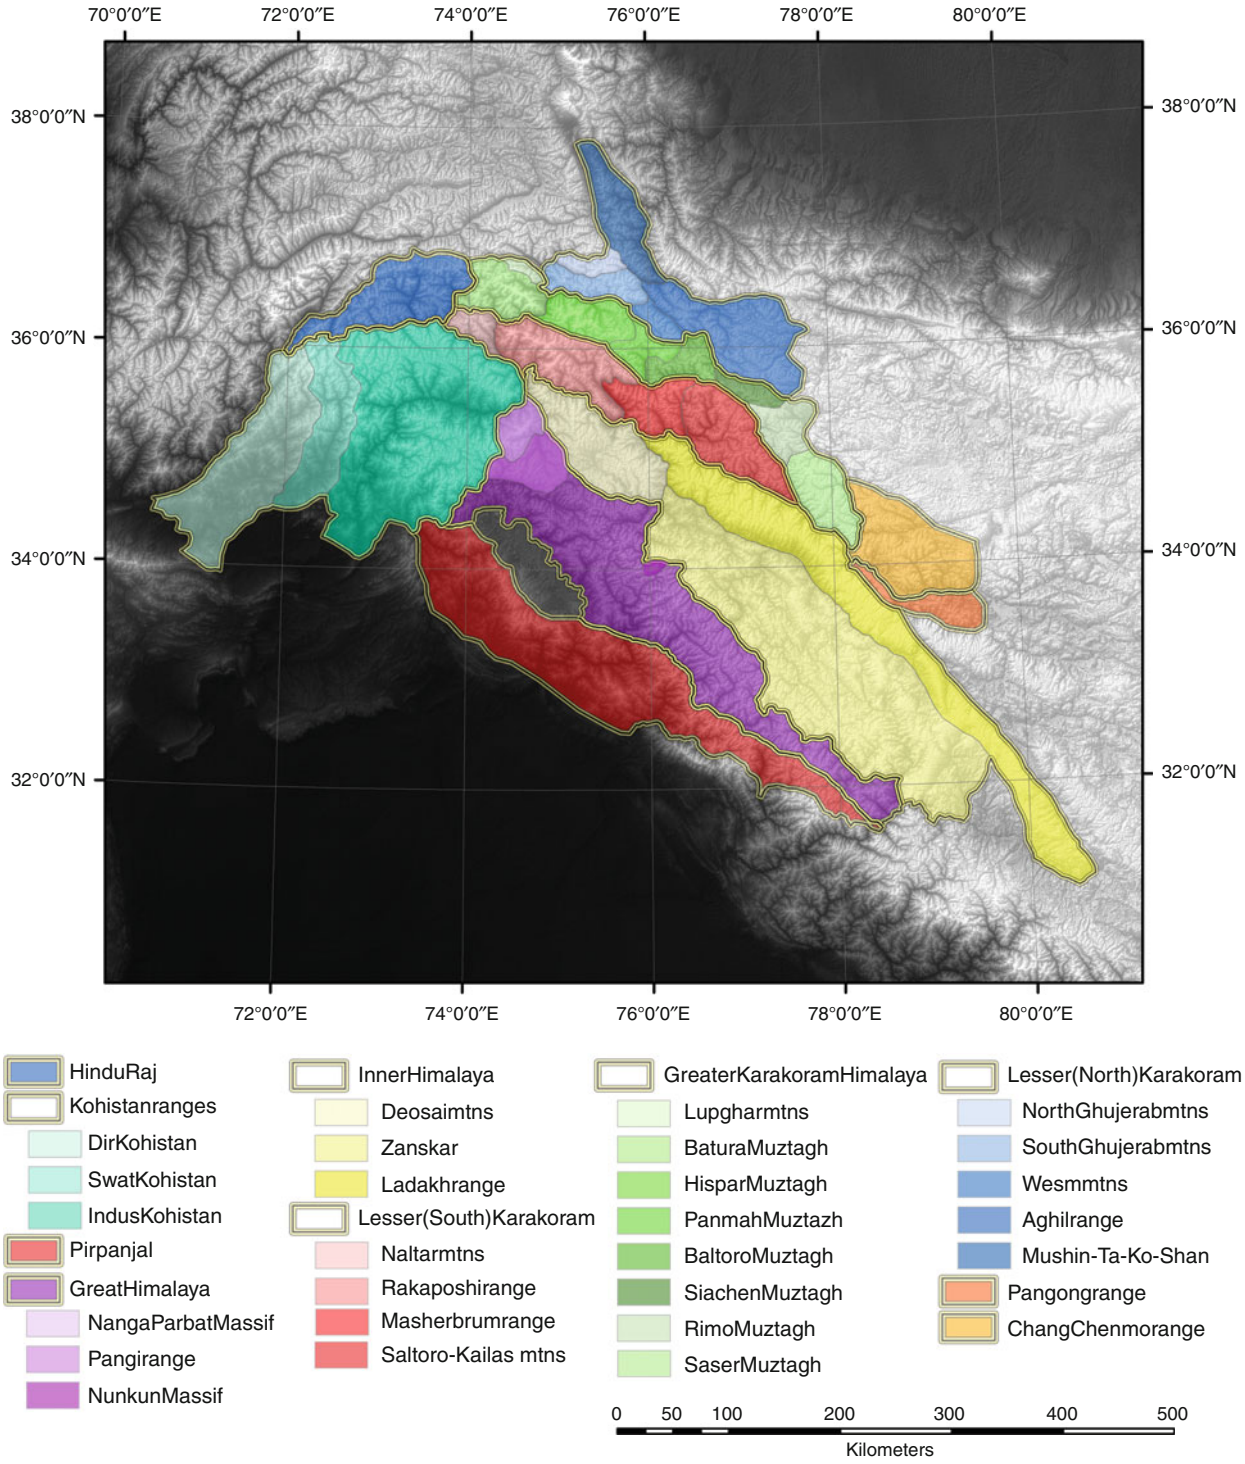
The Pir Panjal and the Dhauladhar ranges occur as two lesser ranges in the front or the southernmost side of the Himalaya and both start at about the Pakistan–India border. The Pir Panjal mountains form the southernmost barrier to the Kashmir Valley and their highest peak, Tatticooti (~4,700 m), has glaciers around it. Numerous other small glaciers, moraines, and rock glaciers occur along the range top. The Pir Panjal extend from their start on the Pakistan–India border to the southeast into India, where they finally join with the Great Himalaya at about the point where the Sutlej (Satluj) River cuts through the ranges just upstream from the old Simla summer capital in India. Similarly the Dhauladhar range begins at the Himalayan front at about the Ravi River, extending past Dharmsala where lives the Dhali Lama, and across the Beas and Sutlej rivers to join the Great Himalaya near the Gangotri Glacier and the main source of the Ganges River. South of this mountain junction, the Nag Tibba constitutes the frontal range upon which Shimla is located.

Great Himalaya

The Great Himalaya extends across much of the Himalaya from west to east. The 7,000–8,000 m peaks of this part of the Himalaya in Pakistan and India are notable by the massiveness and considerable height of the Nanga Parbat massif in Pakistan and the Nun Kun massif in India. Nanga Parbat, at 8,126 m with the Indus River at its foot some 6,000 m lower, is one of the highest relief places on the planet and has an exceptionally unusual uplift history caused by rapid erosion from mass movement, glaciers, and rivers that unroofed the crust so rapidly that it developed into a tectonic aneurysm (Shroder and Bishop, 2000; Zeitler et al., 2001a, b), now ringed by a series of glaciers. The Nun Kun area in India is not such a dramatic structural feature but it also has several important glaciers around it.

Inner Himalaya

North of the Great Himalaya are the Deosai Mountains just south of Skardu, Pakistan, and the Pangi Range between them and the Kashmir Basin under Indian control. Numerous small glaciers occur in the Deosai and



Himalaya, Figure 1 Ranges of the Western Himalaya.

a few in the Pangi Range. The continuations of these mountain ranges into India are the Ladakh Range and Zanskar (Zaskar) Range of the Inner Himalaya. The more northerly Ladakh Range extends across the Punjab Himalaya to the Sutlej River in the Kumaun Himalaya of India and Tibet. The Zanskar Range extends to at least the Sutlej River in the Kumaun Himalaya of India, and some would extend it at least as far as the Karnali section

of the Central or Nepal Himalaya where it joins with the Great Himalaya at the Karnali River.

Lesser (south) Karakoram Himalaya of the trans-Himalaya

This group of mountains and ranges extends from the Naltar and Rakaposhi mountains in Hunza, Pakistan, through the Haramosh and Spantik-Sosbun mountains just north of Nanga Parbat, to the Mango-Gusar and Shimshak mountains and the Masherbrum Range from Skardu north along the Baltoro Glacier, all under Pakistani control. From there the zone extends to the southeast into the Saltoro Range and the Kailas or South Saltoro mountains where the armies of India and Pakistan are looking down on the Siachen Glacier to their northeast, over which they have been fighting for decades.

Greater Karakoram Himalaya of the trans-Himalaya

This main part of the Karakoram Himalaya starts in the Batura area of Hunza and extends east and southeast through the Hispar, Panmah, and Baltoro regions under Pakistan control, the Siachen Glacier area under Indian control, and into the Rimo and Saser Kangri areas under Chinese control in some of the highest mountains and longest midlatitude glaciers of the world. Some 33 > 7,000 m peaks and 3 > 8,000 m peaks occur in this region that serve as great traps for arriving moisture so that profuse glaciers descend from the peaks in this militarily contentious area.

Lesser (north) Karakoram Himalaya of the trans-Himalaya

The northern Karakoram in Pakistan and China, which is largely an arid rain-shadow below the main Karakoram to the south, has only a few major peaks >7,000 m but a number of large glaciers from the greater Karakoram do terminate in this area. Several of the lesser peak areas trail off into various ranges in Tibet (Aghil, Mushin-Ta-Ko-Shan) that are not generally considered to be part of the Karakoram.

Kun Lun

These ranges that stand above the great Taklamakhan Depression start just north of the Karakoram and extend to the east to constitute the northern rim of the Tibetan (Xixang) Plateau. They are not mapped or considered further here.

Pangong range of the trans-Himalaya

This small group of mountains mapped in Figure 1 occurs at the southwest edge of Pangong Tso (lake) in Indian territory at the edge of the Aksai Chin, which is the territory claimed by India but taken by China in the war of 1962.

Chang Chenmo range of the trans-Himalaya

This small range is included with the Pangong in Figure 1 but is not further discussed or mapped.

Kailas range (Gangdise Shan) of the trans-Himalaya

This large range is included here but not mapped further.

Central Himalaya

This designation of the Central Himalaya (Figure 2) is not introduced here as being an entirely new designation, having been used by some recent workers (Singh et al., 2007) to combine Mason's subdivisions of the Kumaun Himalaya with his three subsections of the Nepal Himalaya. Nonetheless it is a useful designation and includes some of the most extensively glacierized portions of the Indian Himalaya, as well as all of the Nepal Himalaya.

Lesser Himalaya of the Garhwal and Nepal Himalaya

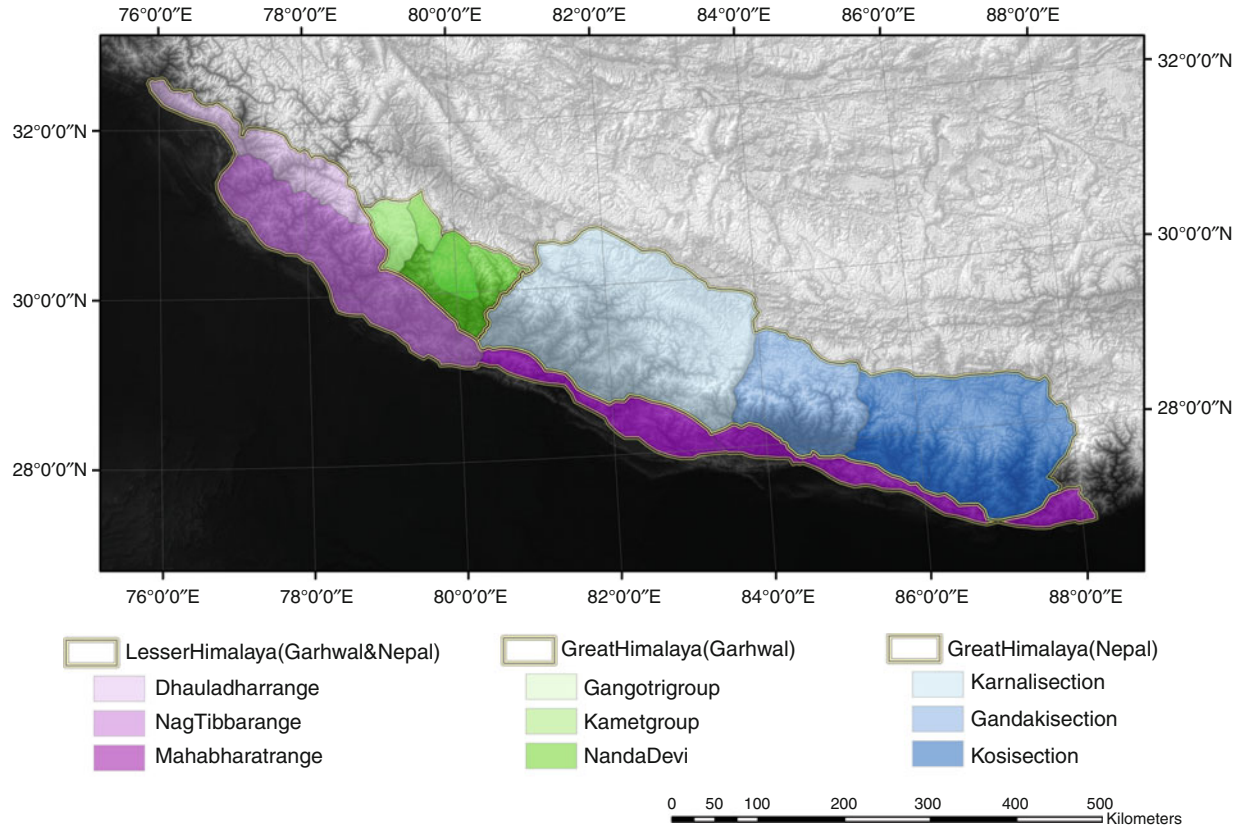
The irregularly faulted and dissected lower ranges on the south side of the Himalaya are diversely aggregated into the Pir Panjal that extends from Pakistan past the southern margins of the Kashmir Basin into India, and the Dhauladahar Range and Nag Tibba Range that extend to the Nepalese border. From there, the Mahabharat Range in several sections constitutes the main lower part of the Lesser Himalaya throughout Nepal.

Garhwal (Kumaun) Himalaya

Originally these two names hark back to the old administrative subdivisions of the British Raj that ruled India before 1947 that described slightly different regions, but nowadays the terms refer to basically the same mountainous areas of the Indian State of Uttar Pradesh. Mason (1955) drew his boundaries of this region across the ranges from the Tibetan Highlands to the lowlands of India, on its west side approximately through the Sutlej River and the old summer capital of Simla (Shimla), and on its east side along the western India–Nepal political border in the Himalaya. Beginning in Tibet first occurs the Nganglong Kangri range. Directly south of this occurs the Shiquan He (Sengge Khamba) tributary to the Indus River, which rises on the northern slopes of Kailas Range (Gangdise Shan). South of that range is the valley of the Gar Zangbo tributary of the Indus River, and then the southeast end of the Ladakh Range, before dropping down again into the upper valley of the Sutlej River as it passes over the Chinese–Tibet border and into India where an extension of the Zanskar Range forms the border range with the Kamet Group of mountain peaks along it. Directly south of the Zanskar Range, and partly connected to it by ridges between peaks, is the Great Himalaya, which includes such peaks as the Gangotri Group and the Nanda Devi Group.

Nepal Himalaya

The political entity of Nepal was divided by Mason (1955) into three large mountain-ringed drainage basins, from west to east the Gogra (Seti, Karnali, Bheri), Gandak, and Kosi rivers that define the Karnali, Gandaki, and Kosi sections of the Nepal Himalaya. These three sections with



Himalaya, Figure 2 Ranges of the Central Himalaya.

their master drainages, all pass down through a number of subparallel ranges, on their way to being tributary to the Ganges River of India.

Karnali Section: The west part of this section is directly south of the famous and sacred religious site of Mount Kailas in the Kailas (Gangdise) Range, and the well-known lakes of Rakshastal and Manasarovar of the Tibetan Plateau. The well-known east-flowing Tsangpo River of the Tibetan Plateau heads in the Kubi Kangri and Kailas Ranges directly north of this section. The Karnali River system also heads in the Kubi Kangri (Changla Himala) ranges of the Nepal Tibet border region, before breaking south through wall of the Great Himalaya, which is represented by the Byasrikh Himal on the west and the Sisne Himal or Kanj Roba Himal on the east. Several other river tributaries join the Karnali, including to the southeast, the Thuli Bheri from the north side of the heavily glaciated Dhaulagiri massif. The Karnali and its tributaries all pass through the Mahabharat Range, which is only a sixth-order range of the Lesser Himalaya, and finally through the Churia Range of the Siwalik rocks in the foothills.

Gandaki Section: This section is characterized by the numerous tributaries of the Great Gandakhi River that rise from a number of ranges spread across the upper part of the section. For example, the Kali Gandaki tributary heads in the remote Mustang region before passing out of the Damodar Himal and between the Dhaulagiri and Annapurna Himals. To the east of this extensively glacierized region occur the Peri Himal, Larkya Himal, Kutang Himal, and Ganesh Himal, to the Langtang Himal on the far eastern side of the section that is also the beginning of the Kosi section.

Kosi Section: This extensively glaciated section in eastern Nepal is dominated by the peaks of the Great Himalaya, including Cho Oyu, Everest, Makalu, and Kanchenjunga on the east border with the Sikkim Himalaya, and is drained by the tributaries of the Sapt Kosi. The great 8,027 m peak of Shisenpangma occurs in southern Tibet just northeast of the Ganesh Himala and northeast of the Cho Oyu massif. The Langtang and Jugal Himals occur on the west side of this section, with the Lapche Kang and Rolwaling Himal constituting part of the well-glacierized ridge lines up to the Mahalungur or Khumbhakarna Himal in the middle. The chief drainage, which begins on the Tibetan Plateau north of the main ranges, is the Arun River, which begins on the Tibetan Plateau around the Nyonno Ri massif. This river then flows between the Khumbhakarna Himal (Mahalungur) with Everest as the highest peak and the Umba Himal and Singahila Range with Kanchenjunga as the highest peak on the far eastern side of the section.

Eastern Himalaya

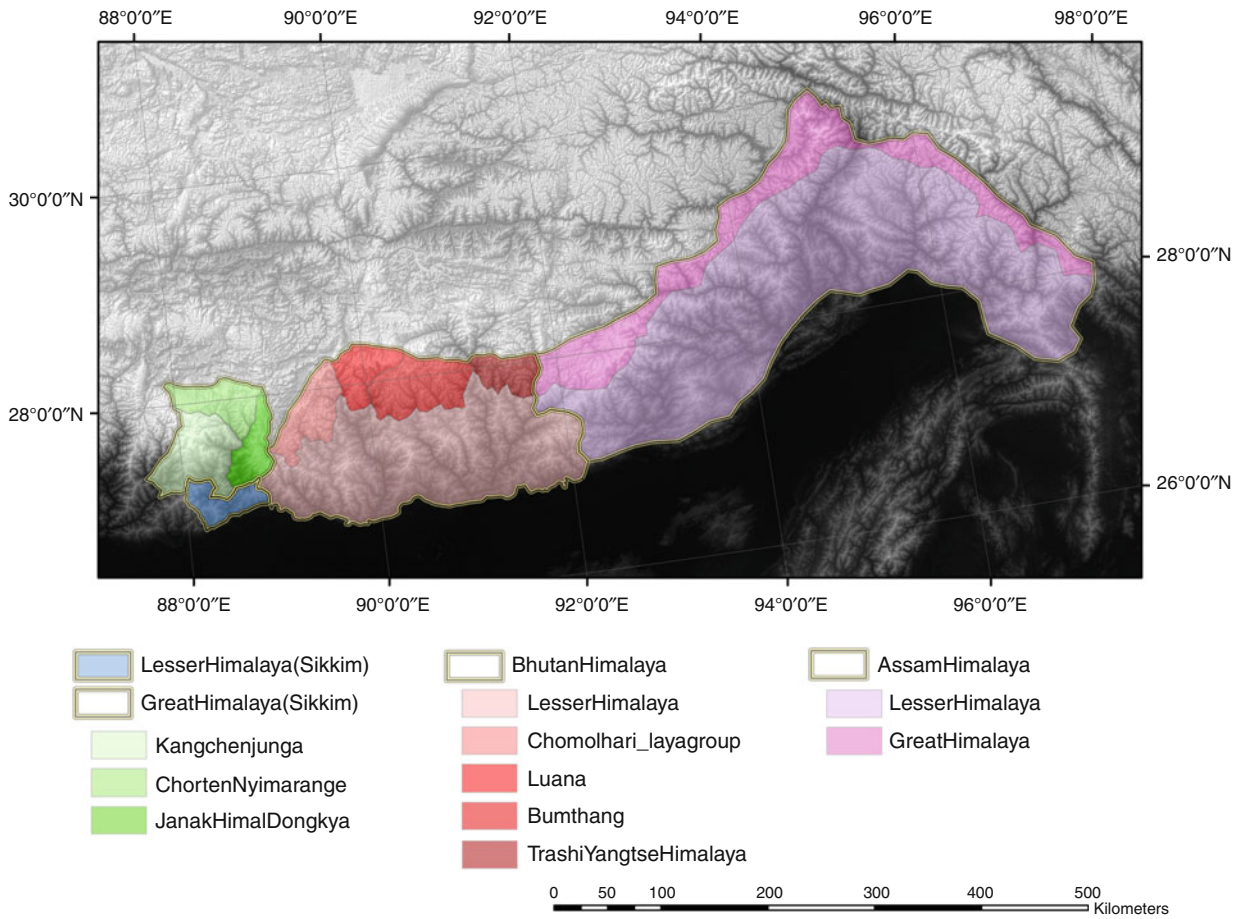
The Eastern Himalaya (Figure 3) is less precisely defined than the Central and Western Himalaya, especially because national borders tend to be the most precise determinative factor of division. Nonetheless, all three regions are basically divided into areas of Lesser and great Himalaya.

Sikkim Himalaya: The state of Sikkim in the central part of extreme northern India is bounded on the west by Nepal and the east by a southward projection of Tibet. The N-S-trending Singalila Range extends up to the high Kangchenjunga (Kangchendzonga) massif and constitutes the western border area. Similarly, the Donkya Ridge does the same on the east where the Yadong valley forms a reentrant south, or projecting "parrots beak" of Tibetan territory between Sikkim on the west and Bhutan on the east.

The Sikkim Himalaya is thus a quite narrow (∼75 km) strip of the higher Great Himalaya that is really only the upper watershed of the Tists River and its tributaries. The Singalila Range of the western border with Nepal, and the eastern Dongkya Ridge both pass north into the more or less W-E-trending, high Himalaya of crystalline gneisses, which form most of the W-E-trending, Chortan Nyima Range and the Janak Himal of the Tibetan border with Sikkim.

Bhutan Himalaya: The independent country of Bhutan is an approximately rectangular-shaped mountain kingdom drained to the south by 3–4 main drainages (Torsa Chu, Raigve Chu, or Wang [Raichak], Mo Chu or Sankosh, and Manas Chu) that dissect the crystalline rocks of the country into many mountains. These rivers drain south through the peaks of the Lesser Himalaya there, that are generally <∼4,000 m altitude. The higher peaks along the border with Tibet of the Greater Himalaya include the Chomolhari – Laya, Luana, and Bumthang groups that are all extensively glacierized.

Assam Himalaya: The Himalayan ranges in the Assam state of India are not well studied, in part because of the more common jungle and difficult physical and cultural terrains of the region. The Himalayan ranges here are a Lesser Himalaya (<∼4,000 m) constituted by the lower Dafla Hills and Abor Hills and Miri Hills to the west of the Brahmaputra, and the Mishmi Hills east of the river and close to the border with China. To the north of the State of Assam in Chinese Tibet the Yarlung Tsangpo River



Himalaya, Figure 3 Ranges of the Eastern Himalaya.

makes a great loop to the north before bending abruptly back S and then SW through the Great Gorge where it becomes the lowland Brahmaputra River. This is the site of the eastern syntaxis where the capture of the Yarlung Tsangpo and diversion southward occurred when the higher altitude river of the Tibetan Plateau spilled over into the lower altitude Brahmaputra. The subsequent rapid erosional unroofing of the bedrock formed a tectonic aneurysm that caused the geologically rapid uplift of the peaks of Namche Barwa (Namjagbarva Feng) (7,756 m) on the inside of the bend, and Gyala Pelri (7,294 m), just outside the bend to the NW, both with plentiful glaciers.

Hengduan mountains

As this eastern syntaxial bend of rocks continued to be forced into Asia by the inexorable forces of plate tectonics over the past few tens of millions of years, not only did the Namche Barwa – Gyala Pelri massifs rise like a trapdoor or pop-up structure in the rock, but other ranges and rivers to the north and east also became crushed upward. They were dragged into the tightly constrained, topographically crumpled, Hengduan ranges, of southeast China, as well as the parallel rivers between the ranges that wrapped around the uplifted highlands, to cut deep parallel canyon twice as deep as the Grand Canyon in USA (Jenkins, 2009). Between the Nu and Lancang rivers and latitudes 28°–29° N, Mt. Kwagebo (Meili) rises some 6,740 m and hosts a number of strong glaciers on its slopes. Thus the Nu (Nak Chu or Salween in SE Asia), Lancang (Ngom Chu or Mekong in SE Asia), and Dri Chu or Jinsha Jiang (Yangtze) all rise on the eastern Tibet Plateau and all force their way through this farthest extent of the extreme Eastern Himalaya within a few tens of km of each other before escaping the uplands and making their way to the lowlands and out to the sea.

Nyenchen Tangla Shan (Nyainqenanglha)

Just north of the Yarlung Tsangpo and Lhasa, the capital of Tibet, the heavily glaciated ranges of Nyenchen Tangla Shan (Nyainqenanglha or Ninchin-Thang-La) Range also wrap around the syntaxial bend and constitute the last vestiges of Himalayan-style mountains in this region. Directly NW of Lhasa at that end of this range, only one peak is higher than 7,000 m, Nyenchen Tangla at 7,162 m. All of the others are lower, with several around 6,400 m and most being in the >5,000 m range as they curve around to the south at the far eastern ends of the Himalaya.

Overall, the many ranges of the Himalaya, as well as its collateral offshoots, constitute a geologically and topographically diverse series of peaks that are the highest altitude places anywhere on this planet. Because these peaks are so broad and tall, they serve as ideal traps for snow and ice, which over time become strong glaciers. As a result, the Himalaya has the longest and largest midlatitude glaciers on Earth.

Summary

The Himalaya, or "abode of snow" in the ancient Sanskrit language are the highest mountains on our planet, and as such constitute a huge repository of snow and ice, the meltwaters of which nourish many millions of Asian people. The Himalayan mountains are subdivided into the Western or Punjab Himalaya, the Central Garhwal or Kumaun Himalaya, and the Eastern Himalaya. Each one of these Himalayan divisions is further subdivided in separate ranges or groups of ranges, all of which are now located on a new digital elevation model derived from ASTER satellite imagery in Figures 1–3.

HIMALAYAN GLACIERS IN 2010 AND 2035

J. Graham Cogley
Department of Geography, Trent University,
Peterborough, ON, Canada

Introduction

The aim here is to narrate the evolution of a mistaken but often-seen claim that Himalayan glaciers might disappear by 2035, to correct it by providing glaciological and climatic context, and to attempt a more realistic preliminary assessment of how Himalayan glaciers might evolve in the 25 years up to 2035.

Narrative

Early in 1999, S.I. Hasnain gave an interview to a magazine reporter (Chettri, 1999), and was quoted to have said "Glaciers in the Himalaya are receding faster than in any other part of the world and, if the present rate continues, the likelihood of them disappearing by the year 2035 is very high.... There won't be any glaciers left in the central and eastern Himalaya by 2035 if they continue to recede at the present rate." Chettri (1999) also quotes Kotlyakov (1996) as saying "Its total area will shrink from the present 500,000 to 100,000 km^2 by the year 2035."

A prominent science journalist then published another news story (Pearce, 1999) based upon Chettri (1999). Pearce too interviewed Hasnain, but apparently without cross-checking with any other glaciologist. Pearce reports statements similar to those in Chettri (1999). A photo caption above Pearce's text reads "Trouble at the top: Himalayan glaciers will vanish by 2035."

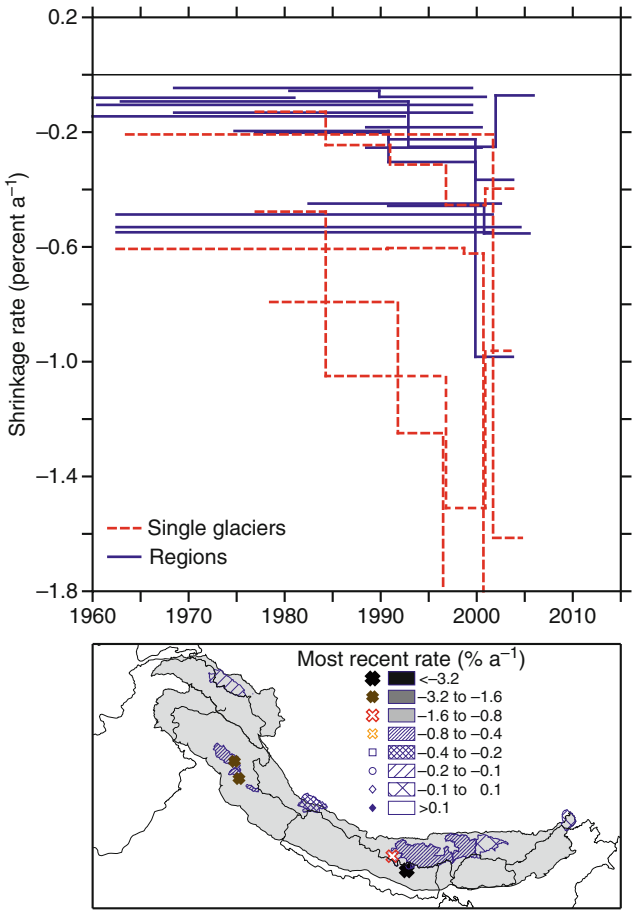
A study mentioned by both Chettri and Pearce was submitted to the International Commission of Snow and Ice (ICSI) by its Working Group on Himalayan Glaciology in July 1999, but remained unpublished until November 2009 when a copy was made available online by the International Association of Cryospheric Sciences, the successor of ICSI (Hasnain, 1999).

The claim that Himalayan glaciers might disappear by 2035 did not become widespread until it was repeated by Cruz et al. (2007), citing an overview prepared by the World Wildlife Fund (WWF, 2005), which in turn cited Pearce (1999).

Without citing Cruz et al. (2007), Raina (2009) challenged the by-then current idea that Himalayan glaciers were wasting abnormally. Bagla (2009) publicized Raina's report and contrasted its findings with statements in Cruz et al. (2007). This prompted investigations, which led to further coverage in the media and to Cogley et al. (2010), a correction that was published online on the same day as a formal retraction by the Intergovernmental Panel on Climate Change of Cruz et al.'s assessment of Himalayan glaciers (IPCC, 2010). The most prominent media report was a story by Pearce (2010), which triggered a spate of public comment and criticism lasting some weeks.

Clarification

Kotlyakov (1996) was not writing specifically about Himalayan glaciers but about all glaciers outside the polar regions and outside basins of internal drainage. He described his estimate of a decrease of total glacier area from 500,000 km^2 to 100,000 km^2 as "rough," noting that it was based on mass-balance records from the 1960s to the 1980s for six Norwegian glaciers. Further, Kotlyakov noted that the Himalaya would be among the regions



Himalayan Glaciers in 2010 and 2035, Figure 1 Measured shrinkage rates of Himalayan glaciers and glacierized regions. In the map, shading illustrates the most recent rate from the graph for each glacier or region; the Himalaya and (in the northwest) the Karakoram are defined by the thick lines, and thin lines are national borders.

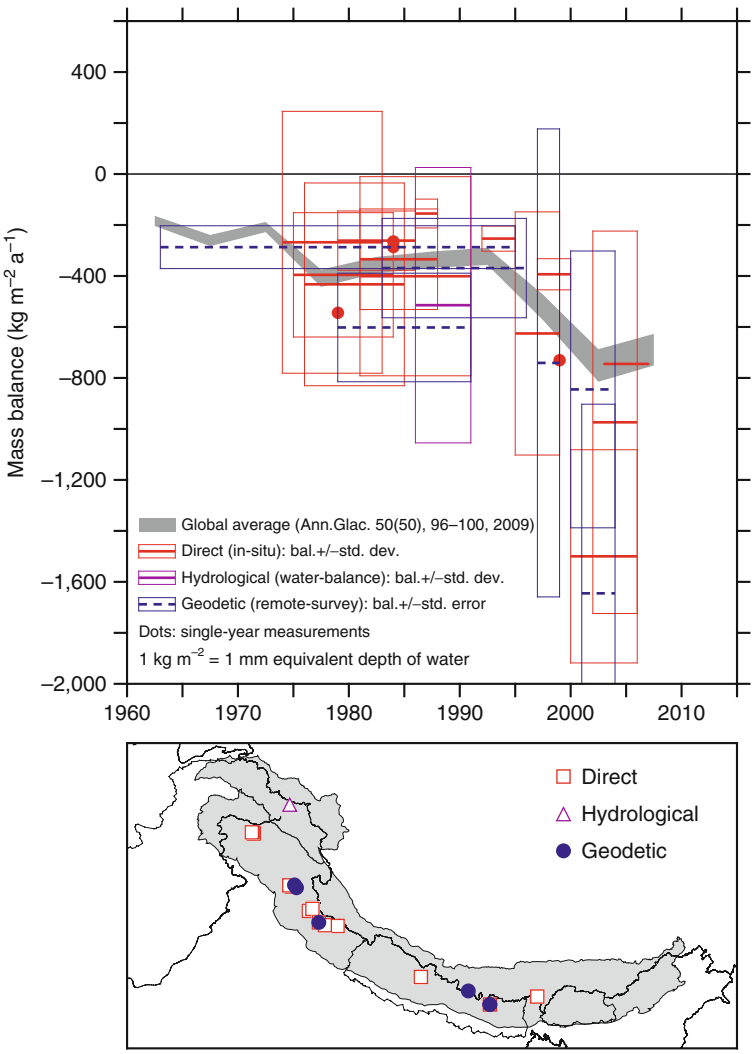
retaining glaciers after a decrease to 100,000 km^2. Most strikingly, Kotlyakov's date for decrease to 100,000 km^2 is 2350, not 2035.

It is all but certain that those who cited Hasnain (1999) before November 2009 had not seen it. If they had, its irrelevance to the claim of disappearance by 2035 would have been obvious, for it does not contain any of the statements attributed to it in Chettri (1999) and Pearce (1999). In fact, all of the restatements of the 2035 claim seen by this author are either copies of text from one of those sources or variants that introduce new mistakes.

The publicly available first and second drafts of Cruz et al. (2007) show that the citation of WWF (2005) was added at a later stage to an originally unreferenced paragraph, and to the wrong sentence in that paragraph. Moreover, collation of Cruz et al. and Chettri (1999) shows that Cruz et al. copied from Chettri rather than from WWF. WWF (2005) is not entirely free from criticism, however, for like others it simply followed Chettri (1999) and Pearce (1999).

Recent state of Himalayan glaciers

The area occupied by Himalayan glaciers is not known with great accuracy. Dolgushin and Osipova (1989) give 33,050 km^2 while von Wissmann (1959), a source for some later estimates, gives 31,530 km^2. For the Karakoram these two sources give 15,400 km^2 and 15,145 km^2, respectively. The differences may be due partly to different definitions of



Himalayan Glaciers in 2010 and 2035, Figure 2 Measured mass balances of glaciers in the Himalaya and the Karakoram. Direct measurements are made in situ on the glacier surface, while hydrological measurements solve the glacier's water balance using estimates of precipitation, evaporation, and runoff; each series average is drawn as a horizontal line contained in a box representing ±1 standard deviation. Geodetic measurements compare a later map to an earlier one, the mean change of elevation being multiplied by glacier area to yield volumetric change and by a suitable density (usually 900 kg m^{-3}) to yield mass change. The box containing each geodetic balance represents the standard error.

the regions. It is not possible at present to assess the contribution of glacier shrinkage, discussed below, to uncertainty in the total glacierized areas.

Total volumes of ice are uncertain, not only because of uncertainty in the areal extent but also because there are only a handful of measurements of glacier thickness. Average thicknesses obtained by volume-area scaling (with the coefficients of Radić and Hock, 2010), relying on glacier areas in the inventory of Cogley (2009b), are 86 m for the Himalaya and 172 m for the Karakoram. The uncertainty in these estimates is large but unknown.

Contrary to the assertions reported by Chettri (1999), measured rates of terminus retreat (e.g., Cruz et al., 2007; Raina, 2009) are comparable to, not faster than, rates elsewhere. This can be verified readily by inspection of the standard compilation (WGMS, 2008), which appears on a 5-yearly basis and in which reports vary from a few tens of m a^{-1} of retreat to a few m a^{-1} of advance, with a clear majority of retreating glaciers. Advancing and stable termini appear to be common in the Karakoram (Hewitt, 2005).

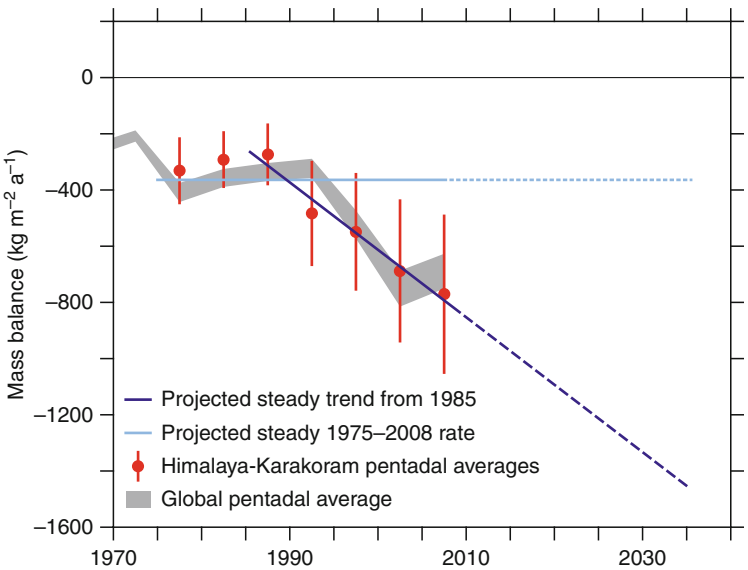
Measurements of rates of shrinkage (reduction of area; Figure 1) are too few for generalization, although there is a suggestion that shrinkage is faster in the central and western Himalaya than in the east or the Karakoram. There are no instances of growth. The graph shows signs of accelerated shrinkage, but it must be interpreted cautiously. Smaller glaciers tend to shrink more rapidly, in percentage terms, than larger ones. Thus, differences between the rates of different regions may be influenced strongly by differences in their glacier size distributions as well as by variations in climatic or other factors.

That said, the arithmetic average of shrinkage measurements whose spans contain the year 1960, weighting each measurement by the initial size or extent, is –0.10% a^{-1}. For 1980, the equivalent figure is –0.18% a^{-1}, and for 2000 it is –0.45% a^{-1}. For context, Cogley (2008) estimated that the global average over the past 50 years has been about –0.10% to –0.20% a^{-1}.

There are no long-term, continuous series of mass-balance measurements from the Himalayan region (Figure 2). This is unfortunate. Because successive annual measurements are uncorrelated, the number of degrees of freedom is equal to the number of measurements, which means that the uncertainty in a multi-annual average decreases with the square root of the length of the series. The longest series of annual measurements is only 10 years long, but there are also some measurements by geodetic methods. Few as they are, the measurements taken together suggest firstly that average mass balance has been negative for the past several decades; and secondly, that the rate of loss has been greater after 1995 than before.

Evolution of Himalayan glaciers to 2035

The future evolution of Himalayan glaciers has not been modeled thoroughly. However, we can extrapolate on two simple assumptions: more conservatively, that the recent average mass-balance rate will remain unchanged; and, perhaps more plausibly, that the recent acceleration of the rate will remain unchanged. Both assumptions are risky, because they neglect concurrent changes in glacier geometry. In particular, they do not account for net shrinkage or for retreat to higher, colder elevations.



Himalayan Glaciers in 2010 and 2035, Figure 3 Five-yearly average mass balance of Himalaya and Karakoram glaciers, as measured and interpolated (*dots* with error bars) and as projected to 2035. Horizontal line (*dotted* in the future) shows the 1975–2008 average. Sloping line (*dashed* in the future) represents the trend fitted to pentadal averages between 1985 and 2008. The interpolated global average is as in Figure 2.

Figure 3 shows estimates of the Himalaya–Karakoram average mass balance for 1975–1976 to 2007–2008, extracted from the calculations of Cogley (2009a). These calculations draw on information from distant glaciers, discounted by a distance-decay function, to supplement local records, and place the beginning of accelerating mass loss somewhat earlier than the local measurements. The average rate is -364 ± 55 kg m^{-2} a^{-1} (1 kg m^{-2} = 1 mm water equivalent, w.e.); the more uncertain recent pentads have less weight, so the average is closer to the pentadal estimates before 1990. If the average were sustained, the glaciers would thin by 9 m w.e. between 2010 and 2035. The trend fitted to the estimates from 1985–1986 onward is –24 kg m^{-2} a^{-2}. If this acceleration were sustained, the thinning between 2010 and 2035 would be 28 m w.e.

These estimates are tentative, and oversimplify the complexity of glacier responses to forcing, but they rest on all of the available information. Although many small glaciers have present-day thicknesses of only 10–30 m, they account for little of the total mass and there is no reason for believing that all Himalayan glaciers might disappear by 2035.

Summary

The assertion that Himalayan glaciers might disappear as early as 2035 is unfounded. Although information is scanty, and does not allow accurate assessment of the total mass of ice, measurements of retreat and shrinkage suggest that Himalayan glaciers are evolving at rates comparable with those observed elsewhere. This does not justify complacency. Extrapolation of the limited measurements of mass balance suggests that mass loss from 2010 to 2035 will be of the order of 10–30 m of water-equivalent thickness. The larger of these numbers represents continuation of the recent trend and may be more probable. A more accurate assessment must await a detailed analysis of the response of the glaciers to projected radiative forcing, but such an analysis will be difficult without more, and more continuous, basic observations.

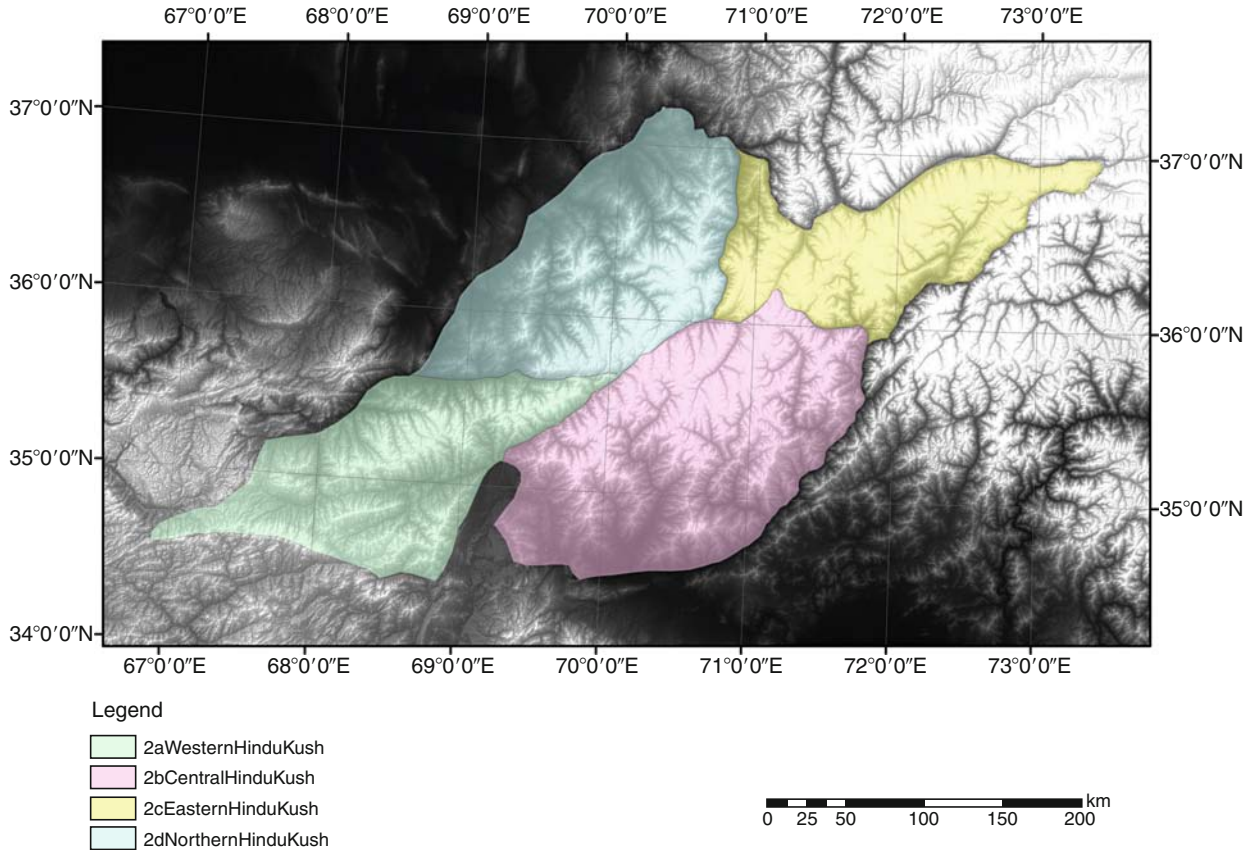
HINDU KUSH

John F. Shroder
Department of Geography and Geology, University of Nebraska at Omaha, Omaha, NE, USA

Introduction

The Hindu Kush is the group of ranges that occur dominantly in Afghanistan and northwestern Pakistan. With the pervasive satellite imagery at all scales now so readily available, it is possible to make new maps of entire



Hindu Kush, Figure 1 The Hindu Kush mountains of Afghanistan and northwestern Pakistan. The mountains to the southeast in Pakistan are the Hindu Raj and the ranges of Kohistan. To the north of the Hindu Kush are the Pamir ranges of Afghanistan and Tajikistan.

complex regions of mountains, to increase understanding of glacier formation and location (Figure 1). Among the complex regions in the mountains of central and south Asia are those that radiate out from the "Pamir Knot," an orographic designation that intrigued many nineteenth and early twentieth century geographers (Burrard and Hayden, 1907). The Hindu Kush ranges constitute the southwest and south parts of this Pamir Knot.

The main glacierized and glaciated mountain chain of Afghanistan is the Hindu Kush, although a number of other smaller ranges are satellite to it, and several others also have glaciers (Afghanistan Pamirs to the north in Badakshan), or have had glaciers in the past (Spin Ghar or Safed Koh to the south; Hesar Range to the west). The Hindu Kush Mountains are dominantly in Afghanistan, although an easternmost extension occurs also in Pakistan that constitutes part of the border along the southern edge of the Wakhan Corridor. A number of different people have subdivided all or parts of the Hindu Kush, but the work of Ervin Grötzbach (1990) is based on his familiarity with the ground, is the best thought out, and the most complete. He divided the Hindu Kush into four basic parts: (1) Western Hindu Kush; (2) Middle or Central Hindu Kush; (3) Eastern Hindu Kush; and (4) the Khwaja Mohammed Mountains, which can be considered as a northern Hindu Kush (Figure 1).

Western Hindu Kush

This region occurs to the north and northwest of the Kabul Basin. The border of this mountain area stretches from the Surkhab and Andarab gorges in the north, and the Khawak Pass in the northeast, south over the main peaks into the upper parts of the Panshir Valley of the Anjuman Pass, and east down the Panshir Valley to the north point of the Kabul Basin, thence southwestward along the edge of the Paghman Range and the Kabul Basin, before turning east again up the headwaters of the Kabul River and the Wonay Pass and into the Helmand headwaters.

The westernmost edge of the Hindu Kush has been placed in different places because of the lack of definitive breaks in the topography there. We find it useful to include the Koh-i-Baba Range where occur the few, southwesternmost ice masses remaining in south Asia, but not the Hesar Range on the west edge of the Yakawlang graben valley where also occurs the northwestern-most cirques and

a possible few small stagnant ice masses or semipermanent snowfields remaining after years of drought and melting.

Middle or Central Hindu Kush

This region occurs to the northeast and east of the Kabul Basin, and includes all of the mountains of Nuristan south and east of the Panjshir Valley and over the Anjuman Pass to the Dorah Pass into Pakistan near Chitral, down to the Kunar River Valley, all of which are in the Kabul River drainage basin. The Mir Samir glacierized area near the Panshir Valley (Gilbert et al., 1969) is important to any study because it received some of the first glaciological work ever done in Afghanistan (Shroder and Bishop, 2009).

Eastern Hindu Kush

This mountainous region extends east from its Kokcha River border with the Khawaja Mohammed Range, and east to the Ab-i-Panj river border of the Wakhan Corridor, as well as from the Anjuman to Dora Pass valley route to Chitral, as far as Baroghil Pass along the Afghanistan–Pakistan border in the Wakhan where it terminates. The Eastern Hindu Kush therefore includes all the high peaks along the Afghanistan–Pakistan border, including Noshak (7,492 m), the highest peak in Afghanistan, as well as Tirich Mir (7,706 m) above Chitral in Pakistan. In the west, close to the Kokcha River border with the Khwaja Mohammed Range, occurs the Koh-i-Bandaka area of glaciers that have been mapped and studied recently (Shroder and Bishop, 2010). The Keshnikhan Glacier in Afghanistan a few km NNE of the Noshaq and Tirich Mir peaks was first mapped and studied by an Austrian Expedition of 1970 (Braslau, 1974), and is again the focus of recent attention (Shroder and Bishop, 2009).

Khwaja Mohammed Range

This northernmost of the main Hindu Kush ranges extends northward from the southern boundary along the line of the Andarab–Khwak Pass–Anjuman Pass, between the Kokcha River on the east and the Surkhab–Kunduz River on the west.

North of the Hindu Kush and still inside Afghanistan are the Pamir ranges of Badakshan and the Wakhan Corridor. Outside of Afghanistan to the north in Tajikistan and neighboring states occur many more ranges of the Pamir, as well as the Pamir Knot.

Collectively the diverse sets of Hindu Kush ranges are characterized by ~3,000 small glaciers in Afghanistan that are almost nowhere more than a few kilometers in length. The glaciers of the Hindu Kush are dominantly nourished by winter westerly precipitation, although those in the southeast of Afghanistan can receive some summer snows from monsoonal augmentation from moisture sources in the Indian Ocean. In fact, the largest glaciers of the Hindu Kush actually occur on the south side of the Eastern Hindu Kush of northwest Pakistan where the Tirich Mir (7,690 m) and Noshaq (7,492 m) massifs tower high enough to intercept sufficient monsoonal moisture to produce a very few glaciers up to 24 km in length.

Summary

The Hindu Kush ranges of Afghanistan and the Pakistan border region can be subdivided into a Western, Central, and Eastern Hindu Kush, as well as a Northern or Khwaja Mohammed Range. Collectively the Hindu Kush ranges have many small glaciers that are dominantly only a few km in length. Meltwater from these glaciers constitutes a vital late season supply of critical irrigation that is threatened with climate change in this chronically drought-torn region.

HOLOCENE GLACIER FLUCTUATIONS

Johannes Koch
Department of Earth Sciences, Simon Fraser University, Burnaby, BC, Canada

Definition

Holocene is the most recent geological Epoch spanning the past 10,000–12,000 years.
Glacier fluctuations are advance and retreat phases of individual glaciers due to changes in their mass balance.

Introduction

Glacier extent during the Holocene was limited compared to the Pleistocene, but recent studies point to significant, rapid fluctuations of climate throughout the Holocene (e.g., Mayewski et al., 2004). One proxy of Holocene climate variability that has long been used is alpine glacier fluctuations (e.g., Denton and Karlén, 1973). Most alpine glaciers react rapidly to changes in their mass balance and thus to changes in temperature and precipitation, and studies of past glacier fluctuations allow reconstruction of climate variability on centennial and decadal timescales.

Reconstruction of Holocene glacier fluctuations is compromised by the fact that glacier advances in the Northern Hemisphere during the last millennium were generally the most extensive of the Holocene and obliterated or obscured most of the evidence of previous advances. Older moraines have been identified at few of the sites that have been investigated (e.g., Ryder and Thomson, 1986; Bakke et al., 2005), but dating control of these moraines is often poor. More complete Holocene histories have been inferred from sediments in lakes downvalley of glaciers (e.g., Karlén, 1988; Bakke et al., 2005), but these records can be complicated by nonclimatic factors. The most direct evidence for glacier advances that predate the last millennium is found in areas deglacierized in the twentieth century. Remnants of forests in these forefields include in situ tree stumps and detrital logs and branches. In addition, organic soils and detrital wood are exposed in composite lateral moraines. High-quality data on Holocene glacier fluctuations have been retrieved from many of these forefields and moraines (e.g., Luckman, 2000; Nicolussi and Patzelt 2000; Glasser et al., 2004; Holzhauser et al., 2005; Koch et al., 2007; Barclay et al., 2009).

This entry summarizes Holocene glacier fluctuations in mountainous areas around the world in chronological order. The summary benefits from recent regional reviews (Barclay et al., 2009; Briner et al., 2009; Geirsdóttir et al., 2009; Hall, 2009; Ivy-Ochs et al., 2009; Kelly and Lowell, 2009; Menounos et al., 2009; Nesje, 2009; Owen, 2009; Rodbell et al., 2009). Data presented here cover western North America, the North Atlantic region (Baffin Island, Greenland, Iceland), Europe (Scandinavia, Alps), Asia (Tibet, Himalaya, Tian Shan, Pamir-Alai, Altai, Caucasus, Polar Urals, Yakutia, and Kamtchatka), Africa, South America, New Zealand, and Antarctica. Chronological control for most of these studies was provided by dendrochronology, lichenometry, radiocarbon dating of fossil wood in moraines, cosmogenic surface exposure dating, proglacial lake sediments, tephras, and radiocarbon dating of basal organics in pits, bogs, and lakes that provide minimum limiting ages.

Global Holocene glacier fluctuations

There is evidence for broadly synchronous periods of glacier advance around the world at 8.6–8.1, 7.3–5.9, 5.1–4.2, 4.2–1.9, 1.9–0.9 ka (ka is used here instead of cal. years BP), and during the past millennium. The broad age ranges of the six periods of more extensive glaciation are the result of large uncertainties introduced by calibrating radiocarbon ages. Glacier extent at the end of each of the six periods, however, was much greater than at the beginning of the following advance period. Several areas presented here were still heavily glaciated in the early Holocene as glaciers retreated from their Last Glacial maxima, and there is strong evidence that glaciers might have disappeared completely prior to about 6 ka in some Northern Hemisphere locations.

Early Holocene advances

Evidence for glacier advances prior to the 8.2 ka event is sparse. A few glaciers in western Canada advanced slightly between 9.5 and 8.5 ka (Koch et al., 2007). Alpine glaciers in western Greenland advanced between 9 and 10 ka (Kelly and Lowell, 2009), and glaciers in Norway advanced around 9.7 and 9.2 ka, but this evidence has been questioned by more recent interdisciplinary studies (Nesje, 2009). Nicolussi and Patzelt (2000) report a short-lived advance in the Austrian Alps about 10.1 ka, while data from the central Swiss Alps indicate smaller than present glaciers about 9.7 ka (Hormes et al., 2001). In Tibet glaciers advanced 9.4–8.8 ka, and continental glaciers in northwestern China around 9.3 ka (Owen, 2009). Glaciers in the Southern Hemisphere appear to have been as extensive or more extensive in the early Holocene than during the past millennium with two advances recorded in the Patagonian Precordillera and New Zealand (Röthlisberger, 1986; Gellatly et al., 1988; Wenzens, 1999).

The 8.2 ka event

Evidence for this event is also sparse. Detrital wood along with an increase in clastic sediment in proglacial lakes in the Coast Mountains indicate a minor advance coeval with this event (Menounos et al., 2009). Alpine glaciers on Baffin Island advanced (Briner et al., 2009), and glacier expansion in Scandinavia was widespread (Nesje, 2009), with some glaciers likely more extensive at this time than during the past millennium. Brief advances of limited extent occurred in Austria (Nicolussi and Patzelt, 2000), but Hormes et al. (2001), argue for less extensive glaciers in the central Swiss Alps. Glaciers advanced in the Himalaya and Karakoram (Owen, 2009), as well as in Kamtchatka (Yamagata et al., 2002). Moraines well beyond the past millennium extent were deposited in the Patagonian Precordillera (Wenzens, 1999) and near the Northern Patagonian Icefield (Rodbell et al., 2009).

7.3–5.9 ka events

Evidence for these events is widespread in both hemispheres. Glaciers in the Coast and Rocky Mountains in western Canada advanced during this time (Menounos et al., 2009), and the data indicates that glaciers advanced two or three times and reached positions within 1 km of their Holocene maximum extent (Koch et al., 2007). Hubbard Glacier in coastal Alaska advanced and remained extensive for the next millennium (Barclay et al., 2009). Glaciers in the Brooks and Alaska Ranges advanced, and some may have attained greater extents than at later times (Calkin, 1988). Evidence from the European Alps also indicates three advances (Nicolussi and Patzelt, 2000), with less extensive glaciers than today between advances (Hormes et al., 2001). Glaciers in western Greenland and Scandinavia underwent two minor advances (Karlén, 1988; Kelly and Lowell, 2009; Nesje, 2009), while

glaciers in Iceland, on Baffin Island, in Kamtchatka, in continental northwestern China, and on Mount Kenya advanced once (Karlén et al., 1999; Savoskul, 1999; Briner et al., 2009; Geirsdóttir et al., 2009; Owen, 2009). Evidence for two advances comes from the central and the southern Andes (Rodbell et al., 2009), the Northern Patagonian Icefield (Rodbell et al., 2009), the Patagonian Precordillera (Wenzens, 1999), and the central Andes near Mendoza (Espizua, 2002), where moraines were deposited well beyond the past millennium moraines. Glaciers on the Antarctic Peninsula and South Atlantic islands fluctuated (Hall, 2009), and in New Zealand moraines were deposited (Schaefer et al., 2009).

5.1–4.2 ka events

Evidence for one or more advances during this time is widespread in both hemispheres. Glaciers in the Coast and Rocky Mountains in western Canada advanced twice (Menounos et al., 2009). Similarly, glaciers in Alaska appear to have advanced one or two times (Calkin, 1988; Barclay et al., 2009), and there is evidence for an advance in the Cascades (Davis, 1988). Moraines were deposited in Iceland (Geirsdóttir et al., 2009), and glaciers in Scandinavia expanded in some cases to positions outside maximum past millennium limits (Karlén, 1988; Nesje, 2009), while in northern Folgefonna glaciers reformed (Bakke et al., 2005). Glaciers in Austria advanced twice (Nicolussi and Patzelt, 2000), while glaciers in the central Swiss Alps appear to have been less extensive than today (Hormes et al., 2001). Glacier advances are recorded in the Himalaya and Karakoram, in northwestern China, in the former USSR, and on Mount Kenya (Serebryanny and Solomina, 1996; Karlén et al., 1999; Owen, 2009). Glaciers in the tropical and Patagonian Andes advanced (Glasser et al., 2004; Rodbell et al., 2009), and some deposited moraines well outside their past millennium margins (Wenzens, 1999). Evidence from New Zealand also indicates two advances during this time (Gellatly et al., 1988), while evidence in Antarctica is poorly constrained (Hall, 2009).

4.2–1.9 ka events

Glacier advances during this time have been identified in both hemispheres. Many glaciers in Canada achieved extents only slightly smaller than during the past millennium, with evidence that some were even more extensive (Ryder and Thomson, 1986). Multiple advances, up to three, are evident in the Canadian Rockies and Coast Mountains (e.g., Koch et al., 2007). Three advances deposited nearly synchronous moraines in the Brooks and the Alaska ranges (Calkin, 1988). Many glaciers in coastal Alaska as well as the Wrangell Mountains also expanded at this time, but the advances were less extensive than those of the past millennium (Barclay et al., 2009). Moraines were deposited in Iceland by two advances (Geirsdóttir et al., 2009), up to three advances are recorded on Baffin Island (Briner et al., 2009), and there is some evidence for glacier advances in Greenland (Kelly and Lowell, 2009). Multiple advances, up to five, occurred in the European Alps (Nicolussi and Patzelt, 2000; Holzhauser et al., 2005), with glaciers being possibly less extensive than today between some of these advances (Hormes et al., 2001). Glaciers in Scandinavia expanded several times, in some cases to limits beyond those of the past millennium (Karlén, 1988; Bakke et al., 2005; Nesje, 2009). Glaciers advanced several times in the Himalaya and Karakoram, in Tibet, in the former USSR, and on Mount Kenya (Serebryanny and Solomina, 1996; Karlén et al., 1999; Owen, 2009). Glaciers in the tropical Andes advanced once, and possibly twice in the Patagonian Andes, the Patagonian Precordillera, the Cordillera Darwin on Tierra del Fuego, and the south-central Andes (Wenzens, 1999; Espizua, 2002; Glasser et al., 2004; Rodbell et al., 2009). Glaciers in South America were generally more extensive at this time than during the past millennium (Espizua, 2002; Glasser et al., 2004). Three separate advances that deposited moraines have been identified in New Zealand (Gellatly et al., 1988; Schaefer et al., 2009), and glaciers in Antarctica advanced (Hall, 2009).

1.9–0.9 ka events

Glacier advances during this time have been identified in both hemispheres, and numerous sites show evidence for multiple phases. Evidence for this event is widespread in western Canada (Menounos et al., 2009), but glacier extent generally appears to have been smaller than during the previous and following events. In the Brooks and Alaska Ranges moraines indicate up to three advances (Calkin, 1988), and glaciers in maritime Alaska show a peak of activity around AD 600–650 (Barclay et al., 2009). Some glaciers on Baffin Island, in Greenland, and in Iceland advanced in the first millennium AD (Briner et al., 2009; Geirsdóttir et al., 2009; Kelly and Lowell, 2009). Ice cover in Scandinavia expanded twice (Karlén, 1988; Bakke et al., 2005; Nesje, 2009), and some glaciers were more extensive then than during the past millennium (Karlén, 1988; Nesje, 2009). Up to three advances are well documented in the European Alps, each separated by significant recession (Nicolussi and Patzelt, 2000; Hormes et al., 2001; Holzhauser et al., 2005). Maritime-influenced glaciers in southeastern Tibet advanced once, while glaciers in the Himalaya and Karakoram advanced twice (Owen, 2009). Glaciers also advanced in the former USSR and on Mount Kenya (Serebryanny and Solomina, 1996; Karlén et al., 1999). Glaciers in the tropical and Patagonian Andes advanced (Glasser et al., 2004; Rodbell et al., 2009), and moraines were deposited in the Patagonian Precordillera (Wenzens, 1999) and the tropical Cordillera Blanca (Rodbell et al., 2009). On the Antarctic Peninsula and on South Atlantic islands glaciers advanced (Hall, 2009), and moraines in New Zealand provide evidence for three separate advances (Gellatly et al., 1988; Winkler, 2004).

0.9–0.1 ka events

Evidence for these events is ubiquitous in both hemispheres, and the period is generally referred to as the Little Ice Age (Grove, 1988). Abundant evidence for several advances has been reported from numerous glaciers in Canada, and most reached their maximum Holocene extent during this interval. The Little Ice Age here began about AD 1050 and lasted until the early twentieth century (Luckman, 2000; Menounos et al., 2009). Evidence suggests that glaciers fluctuated significantly throughout this time period, but generally were more extensive than they were in the late twentieth century. Similarly, the Little Ice Age in Alaska began as early as AD 1100 (Barclay et al., 2009) and continued until the late nineteenth century (Calkin, 1988; Barclay et al., 2009). Most glaciers in Alaska achieved their maximum Holocene extent during the Little Ice Age. In the Cascade Range, Olympic Mountains, and Montana Rocky Mountains early advances occurred before the thirteenth century and continued until the early twentieth century (Davis, 1988). Glacier advances on Baffin Island, in Greenland, and in Iceland are generally the most extensive since late-glacial time (Briner et al., 2009; Geirsdóttir et al., 2009; Kelly and Lowell, 2009), but moraines deposited at Langjökull ice field in Iceland indicate smaller extents than during earlier advances (Geirsdóttir et al., 2009). Little Ice Age fluctuations of glaciers in the European Alps have been reconstructed in detail back to AD 1100, and indicate several distinct advances, which were the most extensive in the Holocene (Nicolussi and Patzelt, 2000; Holzhauser et al., 2005). Historical records for many glaciers date back to the mid-seventeenth century (Nicolussi and Patzelt, 2000; Holzhauser et al., 2005). The Little Ice Age in Scandinavia began about AD 1080, and lasted until the early twentieth century, with most Scandinavian glaciers attaining their maximum Holocene extent (Karlén, 1988; Bakke et al., 2005; Nesje, 2009). Glaciers in the former USSR and in Tibet and surrounding areas provide evidence for Little Ice Age advances, but those advances were generally less extensive than earlier advances (Serebryanny and Solomina, 1996; Owen, 2009). Glaciers in the tropical Andes advanced as early as the twelfth century, and moraines were formed between AD 1600 and 1900 (Rodbell et al., 2009), while on Mount Kenya advances occurred between AD 1400 and 1600 (Karlén et al., 1999). Moraine-building advances in Patagonia occurred as early as the mid-thirteenth century, but generally the Little Ice Age culminated sometime in the seventeenth century (Koch and Kilian, 2005). In New Zealand advances started around AD 1150, and lasted until the early twentieth century (Gellatly et al., 1988; Schaefer et al., 2009), and glacier expansion in Antarctica is evident at all sites (Hall, 2009).

Twentieth century

Glacier fluctuations during the twentieth century have been documented from photographic and historical evidence, and detailed reconstructions are available for many glaciers. Most glaciers throughout the world receded during the twentieth century, but some tidewater and surging glaciers in Alaska and Patagonia are at or near their Holocene maxima, while some glaciers in Scandinavia and New Zealand advanced late in the twentieth century. Most records show slow recession between 1900 and about 1910, followed by stillstands and minor readvances in the second and third decades of the century. Recession was most rapid between about 1930 and the 1950s, followed by another period of stillstands and minor readvances in the 1950s, 1960s, and 1970s. Most glaciers have receded rapidly since the mid-1980s.

Conclusions

Holocene glacier advances in both hemispheres are broadly synchronous at timescales of centuries and occurred during six periods: 8.6–8.1, 7.3–5.9, 5.1–4.2, 4.2–1.9, 1.9–0.9 ka, and the last millennium. Recent studies provide evidence that most of these events were marked by glacier behavior as complex as that of the past millennium. Synchronicity implies that one or more mechanisms have operated on a global scale to force Holocene glacier fluctuations. Early Holocene glacier advances in the Southern Hemisphere were generally more extensive than late Holocene advances, but dates are minimum ages and dating control is often not well constrained. In contrast, early Holocene advances in the Northern Hemisphere were generally less extensive than those of the late Holocene, with the latter, however, often wiping out evidence of previous events. A more complete and complex picture of glacier behavior since the Last Glacial Maximum in many places has only surfaced in the past decade and one can expect further advances on timing and extent of events around the globe due to new techniques.

HORIZONTAL COMPONENT OF ABLATION

Rijan B. Kayastha
Himalayan Cryosphere, Climate and Disaster Research Center (HiCCDRC), Kathmandu University, Dhulikhel, Kavre, Nepal

Horizontal component of ablation is the ablation which removes ice from a glacier margins. This is the main component which determines advance or retreat of glaciers.

Glacier terminus retreat will occur when the horizontal component of ablation is greater than the horizontal component of velocity of the glacier. Glacier margin will remain in the same position when the horizontal component of ablation equals the horizontal component of velocity, that is, when

$$U_{tx} = a_b/\tan\alpha$$

where U_{tx} is the horizontal component of velocity, a_b is the ablation rate, α is the glacier surface slope, and $(a_b/\tan\alpha)$ is the horizontal component of ablation (Boulton, 1986). Although the terminus position is stationary in this case, the ice itself is in motion but is removed from the leading edge at a rate equal to the velocity.

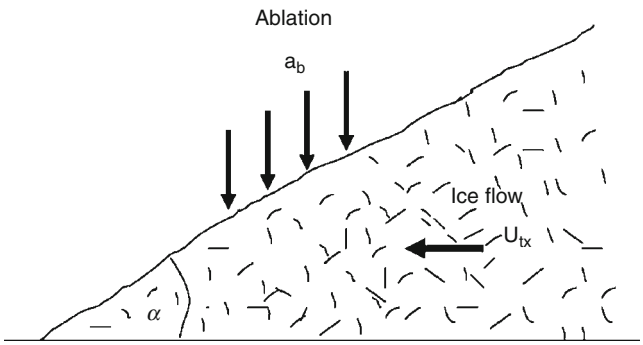
HORIZONTAL COMPONENT OF VELOCITY

Rijan B. Kayastha
Himalayan Cryosphere, Climate and Disaster Research Center (HiCCDRC), Kathmandu University, Dhulikhel, Kavre, Nepal

Horizontal component of velocity represents the rate of movement of glacier horizontally. This component of velocity varies widely depending upon on the amount of surface melt water available and its pressure at the interface between ice and bed rock. The water pressure increases the sliding velocity of glacier. Mathematically, the horizontal component of velocity U_{tx} can be written as:

$$U_{tx} = a_b/\tan\alpha$$



Horizontal Component of Velocity, Figure 1 Schematic diagram showing the influence if velocity, ablation rate and ice surface on glacier retreat and advance.

where a_b is the ablation rate, α is the glacier surface slope, and $(a_b/\tan\alpha)$ is the horizontal component of ablation (Boulton, 1986). The relation will be valid when the glacier margin remains in the same position (Figure 1). Iken and Bindschadler (1986) measured both horizontal velocity and subglacial water pressure on Findelegletscher and found the high horizontal velocity at high water pressure.

HUMMOCKS (PEAT)

Subhajit Sinha
DBS College, Dehradun, Uttarakhand, India

Hummocks, small earth or peat mounds, are widely distributed in the arctic and develop as a consequence of biomass accumulation and cryoturbation in the active layer and in general the boreal peatlands is frequently hummocky. The hummocks and hollows develop from the peat and remain stable over long periods of time, even while climate and other environmental conditions change. The processes leading to the formation of these hummocks are not clearly understood. However, many types of simulation have generated satisfactory results of their formation. Recent studies have brought up a general consensus that the type of vegetation covering peat hummocks may alter the accumulation rate of organic material and thus hummock growth and local carbon sink dynamics.

HYDROCHEMICAL CHARACTERISTICS OF SNOW, ICE, AND GLACIERS

Jacob Clement Yde
Center for Geomicrobiology, University of Aarhus, Århus C, Denmark
Bjerknes Centre for Climate Research, University of Bergen, Bergen, Norway

Introduction

Studies on hydrochemical characteristics of snow, ice, and glaciers have traditionally been motivated by an interest in the role of chemical weathering in the regulation of atmospheric CO_2 on long time scales (>10,000 years) (Meltwater Quality as an Indicator of Subglacial

Processes). For instance, tectonic uplift has been suggested as a principal mechanism for increasing silicate weathering and thus enhancing atmospheric CO_2 drawdown and thereby causing global cooling (Raymo et al., 1988; Raymo and Ruddiman, 1992), but this theory remains controversial (Blum and Erel, 1995; Blum et al., 1998; Kump et al., 2000). Also, the shifting glacial–interglacial climate throughout the Quaternary has caused changes in the silicate weathering rate, but model results are still inconclusive (Gibbs and Kump, 1994, 1996; Kump and Alley, 1994; Tranter, 1996; Jones et al., 1999; Ludwig et al., 1999; Foster and Vance, 2006; Vance et al., 2009).

Mineral dissolution is strongly dependent on temperature, which theoretically will be reflected in the chemical composition of natural cold waters such as snowmelt, icemelt, and bulk meltwater emanating from glaciers (Chemical Composition of Snow, Ice, and Glaciers). However, in the field the temperature signal related to chemical erosion is often obscured by other factors related to climate (e.g., precipitation, runoff, continentality), lithology, tectonics (e.g., mechanical weathering, sediment transport, bedrock exposure and age), biomass effects, and anthropogenic effects (e.g., pollution, emission of greenhouse gasses, urbanization, land use, infrastructural effects). In glacial waters, the primary control is considered to be runoff, whereas lithology is a significant secondary control (Anderson et al., 1997; Hodson et al., 2000). Extensive reviews on hydrochemical characteristics of snow, ice, and glaciers can be found in Tranter (1991, 2003, 2006), Tranter and Jones (2001), and Brown (2002).

Meltwater characteristics

The primary characteristic of meltwater quality is that it generally is very dilute compared to other pathways in the hydrochemical cycle. In glacierized catchments, an inverse correlation exists between runoff and concentration so that low discharge waters are concentrated and high discharge waters are dilute (Tranter, 2006). This is reflected in solute concentration variations on diurnal and seasonal scales due to fluctuations in the intensity of ablation and retention time (Chemical Composition of Snow, Ice, and Glaciers and Solute in Glacial Meltwaters). For instance, preferential leaching of ions from snowpacks may cause large fluctuations in ion concentrations and ion ratios (e.g., Johannesen and Henriksen, 1978; Goto-Azuma et al., 1993; Raben and Theakstone, 1998). As a consequence of the low solute content of meltwater, concentration-derived parameters such as electric conductivity and ion strength are relatively low as well.

Another characteristic feature of glacial meltwater is the high suspended sediment concentration (Suspended Sediment Dynamics and Suspended Sediment Load) due to subglacial mechanical weathering (Mechanical Weathering, Physical Weathering, Subglacial Weathering, and Meltwater Quality as an Indicator of Subglacial Processes). Chemical weathering of the suspended sediments continue all the way from-source-to-sink and even after deposition. Therefore, the total glacier-derived solute yield is not only restricted to the solute flux from glacierized catchments (i.e., based on measurements at a station near a glacier portal), but is a result of biogeochemical processes all along water and airborne sediment transport trajectories to the suspended sediment sinks (Anderson, 2007).

Elemental ratios

The chemical composition of meltwater is closely related to solute provenance and governing controls. Therefore, the application of chemical mass balance budgets has become the standard approach in discriminating solute provenances in bulk meltwater (Sharp et al., 1995; Hodgkins et al., 1997; Hodson et al., 2000, 2002; Krawczyk et al., 2003; Yde et al., 2005, 2008, Krawczyk and Bartoszewski, 2008). Solute sources include sea-salts, acid aerosols, atmospheric sequestration, crustal denudation, organic sources, geothermal emission, and anthropogenic pollution.

While solute fluxes are important in studies on solute yield to the oceans and elemental cycles, they are not very useful in water quality and chemical weathering studies. Hence, elemental ratios are used as they are more conservative than absolute concentrations and permit comparisons between streams with high and low runoff (Négrel et al., 1993; Gaillardet et al., 1999). The molar K/Na, Ca/Si, and HCO_3/SO_4 ratio distributions in glacial waters have been reported to deviate from non-glacial waters and are therefore considered as distinctive hydrochemical characteristics of glacial waters. The K/Na ratio is suggested to be distinctly higher than in non-glacial runoff due to preferential weathering of K-mica minerals, resulting in high K concentrations (Anderson et al., 1996, 1997). The Ca/Si ratio is postulated to be higher in glacial waters due to preferential weathering of carbonates and slow weathering of silicates (Tranter, 2006), whereas the HCO_3/SO_4 ratio is proposed to be lower due to preferential weathering of sulfides (Tranter, 2006).

While elemental ratios allow comparisons between catchments with different runoff, they do not compensate for temperature effects due to cold waters. Also, coastal regions receive more marine-derived Na deposition than more continental regions such as the Alps and the Himalayas, affecting the K/Na ratio. Reference to global river chemistry may also be compromised by significantly anthropogenic pollution such as urban sewerage and salinization, and industrial and agricultural effluxes in non-glacial waters (Meybeck, 2005), and natural factors such as the global distribution of evaporites, which causes a strong bias because only a few glacierized regions are located on evaporitic outcrops, whereas on a global scale halite weathering delivers about 55% of the crustal-derived Na in rivers (Meybeck, 1987).

Summary

Despite many years of research, our understanding of hydrochemical characteristics of snow, ice, and glaciers and their controls remain unclear. The present impact on solute fluxes from glacial water on global geochemical cycles is limited, but this may have been different during periods of intense deglaciation such as during the Late Pleistocene. It must be recognized that we will always have very limited knowledge on the temporal and spatial variations in the hydrochemistry of snow, ice, and glaciers. The low number of sampling sites in glacierized regions may cause biased elemental ratios as they may not be representative as global average values. Also, the sampling frequency is often restricted to a short period during the ablation season or monthly sampling. Nevertheless, future hydrochemical modeling should change the scale from catchment to a regional or global perspective using careful extrapolations in order to provide more holistic views on the role of meltwater in the hydrochemical cycle (Anderson, 2007). Studies on minor and trace ion concentrations (Mitchell et al., 2001, 2006; Mitchell and Brown, 2007) and combining ion ratios with isotopic ratios (Isotopic Characteristics of Ice, Snow, and Glaciers) will provide new insights into the dominant control mechanisms of meltwater characteristics. Recent studies have focused on ecological aspects of nutrient characteristics in snow, ice, and glaciers (e.g., Hodson et al., 2005, 2008). It has been hypothesized that microbial processes significantly contribute to annual solute fluxes from glaciers (Skidmore et al., 2005), but it remains to be demonstrated (Chemical and Microbial Records in Snow and Ice, Glacial Ecosystems, and Microorganisms Associated with Glaciers).

Definition

Hydrogen is the first element of the periodic table. It has three isotopes, two stable, that is, ^{1}H (protium) and ^{2}H (deuterium), and one radioactive ^{3}H (tritium). It is a very important component of atmosphere as it is present in water. The combinations of water like $^{1}H^{1}H^{16}O$, $^{1}H^{2}H^{16}O$ or $^{1}HD^{16}O$, $^{1}HD^{18}O$, $^{1}H^{1}H^{17}O$, and $^{1}HD^{17}O$ are considered important. Tritium (^{3}H) has very low abundance (around one part in 10^{18} parts of total hydrogen). It is a radioactive isotope of hydrogen with a half-life of 12.32 years. The natural occurrence of few very important types of water molecules is given below:

$H_2{}^{16}O \sim 997{,}640$ ppm (99.7640%)
$H_2{}^{18}O \sim 2{,}040$ ppm (0.204%)
$HD^{16}O \sim 320$ ppm (0.032%)

Origin

Hydrogen and deuterium occur naturally, while the tritium can be cosmogenic, lithogenic, or anthropogenic. Natural production of tritium in the atmosphere is very low. Due to the advent of thermonuclear technology, this production in the atmosphere has been supplemented by anthropogenic production. All atmospheric tritium, whether cosmogenic or anthropogenic, is rapidly incorporated into water molecules and falls in meteoric precipitation to enter the hydrologic cycle.

Uses

The $\delta^{2}H$ or $\delta^{18}O$ values offer the possibility for detecting the accumulation rates in an ice core of past periods and separation of runoff components. Climate change causes a shift of the ^{2}H or ^{18}O contents in precipitation, which can be preserved in old polar ice. Thus, it can be used to study the paleoclimates (Payne, 1983). Tritium is mainly used for dating the age of recent groundwater recharge. High levels of tritium (>∼30 TU) indicate water that was recharged during the late 1950s or early 1960s; moderate concentrations indicate modern recharge; levels close to detection (∼1 TU) are likely submodern or paleogroundwaters that have mixed with shallow modern groundwaters (Clark and Fritz, 1997).

HYDROGRAPHS

Ian C. Willis
Department of Geography, Scott Polar Research Institute, University of Cambridge, Cambridge, UK

Definition

Hydrograph. A chart or graph showing changes in water quantity in a stream or river over time (Singh and Singh, 2001). Water quantity may be in units of stage (height above some datum), velocity, or Discharge. The time interval may be minutes, hours, days, months, years, or decades. Typically a hydrograph is depicted as discharge measured in cubic meters per second ($m^3\ s^{-1}$) sometimes abbreviated to cumecs.

Introduction

In snow and ice covered catchments, scientists and water resources managers are particularly interested in *diurnal hydrographs* (the change in discharge over a 24 h period, which typically increases during the day and decreases at night in response to diurnal variations in solar radiation and air temperature) (Diurnal Cycle of Runoff), *storm hydrographs* (the change in water quantity associated with a precipitation event), *flood hydrographs* (which may be associated with particularly high snow and ice melt or rainfall, but may also be due to the sudden release of water stored in the catchment) (Peak Flood Glacier Discharge), and *seasonal* or *annual hydrographs* (the variation in water quantity over a season, typically the "melt season" of late spring, summer, and early autumn, or a whole year).

The shape of a catchment hydrograph is a function of the patterns of water inputs to the catchment (from snow or ice melt or rainfall) (Melting of Snow/Ice and Meteorological Conditions) and the nature of the flow pathways (Catchment Routing) as the water travels through it (which will be affected by patterns of vegetation, soil type, extent of snow and ice cover, geology, and the overall size, shape, and altitude distribution – Hypsometry – of the catchment).

Diurnal, storm and flood hydrographs posses several characteristics, notably a *peak* (the highest point on the hydrograph when there is the greatest amount of water), the *rising limb* (the part of the hydrograph up to the peak), and a *falling limb* (the part after the peak). Under certain conditions, diurnal, storm, and flood hydrographs may possess *multiple peaks*. These could arise in a simple catchment where there are multiple water sources (e.g., a rainstorm following peak radiation-driven melt rates) or in a complex catchment where there are multiple water pathways (e.g., one containing both impermeable and permeable bedrock). Another important hydrograph characteristic is its *lag time*, the length of time between peak rainfall or peak melt rate and peak discharge.

Seasonal hydrographs

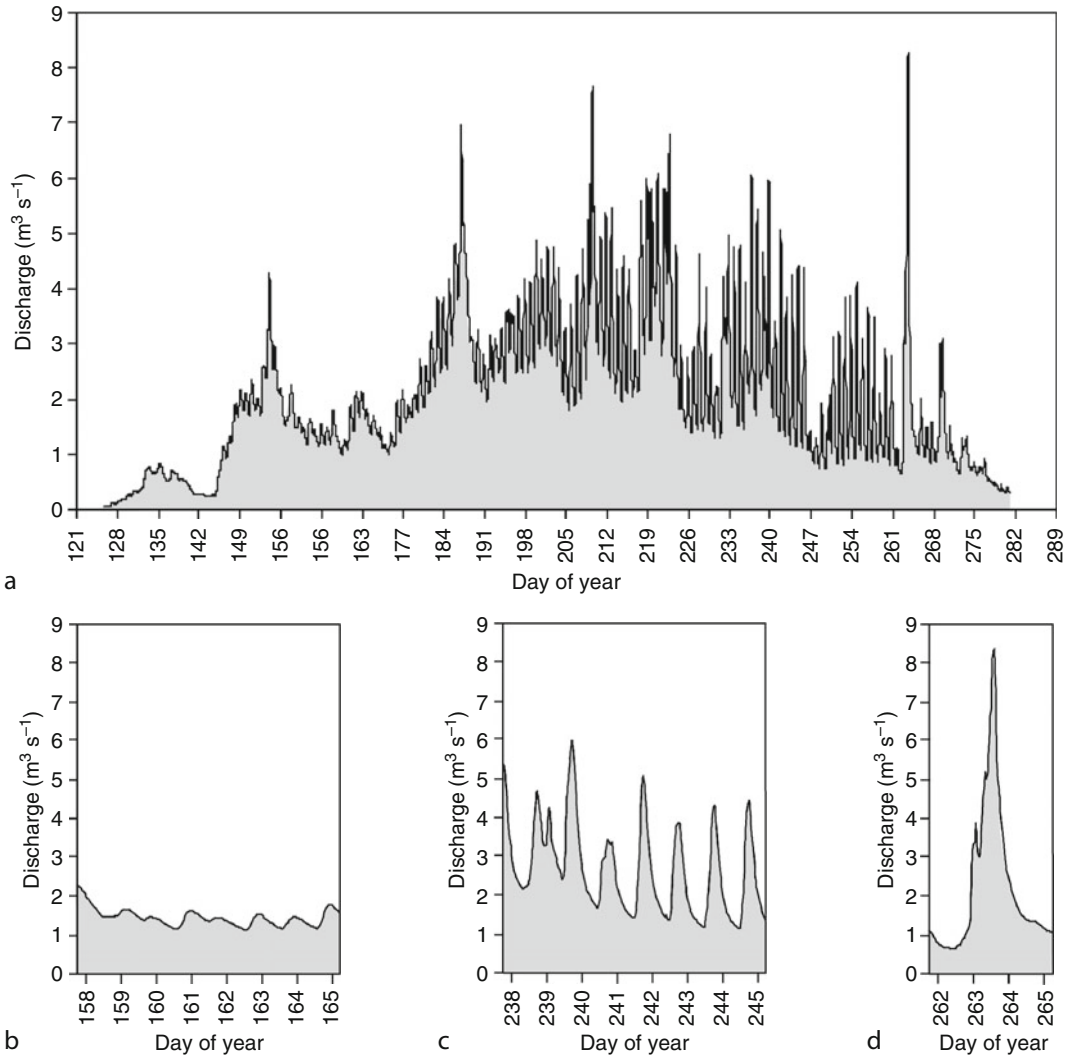
Figure 1a shows a typical seasonal hydrograph from a snow and ice covered catchment in Switzerland. Discharge is negligible during the winter and starts to increase in spring in response to greater radiation receipts and air temperatures causing snow melt (Melting Processes), especially in the lower part of the catchment (DeWalle and Rango, 2008; Jordan et al., 2008). Discharge increases during the summer as radiation receipts and air temperatures rise. It also increases due to the overall decrease in catchment Albedo as the snow melts exposing the underlying ground (thereby increasing air temperatures further) and underlying glacier ice (thereby increasing net shortwave radiation fluxes). It is for these reasons that seasonal discharges typically peak in late summer, several weeks after the summer solstice and maximum radiation receipts.

Diurnal hydrographs

Another key aspect of the snow/ice covered catchment hydrograph is the changing shape and lag times of the *diurnal hydrographs* during the season (Figure 1). They gradually evolve from low amplitude, fairly symmetrical hydrographs peaking many hours after solar noon (Figure 1b) to more peaky, high amplitude hydrographs with maximum values shortly after solar noon (Figure 1c). These changes reflect not only the changing sources of water in the catchment but also its routing. In spring, the dominant source is snow melt across the lower catchment, which is routed relatively slowly to the outlet as it moves vertically through the snowpack (Meltwater Percolation) and laterally across sediment and rock surfaces and as groundwater flow (Base Flow/Groundwater Flow). In late spring/early summer, snowmelt on the glacier is also retarded as it moves through firn. Snow/ice melt on the glacier is delayed as it moves across ice, and within constricted englacial (Englacial Conduit) and subglacial (Subglacial Drainage System) pathways, which have typically shrunk during the winter in response to Formation and Deformation of Basal Ice. By late summer, the dominant water source is glacier ice melt, which is routed quickly across the glacier surface to the edge and in ice marginal streams, or through large englacial and subglacial passageways that have enlarged in response to melting by the flowing water.

Storm hydrographs

Storm hydrographs are common in snow and ice covered catchments in the summer in response to frontal or convective rainfall, and are especially common in areas affected by monsoon rains. Figure 1d shows a storm rain-generated hydrograph, which disrupts the normal diurnal melt-generated hydrograph producing a bigger peak and longer duration hydrograph than usual. In the catchment of the Dokriani Glacier, Garhwal Himalaya (Himalaya), the ability of Summer Monsoon storms to affect diurnal and daily hydrographs depends on the



Hydrographs, Figure 1 (**a**) Hydrographs for the catchment of Haut Glacier d'Arolla, Switzerland. (**a**) Melt seasonal hydrograph from early May to mid-October 1999; diurnal hydrographs for (**b**) 7–14 May, and (**c**) 26 August–2 September; (**d**) storm hydrograph for 19–22 September. Note the multiple peaks on 27 August (Day 239); the first peak is the diurnal melt peak and the second is due to a rainstorm. Data kindly provided by Grande Dixence S.A.

season, intensity, duration, and distribution characteristics of the storm (Thayyen et al., 2005). Monsoon storms typically affect diurnal stream hydrographs early in the summer when the contribution from snow and ice melt is low, but later in the summer comparable rainstorms often have little or no influence as the higher discharges from snow/ice melt mask the effects. Rainstorms with intensities >30 mm day^{-1} always affect daily hydrographs. Those with intensities between 20 and 30 mm day^{-1} sometimes influence daily hydrographs depending on their duration and the time of year; those between June and August are more likely to affect daily hydrographs, whereas those in May or October are not, due to the influence of snow cover or reduced area experiencing liquid precipitation at these times. Intensities from 10 to 20 mm day^{-1} typically have negligible effect on diurnal hydrographs as the associated radiation and air temperature reduction lowers the melt contribution, compensating for the extra rain contribution. Intensities $<$10 mm day^{-1} typically reduce the daily discharge hydrograph due to the associated melt reduction.

Flood hydrographs

Flood hydrographs may be synonymous with storm hydrographs but may also be caused by the sudden release of water from ice marginal, supraglacial, or subglacial locations in what are often referred to as Glacier Lake Outburst Floods (GLOFs) or by their Icelandic name, jökulhlaups (Tweed and Russell, 1999). Ice marginal floods may be generated from moraine dammed lakes

where either the moraine dam fails or is overtopped, precipitating rapid incision and lake drainage. Similarly, floods may be released from ice dammed supraglacial or ice marginal lakes where either the Ice Dams is eventually overtopped leading to incision, or the lake level floats the adjacent ice and escapes underneath. Hydrographs from such floods are rarely recorded but some have been reconstructed from eyewitness accounts and empirical hydraulic formulae. For example, in 1985 a moraine-dammed lake in the Khumbu area of east Nepal was breached following a large ice avalanche into the lake (Vuichard and Zimmermann, 1987). The resulting flood caused massive destruction to infrastructure and valuable arable land over a distance of ~40 km downstream. The reconstructed flood hydrograph was asymmetrical with a steep rising limb and gentle falling limb, a peak discharge of ~1,500 $m^3 s^{-1}$, and a duration of ~5 h. The magnitude and frequency of such ice marginal floods may be expected to rise as glaciers continue to retreat rapidly from their Little Ice Age moraines (Haeberli and Beniston, 1998; Richardson and Reynolds, 2000). Subglacial floods occur when water builds up in a lake beneath an ice mass and eventually reaches a critical depth, allowing it to start escaping. Initially the escape route is small and hydraulically inefficient, but once water starts to flow, the frictional heat is able to melt an increasingly bigger and more hydraulically efficient drainage pathway allowing more and more water to drain. Consequently, the flood hydrographs typically possess a rising limb that gets progressively steeper up to the peak, reflecting the progressive enlargement of the drainage pathway, followed by a very steep falling limb as the water supply ceases or the drainage pathway closes due to the reduced water pressure. The best-documented subglacial floods are from Iceland Glaciers due to high geothermal heat fluxes and Subglacial Volcanism, especially those from the Grímsvötn caldera beneath Vatnajökull, which recur with a periodicity of around 5 years (Björnsson, 2003).

Floods are recognized as being an important feature of ice sheets, as well as many glaciers and ice caps. Flood hydrographs of surface lakes draining via hydrofracture into the Greenland Ice Sheet have been reconstructed from the monitoring of surface lake levels. These suggest that floods lasting a few hours with peak discharges of the order of 10^3–10^4 $m^3 s^{-1}$ (greater than the average flow rate of Niagara falls) may not be uncommon (Das et al., 2008). GPS monitoring of ice surface speed and elevation changes during the floods suggest the water is soon dissipated as it flows beneath the ice sheet to the margin. Subglacial floods have also been inferred from repeat satellite altimetry measurements of the Antarctic ice sheet, which show the rapid movement of water between Subglacial Lakes, Antarctic (Wingham et al., 2006; Fricker et al., 2007). Flood hydrographs have been constructed from the application of physics-based models fitted to the available data and suggest a progressively steepening rising limb lasting for several years reaching peaks of the order 10^2–10^3 $m^3 s^{-1}$ (Carter et al., 2009; Peters et al., 2009).

Climate and hydrograph analysis

Since hydrographs change their characteristics in response to changes in catchment processes, hydrographs and meteorological data from snow and ice covered catchments can be analyzed through time in an attempt to infer changing patterns of water sources and water routing. A variety of time domain statistical techniques (e.g., regression, cross-correlation, autoregressive integrated moving average, and transfer function-noise models) have been applied to climatic and hydrological time series from snow and ice covered catchments. These have been used to infer changing catchment processes through time, for example, switch from snowmelt to ice melt dominated; evolution from slow attenuated water transfer through a thick largely unsaturated snowpack to more rapid transfer through a thinner, more saturated snowpack; and change from moderately slow transfer through a distributed subglacial drainage system to rapid transfer through a channelized, hydraulically efficient subglacial drainage system (Gurnell et al., 1992; Hannah et al., 2000; Hodgkins, 2001). A problem with these time domain techniques is that the 24 h discharge cycle is not static, and the temperature–runoff relationships are highly dynamic. Several steps of data preparation are required prior to analysis and the time series need to be subdivided into periods of similar behavior before seasonal changes in the hydrograph characteristics can be evaluated. For these reasons, continuous spectral (Fourier Transform) analysis has also been used to investigate the meteorological – runoff relationships in nival and glacial catchments. For example, continuous wavelet analyses of hourly time series of air temperature, precipitation, and stream discharge were used to examine how seasonal and inter-annual variations in water sources and flow routing differed between the two main catchments upstream of Bow Lake, Alberta: the glacial stream draining the Wapta Icefields, and the snowmelt-fed Bow River (Lafrenière and Sharp, 2003). Several characteristics were identified, including: (i) rainfall had a bigger influence on stream hydrographs and followed quicker flow paths in the nival catchment than in the glacial catchment; (ii) snowpack thickness and catchment size were the primary controls on the phase relationship between diurnal temperature variations and diurnal hydrographs; and (iii) the diurnal glacial hydrograph signal was orders of magnitude higher in 1998 than in other years, suggesting that the 1997–1998 El Niño caused lower winter snowfall, greater summer ice exposure, and therefore the development of channelized hydraulically efficient glacial drainage.

Hydrograph separation

In addition to the analysis of climate and runoff hydrographs, several studies have attempted to separate a bulk hydrograph from a catchment into two (or more) component parts on the basis of stream chemical (Solute in Glacial Meltwaters) or isotope characteristics. Such "mixing models" make several assumptions. The first is that

there are two (or more) distinct flow pathways within a catchment, such as a "quick flow" and a "delayed flow" pathway that may be equated with specific types of drainage route (e.g., englacial/subglacial channelized flow and subglacial distributed flow within a glacierized catchment, or overland, soil water, and groundwater flow within a nival catchment). Second, that the water in the different flow pathways has unique and constant chemical or isotopic compositions. Third, that the flow components merge close to the catchment outlet monitoring station and that mixing is conservative, that is, there are no post-mixing chemical reactions. Collins (1979) was the first to use chemically based mixing models in glacial catchments and using stream electrical conductivity (a surrogate for total solute concentration) separated the bulk hydrographs of the adjacent glaciers Findelengletscher and Gornergletscher, Switzerland, into dilute "quick flow" and more chemically enriched "delayed flow" components. Interestingly, both hydrographs varied in phase with bulk flow at Findelengletscher, but at Gornergletscher the delayed flow hydrograph was out of phase with both the quick flow and bulk flow. This suggested that the two glaciers were dominated by distributed and channelized subglacial drainage systems, respectively. Since Collins's (1979) pioneering work, detailed hydrochemical analysis of waters in glacierized catchments, including in situ waters collected from the base of boreholes, together with laboratory dissolution experiments, have shown that the three key assumptions for chemically based hydrograph separation are questionable (Sharp et al., 1995; Brown, 2002). The second and third assumptions are more valid for isotopes. These may be used, therefore, to examine the proportion of bulk runoff that is derived from snow and ice ("recent" and "old," respectively), since snow and ice typically have distinct isotopic compositions (e.g., Wagnon et al., 1998). See *Hydrogen Isotopes* for more details.

Summary

Hydrographs depict the changes in water quantity, usually expressed as discharge, in a stream or river over time. In snow and ice covered catchments, discharge varies over a range of scales and it is possible to identify diurnal, storm, flood, and seasonal hydrographs. Since catchment hydrographs vary in response to variations in water inputs (from snow and ice melt or rainfall) and water routing, the analysis of hydrograph characteristics can be used to infer a variety of catchment processes. Increasingly, hydrologists and water resource planners are adopting a more conceptual or physics-based approach to modeling catchment hydrographs that may be used for predictive purposes (Hydrological Response in Glacierized Basins).

Synonyms

Water cycle; Precipitation; Snow hydrology

Definition

Hydrologic cycle. Hydrologic cycle is the continuous movement of water through the atmosphere and on and below the earth's surface.
Precipitation. Any of the forms of water particles, whether liquid or solid, that fall from the atmosphere and reach the ground. The forms of precipitation are: rain, drizzle, snow, snow grains, snow pellets, diamond dust, hail, and ice pellets. (Source: National Snow and Ice Data Center, http://nsidc.org/arcticmet/glossary/precipitation.html.)
Snow. Precipitation in the form of crystalline water ice.
Interception. The component of precipitation that is intercepted by plants that evaporates or sublimates back to the atmosphere without reaching the earth's surface.
Runoff. The component of precipitation that moves across the land surface or through surface channels.
Snowmelt. The runoff that results from melting snow.
Evaporation. The physical process by which a liquid or solid substance is transformed to the gaseous state. In meteorology, evaporation usually is restricted in use to the change of water from liquid to gas. (Source: National Snow and Ice Data Center, http://nsidc.org/arcticmet/glossary/precipitation.html.)
Sublimation. The transition of a substance from the solid phase directly to the vapor phase, or vice versa, without passing through an intermediate liquid phase. Snow would sublime when exposed to solar radiation and at certain atmospheric pressure regimes. (Source: National Snow and Ice Data Center, http://nsidc.org/arcticmet/glossary/precipitation.html.)
Snow Hydrology. The hydrologic study of composition, dispersion, and movement of snow and ice.

Introduction

During the winter period, precipitation falls predominantly in the form of snow when the air temperature is below freezing ($<0°C$). In the hydrological cycle, this means that water is temporarily stored at the soil surface after which it is released in the form of meltwater (snowmelt). In many mountainous regions in the world, this water is of vital importance as a drinking water supply. During the summer, warm temperatures release this stored water as meltwater from higher elevation regions. Often, these regions have a small subsurface catchment volume and steep gradients, which support only limited groundwater storage.

Snow climatology and generation

Snow hydrology impacts the hydrologic processes in higher altitude and latitudes of the earth. Hence, understanding of the processes that lead to snowfall and its distribution is critical. According to McKay and Gray (1981), "The occurrence of snowfall in a region is generally dependent on several geographic and climatic factors: latitude, altitude, the distance from major water bodies, and the nature of regional air mass circulation." Snowfall does not occur in lower latitudes because the heat balance at the earth's surface renders air temperatures well above the freezing temperature during winter. Air temperature decreases with altitude; hence, higher altitudes experience more snowfall than lower areas. Both proximity to large water bodies and atmospheric circulation needed to transfer water vapor affect the moisture supply needed for snowfall when temperatures are low enough at the earth's surface. So, given cold air and an adequate supply of moisture, the local and regional snowfall climatology is governed by the atmospheric circulations (DeWalle and Rango, 2008).

Snow precipitates by the type of mechanism associated with its formation (Singh and Singh, 2001; DeWalle and Rango, 2008). There are four distinguished mechanisms of snow formation and each has characteristics that have important hydrologic consequence. These mechanisms of formation are (1) convective, (2) cyclonic, (3) orographic, and (4) turbulence. Heavy snowfall is mostly associated with cyclonic or orographic mechanisms, while turbulence in the atmosphere might produce fine snowfall.

Convective precipitation is usually limited to the tropics and is not a mechanism for snowfall.

Distribution of snow

Mountains have a strong impact on spatial distribution of precipitation (Singh and Singh, 2001). The knowledge of spatial distribution of snow is critical in planning and management of water resources, runoff simulations, and assessment of precipitation in a region. Singh and Singh (2001, Table 2.4, p. 79) have provided a summary of world-wide precipitation distribution studies in which they specifically conclude that snowfall increases linearly with altitude. They also conclude that the ratio of snowfall to annual precipitation varies linearly with altitude and that more than 60% of annual precipitation is in the form of snow in the regions that are above 2,000 m in altitude.

Another mechanism of distribution of snow is by lake-effect snowfall (DeWalle and Rango, 2008). Lake-effect snowfalls can cause some of the highest snowfall intensities from large water bodies such as the great lakes of the USA. The contrast in temperature between the air and the water and the evaporation rates from the unfrozen lakes are generally very high during the early winter period resulting in greater lake-effect snowfall, downwind from the lake. The factors that control the lake-effect snowfall are increase in ground elevation downwind of the lake and rough shoreline terrain causing *turbulence* in the atmosphere.

According to DeWalle and Rango (2008), "The Southern Oscillation which gives rise to El Niño conditions, or its counterpart La Niña conditions, is now known to have far-reaching effects on global climate and snowfall." They further state, "Snowfall totals in moderate to strong La Niña years averaged higher than in moderate to strong El Niño years, while neutral years generally had intermediate snowfall totals." Besides the Southern Oscillation, snow is also transported and distributed over large distances by the wind before it sublimates or comes to rest in a snowpack. Sublimation of blowing snow results in more than 50% of the loss in winter precipitation. Such magnitude of loss in regions of low precipitation and without supplemental irrigation can have significant impact in spring soil moisture levels and agricultural productivity. The blowing snow is usually transported by turbulent suspension, saltation, and creep (DeWalle and Rango, 2008). Such transport and distribution render uneven snowpack distribution that results in uneven meltwater delivery in spring.

Interception of snow

Snowfall often interacts with the vegetation prior to forming a snowpack. DeWalle and Rango (2008) define two important processes that are components of the hydrologic cycle:

> Snow that is lodged within the canopies of plants is referred to as intercepted snow, while snow that falls or drips to the ground from or through the canopy is termed throughfall. Throughfall from intercepted snow can be in the form of ice particles dislodged by the wind that filter through the canopy during cold, windy conditions or in the form of large masses of intercepted snow that slide from the plant branches during warm, melting conditions or as branches bend under the weight of intercepted snow. Meltwater from intercepted snow that reaches the ground by flowing down the stems of plants is called stemflow. Stemflow is a minor pathway for intercepted water to reach the ground (Brooks et al., 1997; Johnson, 1990), especially in winter when melt rates from intercepted snow are often much less than rainfall rates. Intercepted snow can be sublimated or evaporated from the canopy before reaching the ground and the mass lost to the atmosphere is referred to as interception loss. Interception loss can occur while the snow is stored within the canopy or as the intercepted snow is being redistributed within and over the landscape by the wind. Knowledge of the distribution and type of vegetation across a watershed is essential in successfully modeling effects of interception on snowmelt runoff.

Snowmelt runoff

The study of snowmelt runoff is complex. Understanding the generation of streamflow from snowmelt involves integration of processes that produce meltwater within the snowpack, processes that delay and store liquid water in the snowpack, and processes that direct the flow of meltwater through watersheds to stream channels (DeWalle and Rango, 2008). Once the outflow from the snowpack reaches the land surface, active hydrologic flow paths can cause such outflows to rapidly transition into streamflow depending on existing conditions such as soil frost, permafrost, or saturated subsurface. Flow paths for meltwater may be channels, overland flow, interflow, or groundwater recharge. Snowpack outflow onto frozen, impermeable ground may result in rapid streamflow response through overland flow while a portion of it might be stored or intercepted in surface ditches. Such rapid delivery of meltwater poses considerable problems in the arctic and sub-arctic watersheds. Micrometeorology determines energy supply on scales of meters due to canopy shading and unsaturated fingered flow in the snowpack controls' heterogeneous liquid water distribution in time and space over scales of centimeters (Waldner et al., 2004). Many of these processes equilibrate over watershed scales and multiple years, which make simulation of snowmelt runoff possible at these scales with intensive calibration. These models are not very transferable to other regions due to a lack of data and physical input required for model simulation. Besides, the prediction of the depth of soil frost, the infiltration capacity of the frozen ground becomes critical in modeling streamflow from snowmelt.

In arctic watersheds with low-relief and windy conditions, snow dams can alter the downstream delivery of meltwater (Woo and Sauriol, 1980; Woo, 1983). Streamflow in the arctic generally ceases in the winter due to the freezing of the active layer. The redistribution due to blowing snow in these watersheds fills the topographic depressions. During the spring melt, these

deposits act as dams and are responsible for slow downslope migration of meltwater. These deposits often become saturated with meltwater causing slush flows, tunneling in the snowpack, or surface flow over the saturated snow layers. Ponding may also occur in such snow dam conditions thus delaying the movement of meltwater downstream by several days. Snow damming presents special problems for modeling the movement of meltwater along slopes through the snow and prediction of snowmelt runoff in such basins (Hinzman and Kane, 1991).

Effect of uneven snowpack distribution and snow cover on hydrologic cycle

Small scale variations in snow depth affect the terrestrial ecosystem due to its effect on freezing rates. These heterogeneous freezing rates can result in a non-sorted circle environment, where water drives seasonal heaving and subsiding of the ground surface (Daanen et al., 2008a; Daanen et al., 2008b). Spring snowmelt can infiltrate more readily due to this heterogonous freezing because organic material, which is most often found underneath the greatest snow accumulation, dries out as the active layer freezes. This reduces overland snowmelt runoff in tundra regions.

Climate change effects on the hydrological cycle of snow

Seasonal snow cover has a major effect on the earth's climate system due to an increase in albedo when snow is present. This climate effect causes the hydrologic cycle to slow down during the winter over vast regions of the earth. The implications and feedbacks between climate and snow cover are currently a major topic of research. A reduction of snow cover extent results in a major positive feedback to climate warming due to increased absorption of radiation by the earth's surface. Climate warming in cold regions leads to a longer draining and evapotranspirating season with a drying result at the soil surface. Snowfall is, however, projected to increase as a result of increased moisture content in the atmosphere at lower latitudes. The two scenarios of increased input of snow and increased drainage may result in a net water balance with a greater through put of water. Currently, however, the tundra is experiencing dryer conditions and the increased snowfall has not been observed.

Seasonal snow cover also has a major effect on permafrost temperatures. Increase of snow depth insulates the ground more and can in some cases prevent the active layer (seasonally thawed ground on top of permafrost) from freezing (Yoshikawa and Hinzman, 2003). This thawed layer is also called a talik and depending on its location, it can contribute to increased drainage of permafrost affected regions. Increased drainage affects the whole hydrologic system from terrestrial ecosystems to salt concentrations in the Arctic Ocean.

Human impact on the hydrological cycle of snow

Human impact on the hydrological cycle of snow is small when viewed over the globe. However, in cities there is a major effect due to impervious surfaces and the removal of snow from highways and roads. Transportation and stock piling of snowmelts is slower than that of a regular snowpack, but the use of salt and gravels on the streets results in earlier and reduced snowmelt peaks. Air pollution also affects the hydrological cycle of snow, because ice crystals are more efficient in removing pollution from the air than rain droplets. These pollutants are released during the early snowmelt period.

Summary

Snow as a precipitate is a significant component of the hydrologic cycle especially in watersheds of high latitude or higher altitudes. The processes that are responsible for the timing and quantity of snowfall are reasonably well understood. However, estimation of basic liquid input from precipitation and snowpacks for modeling has been a challenge due to blowing snow and interception. Meltwater from snow as runoff has been difficult to model due to ice damming conditions and lack of direct measurements and physical input required for model simulation. Snowfall has considerable effect on landscape changes, global climate, and the hydrologic cycle.

HYDROLOGICAL RESPONSE IN GLACIERIZED BASINS

Ian C. Willis
Scott Polar Research Institute, Department of Geography, University of Cambridge, Cambridge, UK

Introduction

A basin's hydrological response refers to the ways in which its water pathways, stores, and outputs respond to water inputs (Singh and Singh, 2001). Glacierized basins have a different hydrological response to non-glacierized basins due largely to the presence of snow and ice and the lack of vegetation and soil. Inputs are in the form of Melting of Snow/Ice and rainfall. Pathways and stores may be supraglacial (Snow, Firn, Lakes), englacial (Crevasses, Moulins, Englacial Conduit), subglacial (Subglacial Drainage System, Subglacial Lakes, Antarctic), ice marginal lakes, or groundwater. Outputs are usually defined as stream or river runoff at the catchment outlet. The hydrological response of glacierized basins changes rapidly through time, especially during the spring and summer due to variations in snow and ice melt, rainfall, and the evolution of the glacier's hydrological system. Glacierized basins are also prone to flooding following high melt rates or intense rainstorms, changes in the glacier's drainage system, or lake outbursts.

Year to year variations in hydrological response

Glaciers are natural reservoirs, increasing in mass by storing water as snow and ice during wet, cool years; losing mass by releasing meltwater in dry, warm years. Climate ultimately controls the mass balance of a glacier. Year to year fluctuations in climate will affect a catchment's hydrological response depending on how radiation, temperature, and rainfall are affected. A dry, warm year will increase runoff from glacier melt, but decrease it from rainfall – the "compensating effect." Whether total annual runoff goes up or down depends on the relative importance of melt and rain inputs to the catchment, and the ways in which these inputs are affected by climate variability. Year to year runoff fluctuations depend, therefore, on the percentage of the catchment that is glacierized (Röthlisberger and Lang, 1987). Variability is high for catchments that are 0% or 100% glacierized but reaches a minimum for catchments that are ~40% glacierized (Willis, 2005, Figure 1). The "compensating effect" is greatest where catchment runoff is controlled approximately equally by rainfall and glacier melt.

Year to year runoff variability not only depends on the magnitude of annual radiation, temperature, and rainfall changes, but also their timing during the year. For example, in eight glacierized basins in western China between 1953 and 1993 both mean annual temperatures and precipitation were higher after the late 1970s than before (Liu et al., 1999). However, annual stream flow decreased over time, as although precipitation increases occurred throughout the year, temperature rises were concentrated in the winter. This increased winter accumulation and decreased summer melt.

Year to year climate variability not only affects river flows directly, but a long-term climate trend affects them indirectly through its effects on glacier mass balance, geometry, and the relative proportions of snow, firn, and ice area. Summer temperature increases may increase runoff in the short-term, but decrease it due to glacier shrinkage in the long-term (Pelto, 1996). This is particularly true if climate change increases the area of ice compared to firn and snow, since ice melts faster than snow or firn for a given climate due to its lower Albedo.

Season to season variations in hydrological response

Seasonal runoff regime depends largely on the annual distribution of water inputs and depends largely, therefore, on patterns of radiation, temperature, and precipitation throughout the year. Catchments in mid-latitudes have marked variations in radiation and temperature, and relatively small variations in precipitation. The year is divided into a winter accumulation season and a summer ablation season. Here, glaciers are "winter accumulation type" (see Benn and Evans, 1998), storing water as snow and ice during the winter and releasing it during the summer. Mid-latitude glacierized basins are characterized by a long summer melt season, a large annual variation in runoff, and a delay in the timing of maximum annual flow compared to that in an equivalent non-glacierized basin. This is due to meltwater production peaking in mid-summer and the temporary storage of spring meltwater (Willis, 2005, Figure 3a).

High latitude catchments have even greater annual radiation and temperature variations than those in mid-latitudes, with long periods of sub-zero temperatures. They also have moderate annual precipitation variations with lower precipitation totals than the mid-latitudes. High latitude glaciers in maritime areas are "winter accumulation type," but those in continental regions may be thought of as "summer accumulation type." The hydrology of such basins is characterized by a shorter melt season and a lower annual runoff variation compared to mid-latitude basins (Willis, 2005, Figure 3b and c).

Low latitude catchments have small annual radiation and temperature variations, but large fluctuations in humidity, cloudiness, and precipitation. Low latitude

glaciers are either "summer accumulation type," or "year round ablation type." The former occur in high altitude regions, with dry cold winters and high summer precipitation maxima, such as the monsoon-dominated parts of the Outer and Middle Himalayas, Pamirs, Altai, Karakoram, Tien Shan, Kunlun, Qilian, and the high Andes. Here, there is little winter precipitation, with precipitation falling mostly in summer as snow at high elevations, and rain at lower elevations. Annual ablation variations are caused largely by variations in cloudiness and humidity, with sublimation dominating in the winter and melting in the summer. Glaciers tend not to store and release water over annual timescales as they do in mid-latitude basins. Catchments are still subject to large annual runoff variations, with high runoff in the wet season when both melting and rainfall are high (Willis, 2005, Figure 3d). Year round ablation type glaciers occur in high altitude areas in the inner tropics where precipitation occurs throughout the year, although concentrated into one or two wet seasons. Glaciers have fairly even rates of accumulation and ablation throughout the year, although, as with summer accumulation type glaciers, both may be slightly higher during the wetter months. Glaciers do not store and release water over annual timescales and runoff occurs fairly evenly over the year.

Seasonal changes in the hydrological response of glacierized basins depend not only on geographical setting, but also catchment size, hypsometry, and, importantly, percentage glacier cover (Röthlisberger and Lang, 1987; Willis, 2005). Annual runoff variation is at a minimum for catchments with ~30–40% glacier cover, with a higher variation in basins with both lower and higher percentage glacier cover. Catchments with a high percentage glacier cover are small upland catchments with a low elevation range, and, especially in the mid-latitudes and high latitudes, low water inputs in the winter (as precipitation falls as snow and there is little melt), and high inputs during summer (due to rainfall and melt). Conversely, catchments with a low percentage glacier cover tend to be large, have a high elevation range, and extend to the lowlands. Here, liquid water inputs are highest in the winter and lowest in the summer (as most precipitation falls across the catchment as rain and the effects of glacier accumulation and melt high in the catchment are relatively insignificant). Thus, annual runoff variability is again high, but with maximum and minimum discharges in the winter and summer respectively. In catchments with ~30–40% glacier cover, high melt in the upper catchment compensates for low rain in the lower catchment during the summer, and vice versa in the winter. The net result is a fairly even distribution of runoff throughout the year.

Spring to summer variations in hydrological response

Mid-latitude and high latitude glacierized basins undergo large hydrological changes during the spring and summer due to rapid changes in melt inputs and water routing (Catchment Routing). Melt inputs increase as the summer snowline migrates up glacier lowering surface albedo and increasing its roughness, thereby increasing the fluxes of net solar radiation and turbulent heat (Hock, 2005). Water transfer rates increase as the snowpack warms, becomes more saturated, thins, and eventually disappears (Depletion of Snow Cover) (Willis et al., 2002). Firn becomes more saturated (Jansson et al., 2003), surface lakes fill, coalesce and may cause hydrofracture so that water can flow across or into the ice (Boon et al., 2003). Additionally, the englacial and subglacial drainage systems enlarge and become more hydraulically efficient (Fountain and Walder, 1998; Nienow and Hubbard, 2005; Sharp, 2005). Seasonal changes in water inputs and routing cause major changes to the shape, peak magnitude, and lag times of proglacial stream diurnal discharge Hydrographs (Diurnal Cycle of Runoff).

Low latitude glaciers tend not to experience big hydrological changes during the spring and summer, as accumulation and ablation occur more evenly through the year, and annual variations in water inputs and routing are therefore small.

Flooding

Floods are a common occurrence in glacierized basins. The biggest are Glacier Lake Outburst Floods also known as jökulhlaups caused by the rapid drainage of either ice-dammed subglacial lakes or of moraine- or ice-dammed ice-marginal lakes (Tweed and Russell, 1999).

The most documented subglacial lake floods are from Grimsvötn beneath Vatnajökull, Iceland. Floods recur every 1–10 years releasing 0.5–4 km^3 of water over 2–30 days with maximum proglacial discharges of 0.6–50 $\times$ 10^3 m^3 s^{-1} (Björnsson, 2003). Less predictable floods occur during volcanic eruptions such as that at Gjalp, just north of Grimsvötn in 1996 where 3.2 km^3 of water drained from the lake within 40 h with maximum lake exit discharges of 40 $\times$ 10^3 m^3 s^{-1} (Björnsson, 2003). Grimsvötn floods are typically initiated when lake levels approach the ice overburden pressure, allowing water to escape. However, the unusual 1996 flood occurred once flotation pressures were reached. The flood Hydrographs have an increasingly steep rising limb, as the flowing water melts a drainage pathway between the lake and the snout at an accelerating rate, followed by a rapid termination as the lake level drops to a threshold level sealing off the outlet.

Ice-dammed ice-marginal lakes form in the following three locations: (a) where a main valley glacier blocks the drainage of a glacier free side valley; (b) where a side valley glacier extends across a glacier free main valley; and (c) at the confluence of two valley glaciers (Benn and Evans, 1998). GLOFs are initiated when the lake level overtops the ice, cutting a spillway across the ice or between the ice and the valley side, or when it approaches local ice overburden pressure allowing water to escape underneath. Floods along supraglacial spillways or

ice-marginal channels typically possess a more symmetrical steep rise to, and fall from, the hydrograph peak compared to subglacial conduit floods.

GLOFs from moraine-dammed lakes mostly occur by mechanical failure of the moraine dam, or by the lake water overtopping part of the dam initiating rapid and accelerating incision (Richardson and Reynolds, 2000). Recorded hydrographs from moraine-dammed lake GLOFs are rare but one measured ~100 km downstream of a flood from Luggye Tsho, Bhutan in 1994 shows a rapid 1 h rise to peak followed by a moderate fall, and then a more gradual fall with the entire flood lasting ~22 h (Richardson and Reynolds, 2000).

In addition to large floods associated with catastrophic lake drainage, smaller floods may be generated by high melt rates or rainfall (e.g., Davies et al., 2003), or by the sudden release of water stored within the glacier's englacial/subglacial drainage system, particularly in the spring or early summer. On Temperate Glaciers, such floods appear to be related to a switch in the dominant type of subglacial drainage, from distributed to more channelized, and are often associated with glacier uplift and acceleration, and the purging of sediment; they are termed "spring events" (e.g., Anderson et al., 1999). On Polythermal Glaciers, floods are associated with the release of water stored subglacially beneath the warm-based core of the glacier in the upper ablation area. The water eventually breaks through the "thermal dam" and is able to flow beneath the cold-based lower ablation area to the terminus (e.g., Rippin et al., 2003).

Modelling hydrological response

There is increasing need to model the hydrological response of ice-covered basins for scientific investigation of catchment processes and for practical water resource management purposes (Singh and Singh, 2001; Hock and Jansson, 2005; DeWalle and Rango, 2008). Early models in the 1960s and 1970s were stochastic and involved the use of statistical regression equations to predict proglacial stream hydrographs from nearby climate data. They made reasonably accurate predictions, but lacked a conceptual basis, required long data series to fix model parameters, remained site specific, and could not readily be transferred to other catchments, or used to predict runoff under different climatic regimes in the future.

Since the 1980s, conceptual models have increasingly been used to predict catchment runoff. The catchment is typically treated as a series of linear reservoirs, linked in series, parallel, or some combination, each with a different storage constant to represent, e.g., snow, firn, glacier ice, groundwater. Examples include the single reservoir HYMET model, the two-reservoir UBC model or the three-reservoir "Hock" or "Escher-Vetter" models (Hock and Jansson, 2005). Such models are widely used in operational forecasting, and because they have a conceptual basis, they are more transferable between catchments and climatic regimes.

Although physically based models are increasingly being used in glacierized catchments, they are mainly used for scientific rather than practical purposes. One such model has been developed for glaciers dominated by flow in channels (Arnold et al., 1998) and another for glaciers underlain by thick sediment layers where porous, macroporous (sheet) and groundwater flow dominate (Flowers and Clarke, 2002). The latter model has been adapted to allow channel flow and the transfer of water between a channel and sheet (Flowers et al., 2004). Because the models are complex and require extensive data sets to both set boundary conditions and parameterise and test them, they have been applied only to specific glaciers so far (Haut Glacier d'Arolla, Switzerland, Trapridge Glacier, Yukon, Canada and Vatnajökull, Iceland). Models were able to reproduce key features of measured subglacial water pressure fluctuations and/or proglacial stream hydrographs. Additionally, the "channel" model could simulate measured moulin to snout throughflow velocities determined from dye-tracing experiments (Arnold et al., 1998).

Modelling studies are increasingly concerned with quantifying the effects of climate change on the hydrological response of glacierized basins. A variety of models in a range of geographical settings show that in a warmer climate: (a) spring/summer runoff will be enhanced, with annual maximum flows occurring earlier in the year; (b) flood risk will be greater; and (c) over time, as glaciers shrink, annual runoff will decrease (Singh and Kumar, 1997; Hagg and Braun, 2005; Hagg et al., 2007).

Summary

A glacierized basin's supraglacial, englacial, subglacial, ice marginal, and groundwater pathways and stores, modify the inputs from melt and rain producing its characteristic hydrological response, measured as basin water output. A basin's response varies through time at a variety of timescales in response to variations in water inputs, pathways, and stores. Some of the most notable changes occur in mid-latitude and high latitude catchments during the spring and summer. Less predictable changes are associated with flooding due to high melt rates or intense rainstorms, changes in the glacier's drainage system, or lake outbursts.

HYDROLOGY OF JÖKULHLAUPS

Fiona Tweed
Department of Geography, Staffordshire University, Stoke-on-Trent, Staffordshire, UK

Synonyms

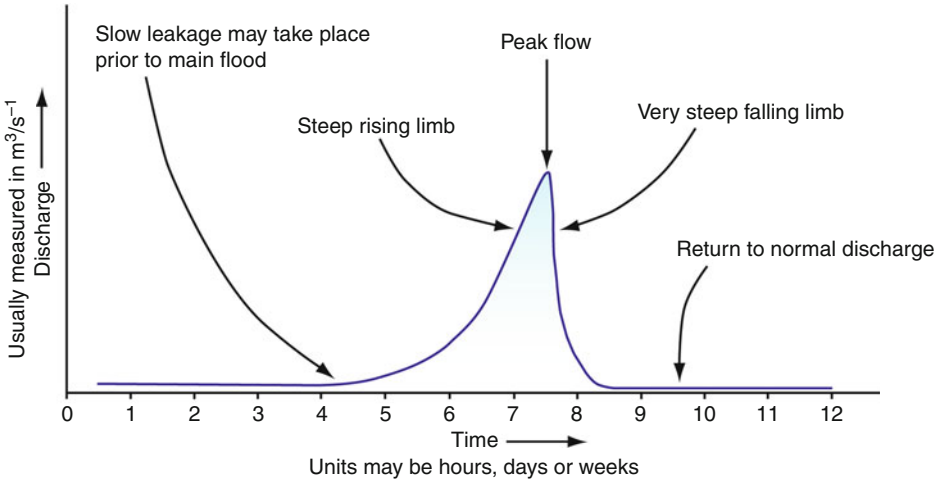
Glacial outburst floods

Definition

"Jökulhlaup" is an Icelandic term derived from the words jökull (Glacier) and hlaup (meaning sprint or burst). A jökulhlaup is a sudden and often catastrophic release of meltwater from a *glacier* or a moraine-dammed lake, resulting in a significant increase in meltwater discharge over a period of minutes to several weeks (e.g., Young, 1980; Roberts, 2005).

Jökulhlaups can originate from meltwater stored in ice-marginal, subglacial, englacial, and supraglacial locations (Ice-Dammed Lakes) although volcanogenic and rainfall-induced floods in glaciated environments can occur without significant water storage (see Tweed and Russell, 1999; Roberts, 2005). The release of meltwater during the termination of glacier surges can also result in jökulhlaups (e.g., Kamb et al., 1985).

Estimates of maximum peak flow range from 1.5×10^6 m^3s^{-1} for historic floods (e.g., Maizels, 1995) to 1×10^7 m^3s^{-1} for jökulhlaups in the late Pleistocene (e.g., O'Connor and Baker, 1992). There is a substantial body of work devoted to the modeling of jökulhlaups



Hydrology of Jökulhlaups, Figure 1 Idealized jökulhlaup hydrograph adapted from Young (1980). The differences in hydrograph shape reflect different mechanisms of water flow through glaciers during jökulhlaups.

(e.g., Nye, 1976; Spring and Hutter, 1981; Clarke, 1982; Björnsson, 1992; Walder and Costa, 1996; Roberts, 2005). The most widely used model of peak discharge estimation was developed by Clague and Mathews (1973) and links maximum instantaneous discharge to maximum water volume thus:

$$Q_{\max} = 75\ V_{\max}^{0.67}$$

where Q_{max} is the maximum instantaneous discharge ($m^3 s^{-1}$) and V_{max} is available water storage ($m^3 \times 10^6$). This model has been modified, but still forms the basis of peak discharge estimation for jökulhlaups generated from *ice-dammed lakes*.

Jökulhlaup *hydrographs* are varied (e.g., Young, 1980; Roberts, 2005); a generalized jökulhlaup hydrograph is illustrated in Figure 1. Some floods generate exponentially rising limbs and others are characterized by a sharp, linear rise to peak discharge. Hydrograph shape is strongly influenced by the flood generating mechanism, subglacial water pressure, and floodwater routing. Floodwater can drain supraglacially, englacially, ice-marginally, or subglacially, via single conduits or multiple floodwater outlets (see Tweed and Russell, 1999; Roberts, 2005). In the case of jökulhlaups generated from moraine-dammed lakes, common drainage initiators include overtopping and concomitant downcutting of the moraine dam or seepage of water through the moraine (e.g., Richardson and Reynolds, 2000). The routing of floodwater during outbursts from glaciers is heavily influenced by the flood trigger mechanism and the nature of the damming *glacier* and its drainage system (Tweed and Russell, 1999; Roberts, 2005).

Jökulhlaups exert a significant potential for landscape change in glaciated environments; they can erode deep canyons, streamline landforms, and create scour marks around obstacles. Jökulhlaups frequently transport large quantities of sediment, depositing boulders, gravel bars, and large gravel and sand dunes with megaripples (e.g., Russell and Knudsen, 1999; Carling et al., 2002; Rudoy, 2002). Evidence of jökulhlaups can be deduced from the sedimentary record on the basis of diagnostic features (e.g., Maizels, 1997; Marren, 2005).

HYDROPOWER: HYDROELECTRIC POWER GENERATION FROM ALPINE GLACIER MELT

Mauri S. Pelto
Department of Environmental Science, Nichols College, Dudley, MA, USA

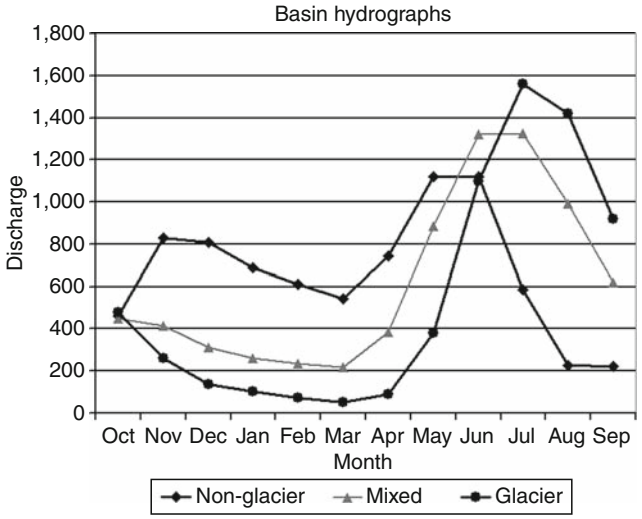
Definition and introduction

Alpine glaciers act as natural reservoirs storing water in a frozen state instead of behind a dam. Glacier's modify streamflow releasing the most runoff during the warmest, driest periods when all other sources of water for hydropower are at a minimum (Stenborg, 1970; Fountain and Tanborn, 1985). This seasonal variation characteristic mitigates low flow intervals and the dependability helps make glacier runoff a valuable water resource for hydropower (Fountain and Tangborn, 1985). Annual glacier runoff is highest in warm, dry summers and lowest during wet, cool summers, further providing a balance to alpine summer runoff, this is the glacier compensation effect (Lang, 1986). Dependable and consistent glacier runoff allows for run of river hydropower and smaller reservoir storage in glaciated basins. For long range planning minimum flows are greater and maximum flows less in glacier fed basins (Fountain and Tangborn, 1985). At the same time that glacier extent has been rapidly declining, the use glacier runoff for hydropower has been expanding (Table 1). This highlights the importance of understanding and quantifying the role of glacier runoff for hydropower.

The amount of runoff provided by a glacier is the product of its surface area and ablation rate. Glacier runoff does not increase or decrease the long term runoff for a basin, total runoff over a period of several years is determined largely by annual precipitation. Glacier runoff peaks at the height of the melt season July and August in the Northern Hemisphere, greatly enhancing summer runoff (Hock et al., 2005). Runoff from non-glacier alpine basins peaks in May and June in all but the monsoon fed alpine regions (Figure 1). The loss of a glacier does not necessarily reduce annual runoff, annual precipitation changes are the key for annual runoff changes. Glacier retreat results in the reduction of runoff in the summer, when other sources are also depleted. The increase in flow will be in the spring when water supply is already high in alpine regions. Glacier retreat results in reduced spatial extent for melting and reduced reservoir capacity. The retreat can initially offset runoff reduction due to the loss in area though increased ablation rate, but quite quickly the reduced melt area overtakes the enhanced ablation rate. Unlike non-glacier runoff, glacier runoff correlates better with temperature than precipitation, due to the dominant role of glacier melt compared to precipitation in summer

Hydropower: Hydroelectric Power Generation from Alpine Glacier Melt, Table 1 The glacier area in selected river basins with hydropower facilities operating and proposed.

Region	Glacier area km^2	Hydropower production	Under construction
Rio Santo, Peru	387	1,540 MW	
Cachapoal and Tinguiririca, Chile	328	76 MW	423 MW
Zongo Valley, Bolivia	25	205 MW	
Bhagirathi, India	286	2,400 MW	520 MW
Alaknanda	100+		140 MW
Parbati-Saltuj, India	4,000	1,200 MW	800 MW
Vaksh River, Tajikistan	11,600	3,000 MW	
Skagit River, United States	126	530 MW	
Columbia River, British Columbia-WA	3,000	24,000 MW	
Rhone River, France	1,150	3,000 MW	
Styggevatnet, Norway	12	288 MW	
Hardanger, Norway	40	620 MW	



Hydropower: Hydroelectric Power Generation from Alpine Glacier Melt, Figure 1 The timing of discharge from non-glacier and glacier streams is highlighted by this comparison of neighboring drainage basins. Non-glacier basin runoff peaks in May and June. Glacier basin runoff in July and August.

runoff from glacierized basins. This is also the reason for the strong diurnal nature of glacier runoff.

There are two changes in glacier runoff that occur as a result of warming and enhanced glacier melt. The initial response is an increase in glacier melt rate enhancing glacier runoff, while the glacier extent is still substantial in comparison to previous size. The initial enhance glacier runoff has been observed in several regions (Andreassen et al., 2005; Braun et al., 2000; Zhang et al., 2008). Eventually the resulting decline in glacier extent reduces the area available for melting causing a decrease in glacier runoff. In several basins a decline of more than 20% in glacier area has led to a decrease in glacier runoff (Pelto, 2008; Stahl and Moore, 2006). There is a threshold of glacier extent reduction dependent on the magnitude of ablation rate increase, where glacier runoff declines, the few examples suggest this is in the 10–20% areal extent loss. In the long run glacier retreat simply results in the reduction of runoff in the summer, when other runoff sources are also depleted. The increase in streamflow will be in the winter and spring when water supply is already high in most alpine regions. Examination of recent changes in glacier runoff indicate several frequent responses, highlighted by comparison of glaciated and unglaciated basins in North America (Fountain and Tangborn, 1985; Fleming, 2005; Pelto, 2008). A specific example is between neighboring basin unglaciated Newhalem Creek and Thunder Creek 14% glacier cover (Pelto, 2008).

1. Streamflow has risen 18% in Newhalem Creek and 19% in Thunder Creek despite only a slight increase, 2% in winter precipitation at Diablo Dam, within 5 km of both basins. Alpine runoff throughout the Pacific Northwest is increasing in the winter (November–March), as more frequent rain on snow events enhance melting and reduce snow storage.
2. Spring runoff (April–June) has increased in both basins by 5–10% due to earlier alpine snowpack melting.
3. Summer runoff has decreased markedly, 27%, in the non-glacier Newhalem Basin with the earlier melt of reduced winter snowpack. In Thunder Basin runoff has in contrast decreased negligibly, 4%. The difference is accounted for in part by enhanced glacier melting. The observed net loss of −0.52 m/a in glacier mass spread over the melt season is equivalent to 2.45 m^3/s in Thunder Basin, which is 10% of the mean summer streamflow.

Selected glacier-dependent hydropower projects

South America

A number of South American countries are highly dependent upon glaciers and glacial runoff for energy production. In the Andes region, hydropower supplies 81% of Peru's electricity, 73% of Colombia's, 72% of Ecuador's, and 50% of Bolivia's, in each country glaciers contribute a significant portion of this runoff. In the Cordillera Blanca, Peru glacial cover has been shrinking since the 1970s, decreasing by 15% over a 25 year span. In the Rio Santa Basin of Peru glacier runoff comprises 35% of the total runoff (Vergara et al., 2008). The Canon del Plato hydropower project would experience a decrease from 1,540 to 1,250 Gwh for a 50% glacier runoff reduction and decline to 970 Gwh for a 100% glacier loss (Vergara et al., 2008). The energy lost from glacier extent loss would be $5.7–$11.5 million $USD. Pacific Hydro has recognized the potential of glacier fed alpine streams for hydropower in Chile and has built a facility on the glacier fed Cachapoal River and is developing projects on the Tinguiririca River. The combination of snow melt, glacial melt and rainfall water sources provides for reliable runoff in these basins. Zongo Glacier is a small valley glacier located north-east of La Paz, Boliva and its runoff is directed to an important hydropower station which supplies La Paz. From 1956 to 1975 the Zongo Glacier was near equilibrium, since it has lost mass. From 1991 to 2005 the glacier has lost 5 m of thickness and retreated substantially (Soruco et al., 2009). A continuing trend in glacier loss will seriously decrease the water reserves stored as ice, reducing melt season runoff.

Asia

In India, 50% of hydroelectric power is generated by runoff from Himalayan glaciers. A key component of India's energy self-sufficiency is more hydropower. Most of the hydropower is from northern India on streams draining Himalayan glaciers. The Alaknanda River headwater is the Satopanth and Bhagirath Kharak Glaciers. India has applied to the World Bank for run of river hydropower along this glacier fed river. In 2005 the Tehri Dam was finished on the Bhagirathi River, it is a 2,400 mw facility that

began producing hydropower in 2006. At the headwaters of the Bhagirathi River are the Gangotri and Khatling Glacier, Garhwal Himalaya. Gangotri Glacier has retreated 1 km in the last 30 years, and with an area of 109 km^2 provides up to 190 m^3/s (Singh et al., 2006). The Himalayan glaciers have one unique aspect, the wet season is the summer monsoon, which coincides with the primary melt season. Thus, the loss of glacier area does not cause as large a change in summer runoff as in other glaciated alpine regions. Parbait Glacier retreated 52 m/a from 1990 to 2003 (Kulkarnil et al., 2005). This is one of 36 glacier feeding the Beas River and the currently under construction Parbati Hydropower Project, slated to provide 800 MW in the Himachal Pradesh.

Nepal is beginning to turn to hydropower, with run of river hydropower development on the glacier fed Arun River opening in 2003. In China glaciers occupy a total area of 59,406 km^2. Runoff from these glaciers yield some 60 billion m^3 annually. On the Yangtze 14 additional dams to the Three Gorges project are proposed that would take advantage of the existing glacier runoff time and again. To date glacier runoff has increased due to increased melt (Zhang et al., 2008). Glacier runoff is forecast to decrease markedly as retreat progresses in China.

Pakistan generates about 45% of its electricity from hydropower on the Indus River. The headwaters of the Indus River are the large glaciers of the Karokoram Range. The Biafo and Baltura are two or the largest. Both glaciers have experience rapid retreat and loss of area in the last 2 decades. The Indus River flows have also declined. Most of the rivers in Tajikistan originate from glaciers. On Vakhsh river, there are already five hydroelectric plants, among which is the largest in Central Asia – the Nurek hydroelectric power station, with a production of 3 Gwh (Normatov and Petrov, 2006). Glaciers provide about 13 km^3 of water during the summer peak melt period and the Abramov and Fedchenko glacier are at the headwaters of the Vaksh River (Normatov and Petrov, 2006). Tajikistan has plans to increase hydropower by several 100%, increasing the importance of glacier runoff.

Europe

Glacial runoff supplies hydropower for 50% of Switzerland's electricity as well (Paul et al., 2007). In Switzerland, 84 out of 85 glaciers under observation retreated in 2006 (WGMS, 2008). Between 1850 and 1973 Swiss glaciers lost 27% of their area. Based on satellite observation, a sample of 270 glaciers also lost 20% of their area between 1973 and 1998. This loss in melt extent is reducing glacier runoff and summer alpine streamflow. The Grand Dixence Dam is situated on the relatively small Dixence River, but collects a large amount of water thanks to a system of water supply tunnels over 100 km long bringing water from other rivers and valleys. Most of the water comes from glaciers providing meltwater during the summer. The lake is usually full of water by late September, and is emptied during the winter, reaching its lowest point by April.

Austria generates 70% of its electricity from hydropower, with many of the larger projects being glacier fed such as Kaprun. The Kaprun power station produces 700 MW, 60% of its water supply is from Pasterze Glacier, which is transferred through a 12 km long tunnel to Mooserboden Reservoir. Pasterze Glacier has been retreating at a rate of 15 m/a, which will reduce melt season runoff.

The Rhone River has 19 hydropower plants supplying 25% of France's hydropower and 4% of the total energy supply. The Rhone River begins at the Rhone Glacier, Switzerland and is fed by the largest glacier in the Alps Gross Aletsch. The Rhone River is also fed by the glaciers of Mont Blanc and the Matterhorn region.

In Norway, 98% of the electricity comes from hydroelectric power, and 15% of the exploited water flow comes from glacier melt. Because a large share of the runoff in the glacial water systems comes from melting, most of this runoff, up to 80%, takes place in the summer. In dry and warm summers, glacial melting helps maintain a substantial water flow. The summer of 2002 had unusually high temperatures resulting in unusually little water flow in rivers without glaciers in their catchment area. The high temperatures provided large amounts of runoff from the glaciers. In the Nigardsbreelva watershed in Jostedalen, where 75% of the catchment area is covered by glacier, water flow approached flood levels throughout much of August. Austdalsbreen outlet of Jostedalsbreen the glacier terminates in Austdalsvatnet, which has been part of the hydropower reservoir Styggevatnet since 1988. Glaciological investigations at Austdalsbreen started in 1986 in connection with the hydropower project have recorded a 459 m retreat since 1988 (Andreassen et al., 2005). In northern Norway, the Svartisen ice cap and smaller ice caps and glaciers in the same watershed cover about 50% of the drainage area that is utilized by the Svartisen hydropower plant in northern Norway (Andreassen et al., 2005). Statkraft runs the Sima Power Station that is fed from Rembesdalsvatnet Reservoir and the larger Sysenvatn fed by the southern glaciers of Hardanger Ice Cap. This system produces 620 Mw of hydropower. The largest glacier draining the western side of the ice cap is the Rembesdalsskaka with an area of 17 km^2. Since the LIA maximum Rembesdalsskaka has retreated almost 2 km.

North America

British Columbia, Canada hydropower accounts for approximately 90% of the electiricity. In dry years glacier runoff constitutes most of later summer inflows to several large reservoirs. In the Columbia River Basin 10–20% of annual flow and 50% of summer flow are from glaciers. In the Columbia River Basin, Mica (1,740 MW), and Revelstoke (1,840 MW) hydroelectric plants are principally glacier fed during the summer (Fleming and

Hydropower: Hydroelectric Power Generation from Alpine Glacier Melt, Figure 2 Dams along the Columbia River that provide hydropower from Mica Dam, BC to Bonneville, WA; there are 14 major dams.

Clark, 2005) (Figure 2). Downstream of these stations are 14 additional dams on the Columbia River each tapping this same glacier runoff for hydropower. British Columbia rivers had a statistically significant decrease in August streamflow from 1976 to 1996, partly due to earlier snow melt (Stahl and Moore, 2006).

Volume loss of BC glaciers over the 1985–1999 was found to be occurring at a rate of 22.48 ± 5.53 km^3/year. Covering an area of 30,000 km^2 and 48% of BC's gaged systems, glacier melt moderates inter-annual variability in streamflow and helps to maintain higher runoff volume in times of extreme warm and dry conditions. Glacier melt also supports ecosystem functions by maintaining cooler water temperatures. However, a large majority of streams in glaciated basins in BC showed a statistically significant decrease in August streamflow during 1976–1996, which suggests that these glaciers even with increased melt rates are providing less runoff (Stahl and Moore, 2006).

North Cascades, Washington currently support approximately 700 glaciers. These glaciers store as much water as all of the states lakes, rivers, and reservoirs combined. North Cascade Glaciers release approximately 800 million m^3 of water during the summer. This water is nearly fully utilized for irrigation, salmon fisheries and power generation.

Hydropower: Hydroelectric Power Generation from Alpine Glacier Melt, Figure 3 Mount Baker's glacier feed Baker Lake, which is impounded by the Baker Dam hydropower facility.

With recent warming in the area all 47 monitored glaciers have been retreating (Pelto and Hedlund, 2001). The loss in glacier volume in the last 25 years has been 20–40%. In the Baker Lake Basin glaciers provide critical water runoff for hydropower at Upper Baker Dam and Lower Baker Dam (Figure 3). These two Puget Sound Energy projects provide 170 MW. The glaciated area in the basin draining is 29.8 km^2. From July 1 to October 1 the average glacier loses 2.7 m of water equivalent thickness from melting. This represents 80 million m^3 of water. The flow in the Baker River in Concrete (USGS) is 520 million m^3 during this period. Glacier runoff then represents 16% of the total flow during this period, peaking at 24% in August. However, the contribution is larger during dry summers and is higher for Baker Lake, which has a smaller basin area. In a dry year such as 1998 glaciers yielded 110 million m^3 of runoff to Baker Lake, 45% of the basin's total flow (Pelto, 2008). The Skagit River drains the heart of the North Cascades and has Seattle City Light hydropower projects at Diablo Dam and Gorge Dam provide 360 MW and are fed substantially by glacier runoff (Fountain and Tangborn, 1985; Pelto, 2008). In both basins glacier area has been declining significantly since 1979 (Pelto, 2008).

Conclusion

It is apparent that the demand for hydropower is increasing in most alpine region. In many alpine regions glaciers are an important contributor of runoff during the melt season when other water sources are typically at a minimum. This led Canada, Switzerland, and Norway in particular to develop this resource over the last century. Today we see Tajikistan, India, Nepal, Pakistan, Chile, Boliva, Peru and China looking to take further advantage of what has over the last century been a dependable supply of glacier runoff. As glacier area is lost there will be a long term decline in glacier runoff and alpine streamflow during the melt season. This will reduce the hydropower output during the melt season. There is also an expansion in the demand for microhydropower and run of river hydropower projects (Paish, 2002). Both types avoid the issue of large reservoirs, but rely on consistent and dependable flow, which glaciers help foster.

Definition

Hypsometry describes the distribution of elevation of land with respect to sea level within an area of interest, with positive values being above sea level and negative values below sea level.

Quantifying hypsometry graphically

One approach to analyzing hypsometry is to produce a histogram of the frequency of different elevation bins. This simple approach requires a compromise between having bins that are too large such that insufficient detail can be extracted, and too small such that an underlying signal is obscured by noise. Alternatively, a graph of cumulative area (0–100%) with altitude can be plotted to show the relative proportion of a region at a specific elevation, known as the hypsometric curve. The elevations may be normalized relative to the range of elevations in the study area (value-minimum)/(maximum-minimum), and the area under this normalized curve is the hypsometric integral, which by definition lies between 0 and 1. The concept of a hypsometric curve has been widely used in geomorphological studies for many years to characterize drainage basins, with differently shaped hypsometric curves associated with different landscape forming processes and stages of landscape evolution. Hypsometry can be defined over a range of scales from a single drainage basin to the whole planet.

Glacier hypsometry

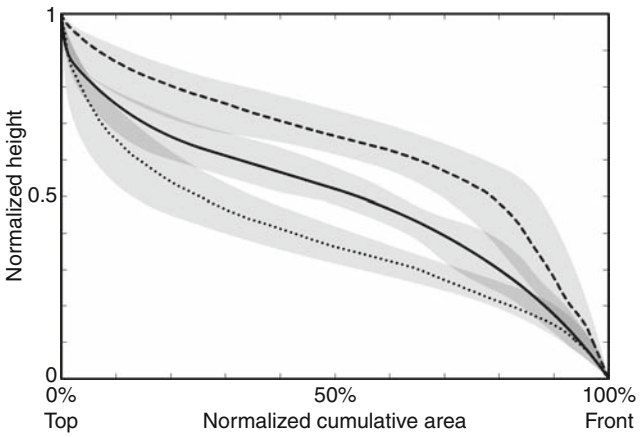
The same principle can be applied to the distribution of the area of an ice mass with altitude, that is, the glacier hypsometry. One of the first people to describe the hypsometry of glaciers and provide a typology for

hypsometric curves was Ahlmann (in Lliboutry, 1956), who defined several types of curves: one for ice sheets, four types for valley glaciers, one for cirque glaciers, and one for piedmont glaciers. These classes were generated by manually calculating glacier areas based upon contour lines.

As an increasing amount of information on surface elevation has become available in digital form, for example from radar and laser altimetry, the construction of hypsometric curves has become more straightforward and they have been derived for many glaciers. One recent source of worldwide (60°N to 56°S) topographic information is the Shuttle Radar Topography Mission (SRTM), available at 90 m resolution outside the USA. This data set is the most recent detailed topographic information for many mountain regions with glaciers, for example, South America, the Himalayas.

Classifying glaciers by their hypsometric curves

From SRTM data, hypsometric curves for glaciers can be digitally derived. In order to classify these curves, they are compared to a theoretical linear hypsometry defined as a model. In this way, three main families of curves are obtained (Figure 1): glaciers with hypsometries above the model (dashed line), glaciers with similar distributions above and below the model (solid line), and glaciers with hypsometries below the model (dotted line). The first type of hypsometric curve (dashed lines) is typical of glaciers with large accumulation areas, located at plateaus surrounded by peaks, from where tongues flow down the valleys, that is, glaciers with predominantly high altitude areas (Figure 2). The second curve (solid line) is associated with glaciers that have similar widths from top to bottom, for example, those located on the flanks of cone-shaped volcanoes. The third curve (dotted line) is associated with piedmont glaciers or glaciers fed by more than one accumulation area whose tongues join at low altitude, yielding a large area at low altitude (Figure 2).



Hypsometry, Figure 1 Main types of hypsometric curves derived from Shuttle Radar Topography Mission (SRTM) data of tens of glaciers with a wide range of areas and types measured in Chile.

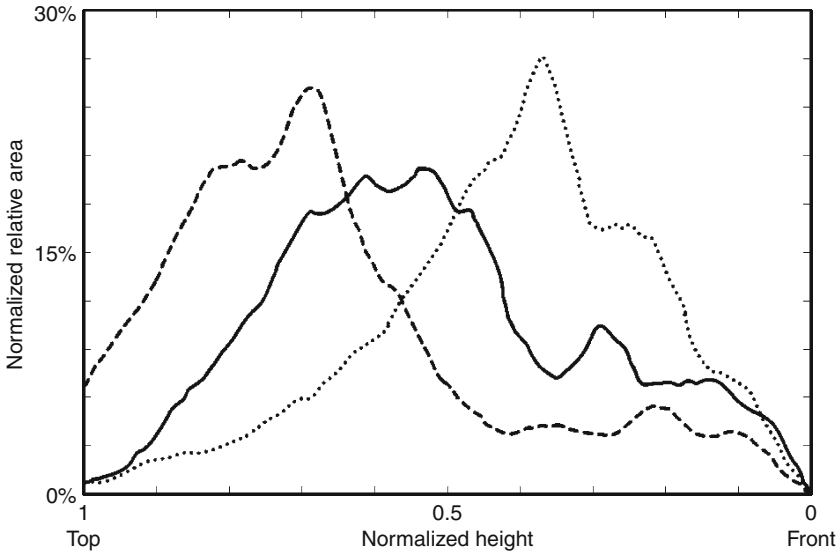
Relationship between hypsometric curve and Equilibrium Line Altitude

The above shapes reveal little about the glacier behavior if they are not analyzed together with the position of the Equilibrium Line Altitude (ELA) of each glacier within the hypsometric curve. Depending on the geometry of the glacier, a small change in the elevation of the ELA might result in a marked change in the areas of accumulation and ablation if a large portion of the glacier is at an elevation similar to the ELA. Conversely if there is only a small area at the ELA even a large change in its height may have little effect. Moreover, two glaciers with an identical ELA may exhibit very different behavior if one has a wide accumulation area with a narrow snout and another has a narrow upper basin and a broad tongue (Furbish and Andrews, 1984). By plotting the ELA on the hypsometric curve, the percentage area in the accumulation and ablation zones of the glacier can be easily calculated, and changes with time constructed. The derived ratio between the accumulation area and the total area of a glacier (accumulation area ratio) is one of the parameters often used to describe a glacier.

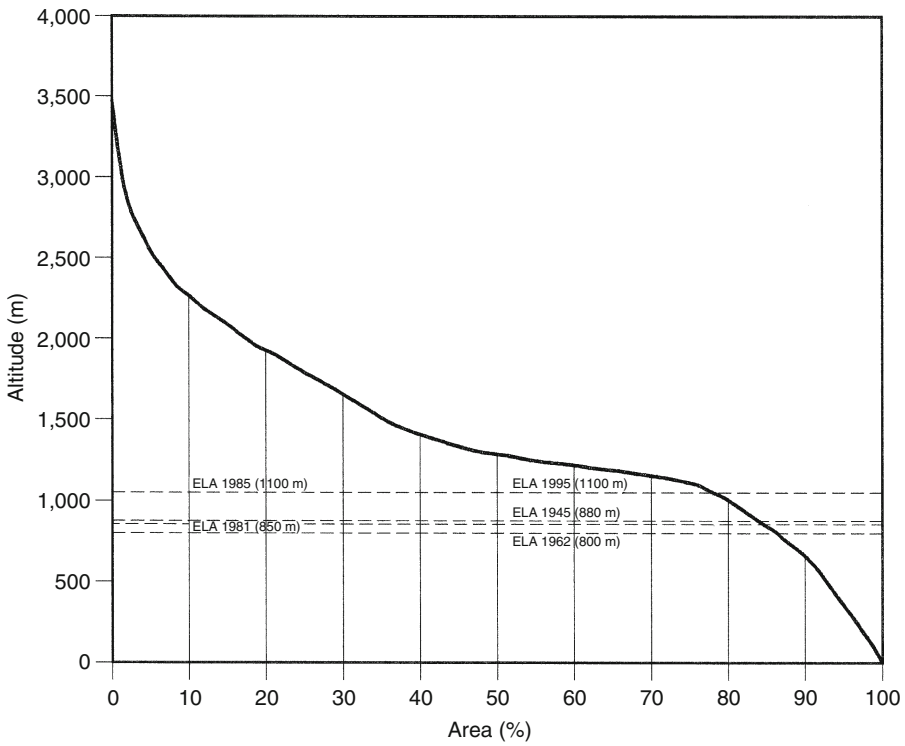
Examples of glacier hypsometric curves

Figure 3 illustrates the hypsometric curve for Pío XI glacier in the Southern Patagonian Icefields of Chile based on a digital terrain model derived from aerial photographs (Rivera and Casassa, 1999). This curve shows a steep slope for altitudes over 2,200 m and less than 1,000 m, indicating relatively small areas of land within these elevation bands. The majority of the Pío XI glacier lies at intermediate heights, especially in the 1,100–1,300 m region where the curve is much flatter (45.2% of the area of the glacier lies between 1,000 and 1,500 m). The ELAs from 5 dates, ranging from 800 m in 1962 to 1,100 m in 1995, are superimposed on the curve showing a general tendency for an increase in elevation over time. For much of this period, the ELA has been confined to the steeper section of the curve (below 1,100 m) so the change in area from accumulation to ablation zone has been small, with minimal impact on frontal behavior. This is one of the reasons why this glacier has been steady or even advancing in recent decades (Rignot et al., 2003). However, regional warming may in the future raise the ELA to a critical position, whereby a small further increase in the ELA may result in a significant loss of accumulation area, with a notable effect on the overall behavior of the glacier.

Comparing the behavior of the Upsala and Moreno Glaciers, also in the Southern Patagonian Icefields, further illustrates the importance of the position of the ELA with respect to the area-altitude distribution. The Upsala Glacier, where the ELA is located in a flat region of the hypsometric curve, has experienced significant retreat in recent decades, with a small increase in ELA due to



Hypsometry, Figure 2 Typical histograms for each main hypsometric curve.



Hypsometry, Figure 3 Hypsometric curve and Equilibrium Line Altitude changes for Pío XI Glacier, Chile (From Rivera and Casassa, 1999).

atmospheric warming resulting in a large decrease in the accumulation area. Moreno Glacier however, with a much steeper hypsometric curve, experienced only small variations in frontal position during the twentieth century and is thus relatively insensitive (up to now) to a rise in ELA (Naruse et al., 1995).

Similar results have been shown by studies on glaciers globally. Oerlemans (1992) illustrated how the large fluctuations, on the order of 4 km, in the front of Nigardsbreen in Norway can be attributed to relatively small climatic changes because of the glacier's geometry, with a narrow tongue fed by a large accumulation area which decreases

markedly in size for a small increase in ELA. On Svalbard, Nuth et al. (2007) found that the glaciers of Prins Karls Forland, with a generally low hypsometric distribution, are generally downwasting, whereas those in Brøggerhalvøya and Oscar II Land with a higher hypsometric weighting are able to maintain their accumulation area.

Oerlemans et al. (1998) further demonstrated the importance of a glacier's hypsometry in understanding its response to climate change by modeling 12 glaciers and ice caps under different climate change scenarios. The authors found that no straightforward relationship between glacier size and fractional change of ice volume was apparent for any given climate scenario, which they attributed to the impact of the hypsometry of individual ice masses on their response.

Reconstructing past glacial conditions from hypsometric curves

The concept of hypsometry is also used to try and reconstruct past glacial limits from estimates of the ELA. Brozovic et al. (1997) postulate that during the Last Glacial Maximum, ELAs in the north-western Himalayan region could have been 600–1,000 m lower than at present, therefore, based on the geomorphological hypsometry, the area above the snowline would have been between 2 and 4 times greater than today, with many areas that are currently unglaciated being under a layer of ice. The hypsometry of glaciated regions can also be used to infer how rates of glacial erosion compare with those of tectonic uplift. Brozovic et al. (1997) showed that the hypsometries of glaciated landscapes around Nanga Parbat are correlated with the snowline elevation and independent of rates of rock uplift, thus indicating that glacial erosion rates can match, and exceed, uplift with climate dominating the evolution of the landscape.

Conclusion

By definition, hypsometry is a single statistic or curve which attempts to quantify a region, and this can be an effective way in which to assess the impact of glaciers on the landscape and their response to change. As concluded by Beedle et al. (2008), using accurate glacier outlines and hypsometries is essential for understanding glacier mass balance, volumetric change, the contribution of ice masses to sea level rise, and relationships between ice masses and climate. However, the hypsometric curve alone cannot explain ice dynamics, the impacts of volcanic activity, and the role of other localized features within individual basins, such as hanging valleys, narrow outlet gorges, or nunataks (rock outcrops surrounded by ice), all of which may also affect the behavior of a glacier. Thus, it is recommended by Brocklehurst and Whipple (2004) that hypsometry should not be used in isolation when assessing glaciers and glaciated landscapes.

HYSTERESIS

Vijay Kumar
National Institute of Hydrology, Roorkee, India

Hysteresis is a phenomenon in which the response of a physical system to an external influence depends not only on the present magnitude of that influence, but also on the previous history of the system. Expressed mathematically, the response to the external influence is a doubled-valued function; one value applies when the influence is increasing, the other applies when the influence is decreasing. It is derived from the Greek word "husteros" which means slow, lagging behind or delayed.

In hydrology, the river discharge, soil moisture tension, solute concentration, and suspended sediment concentrations experience the hysteresis phenomenon. Hysteresis in river discharge occurs during unsteady flow when the water surface slope changes due to either rapidly rising or rapidly falling water levels in a channel control reach. Hysteresis is most pronounced in flat sloped streams. On rising stages, the water surface slope is significantly steeper than for steady flow conditions, resulting in greater discharge than indicated by the steady flow rating. The reverse is true for falling stages. When a flood wave passes down a river channel and through a given cross section, the effect of the wave front when upstream of the cross section is to increase the velocity of approach at the cross section. When the flood peak passes into the reach downstream of the cross section, the rear of the wave increases the backwater conditions and so reduces the velocity at a given discharge at the cross section. Consequently, for the same stage, the discharge is higher during rising stage than during falling stage.

The relationship between soil water content and soil water tension also exhibits hysteresis. Soil water tension at a given soil moisture content depends on the sequence of events of wetting and drying by which the current water content of the soil is attained. For the same soil water content, the soil moisture tension of a drying soil is greater than that of a wetting soil.

Solute concentration tends to be higher on the rising than on the falling limb of a flood wave as a result of the mobilization of soluble material that has accumulated during the pre-storm period, producing a looped trend or clockwise hysteresis in the relationship between concentration and discharge (Walling and Webb, 1988).

Suspended sediment concentrations generally show clockwise or positive hysteresis loops. Suspended sediment concentrations on the rising limb of a storm hydrograph are higher than those measured at equivalent flows on the falling limb. Hence, sediment concentrations typically reach their maximum prior to the hydrograph peak. This effect is caused by, among other factors, sediment depletion in the channel system or the increased portion of the baseflow during the recession limb. However, anti- or counterclockwise hysteresis can occur. This is probably due to bank collapse or sediment originating from distant sources (Baca, 2008).

Definition

Solid phase of water.

Introduction

Natural behaviors on the surface region of the Earth depend on the abundance of solid, liquid, and vapor phases of water and the dynamic variations of Earth's environments involving the phase transitions. When the liquid water is frozen under usual atmospheric conditions or water vapor is deposited at temperatures below 0°C and above about −80°C, the water molecules are arranged in orderly repetitive positions to form a crystalline solid with hexagonal symmetry, which is referred to as normal hexagonal ice, namely ice Ih. Though the ice Ih is only one of at least 13 crystalline phases, which have been observed under different conditions of pressure and temperature, it is the most important and popular phase appearing in the terrestrial and planetary conditions.

The properties of ice should be recognized into two stages, because of the wide scale of the molecular-level to the terrestrial-level ice substance. The crystallographic structure of ice links to the arrangements of water molecules and the properties of single crystals, but on a large scale, ice is always a polycrystalline substance and the mechanical properties of ice are dependent on this polycrystalline structure.

Many books have been published to describe the general information of ice physics (Fletcher, 1970; Hobbs, 1974; Petrenko and Whitworth, 1999; Lock, 1990). The International Conference on Physics and Chemistry of Ice have been held every 4^5 years since 1962. The last conference was held in Japan in 2010 after the conference at Germany in 2006. The next conference will be held in Hanover, New Hampshire, USA in 2014.

Structures and physical properties of ice Ih

The water molecules are arranged in orderly repetitive positions to form a crystalline structure with hexagonal symmetry, which is referred as hexagonal ice, ice Ih, or simply ice. Figure 1 shows the crystalline structure of ice Ih. The oxygen atoms, shown by the open circles, are arranged on a hexagonal lattice with a structure named after the mineral Wurtzite, which is the hexagonal form of ZnS. Each oxygen atom has four nearest neighbors at the corners of a tetrahedron and are covalently connected to each other by a hydrogen bond. The hydrogen atoms, shown as a dark spots, are located on the alternative site of two possible hydrogen sites on each bond to form H_2O molecules in the crystal lattice. A statistical model for the disordered arrangement of the hydrogen atoms in the crystalline lattice of ice Ih is ruled by the assumptions referred as the Bernal–Fowler rules (or ice rule), which are (1) there are two hydrogens adjacent to each oxygen; (2) there is only one hydrogen per bond. As a result, the disordered structures for the orientations of water molecules are realized in three dimensions.

The phase diagram for the equilibrium between ice Ih and the liquid and vapor phases is illustrated in Figure 2. The triple point, where the three phases coexist in equilibrium, is at 273.16 K and 611.7 Pa. As an unusual feature, the ice melting point curve (the boundary between ice and water phases) has a negative slope with increasing pressure and the melting point reach 273.15 K at atmospheric pressure, and this value is taken as the zero degree of the Celsius scale of temperature. The negative slope of the melting curve conduces to the fact that ice floats on water

and vessel and pipe are broken by freezing of ice, the pressurized wire goes through the ice (so-called regelation), etc. This expansion is also very important for the special benefit of the birth and evolution of the terrestrial creatures.

Ice indicates the dielectric and conductive properties and which are unusual and strongly relate how water molecules turn round or protons flow through the crystalline lattice, rather than the molecular arrangement and lattice vibrations of ice crystal. For example, ice exhibits a high static relative permittivity that is comparable to that of liquid water. To explain the electric properties of ice, we have to assume the deviation from the simple ice rules for the proton positions and various types of defects included in the ice crystal lattices.

Ice crystalline structure contains many kinds of point defects, dislocations, and planer defects. For the point defects, there are several categories in ice: molecular defects, impurity defects, electronic defects protonic defects, and combined defects. Dislocations in the ice structure are formed during the growth and the plastic deformation of ice crystal and can be directly observed by X-ray topography. Since the crystal structure of ice consists of (0001) planes of molecules stacked above one another, the stacking fault can be easily introduced as a planer defect normally lying on a (0001) plane.

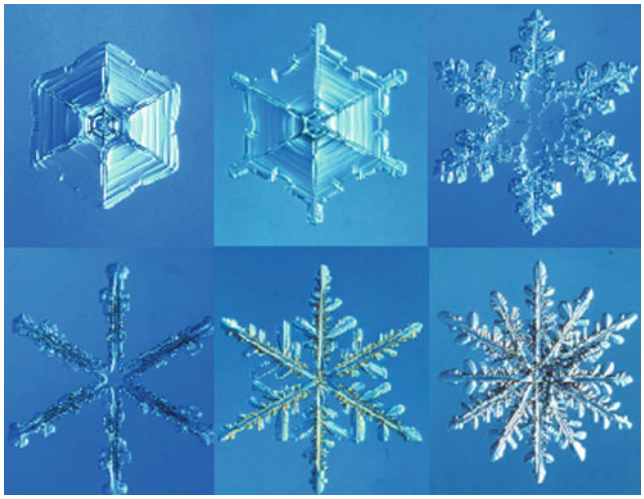
Many of the mechanical properties of ice are determined by line defects or dislocations in common with other crystalline materials. It is well known as the most typical property that the ductile to brittle transition with increasing strain rate is observed. Plastic deformation of single ice crystal mainly occurs by the slip on basal planes. Furthermore, the plastic deformation of polycrystalline ice is also very important in relation to the glacier flow, the Antarctic ice flow, and so on.

Surface properties of ice crystal

It is well known that the ice surface is covered by the thin melted liquid film, which is so-called the quasi-liquid layer or the liquid-like layer, at the temperature range close to the melting point. This phenomenon relates to the surface melting (a kind of first-order phase transition) commonly occurring on the surfaces of various crystalline materials. The process of surface melting begins at a temperature below the melting point of bulk ice. It is due to the weaker binding of the surface water molecules, which are thus more susceptible to thermal disorder than the bulk interior. Further temperature increases lead to breakdown of the surface layers and an increase in the defect density; hence, the water molecule mobility increases. This mobility eventually becomes the same as in the bulk liquid phase, and finally the liquid film thickness becomes arbitrarily large at the melting point. The existence of the melting layer on ice surface relates to various phenomena that occur in the cold climate on the Earth, such as the snow crystal formation, the thunderstorm lightning, the frost heaving, the chemical reaction on ice surface, and so on.

Ices under the nonequilibrium conditions

Ice crystals grow or melt under the nonequilibrium environments of temperature or saturation. Especially the crystal growth of ice is very important in relation to the formations of snowflakes, sea ice, and lake ice. Beautiful patterns of snowflakes with the hexagonal symmetry are formed by their continuous growth from the supersaturated



Ice, Figure 3 Pictures of natural snowflakes.

Ice, Figure 4 A picture of ice crystal grown from supercooled water (D_2O) under the microgravity condition in the International Space Station (ISS). Only three branches of a hexagonal dendrite can be formed, because the crystal is grown at the tip of thin glass capillary (*right edge*).

water vapor in the atmosphere. Figure 3 shows some pictures of natural snowflakes that were taken in central area of Hokkaido, Japan. Ukichiro Nakaya of Hokkaido University, Sapporo was led to start his research of snowflakes in 1932. He classified the snowflakes in about 40 categories of morphology by observing more than 3,000 natural snowflakes within several years, and subsequently succeeded in producing almost all natural snowflake morphologies in the laboratory (Nakaya, 1954). As a result, he elucidated the relationship between the snowflake morphologies and the atmospheric conditions, i.e., the temperature and the supersaturation of atmosphere. His results are summarized in the so-called Nakaya diagram, which allows one to "read" the meteorological information "written" on a snow crystal, because we can infer the weather conditions in the upper air by observing snow crystal morphologies on the ground. In this sense, Nakaya was often quoted referring the snow crystal as "a letter from the sky." The growth of snowflakes is strongly controlled by the surface kinetics, which is the incorporation process of water molecules from the vapor phase to solid phase at the surface. The habit change of snowflake morphology (change between the plate-like and prism-like morphologies) occurring as a function of temperature relates to anisotropic surface melting of ice and the secondary change (from the stable to unstable growth modes) can be explained as the morphological instability. A beautiful review about the formation of snowflakes was given by Kobayashi and Kuroda (1987).

An ice crystal growing in supercooled water changes from circular disk to perturbed disk and finally to developed dendrite with the hexagonal symmetry. Properties of pattern formation are completely different from those of snowflake. The morphological instability occurs at the edge plane on ice disk immediately after its thickness reaches a critical value and then continues to the development of perturbation along the edge plane. Understanding the pattern formation mechanism of ice crystal with these discriminative properties is a new perspective for the general studies of pattern formation and morphological instability based on the anisotropic kinetic effects between the basal and edge planes. In the period from December 2008 to March 2009, microgravity experiments of ice crystal growth in supercooled water were carried out in the International Space Station (ISS) to clarify the mechanism of morphological instability of ice. Figure 4 shows a picture of dendritic ice crystal grown in the KIBO module of ISS. These pictures are very useful to discuss the growth and pattern formation mechanisms of ice.

Summary

Ice is the most important material in relation to the various phenomena in the cryosphere. The physical properties of ice were summarized briefly in this article. Especially, it is to be emphasized that the phase transition dynamics among the vapor, liquid, and solid was important to understand the mechanisms of natural phenomena in the cryosphere.

ICE AGE

Matthias Kuhle
Department of Geography and High Mountain Geomorphology, University of Göttingen, Göttingen, Germany

Synonyms

Glacial epoch; Glacial period; Glacial time; Pleistocene epoch; Pleistocene (ice ages); Period of global Pleistocene glaciations; Quaternary period; Quaternary (ice ages)

Definition

Period of the earth history with global cooling (climatic deterioration) and a vast extent of the glacier cover. An Ice Age Era is a period of time with alternating changes between cold glacials and warm interglacials, that is, rhythmic glaciations.

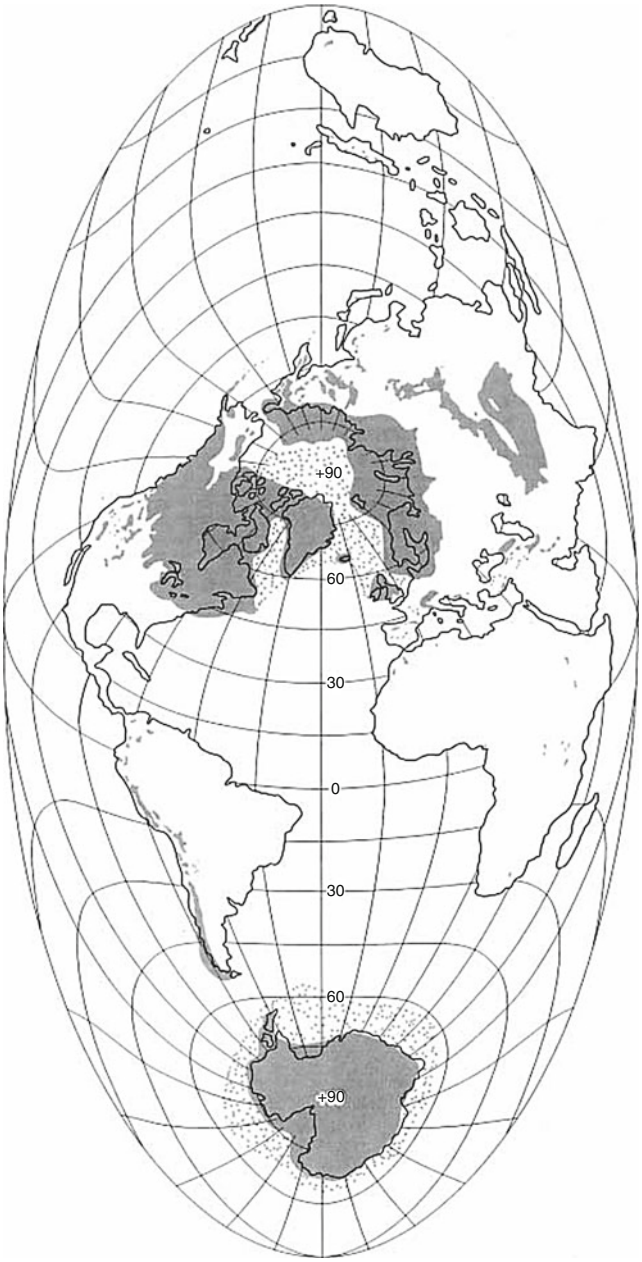
Within an Ice Age, relatively short climatic oscillations can be evidenced by glacier stagnations, small ice retreats, or small advances called interstadials (interglacials), that is, stages (stades).

Introduction

The term "Ice Age" refers mainly to the era of the earth previously called Diluvium, namely to the Pleistocene, that is, the Quaternary ice age. Up to now the beginning of the Quaternary ice age has not been established definitely by a paleontological, that is, biogenetic limit. In consideration is the time mark of the sudden global trend toward increased ice volume that set in about c. 3–2.6 million years BP (Ehlers and Gibbard, 2003) or the beginning of the period with a maximum ice volume before c. 1 (1.3–0.8) million years (Tiedemann et al., 1994). The cooling, however, started already in the Pliocene. For the Last Ice Age (W-ice age: Würm, Weichsel, Waldai (or Valdai), Wisconsin), a maximum ice extent of at least 45 million km² is accepted; for the previous to Last Ice Age, the Riss Glacial, the ice extent was at least 50 million km². These ice extents are roughly three times as great than the current glacier face of c. 15.3 million km² of which the Antarctic alone is 82%. This corresponds to c. 89% of the ice mass on the earth (~25–30 million km³ ice: c.f. Ingólfsson, 2004). During the Würm ice age, these glacier faces covered at least 29% and during the Riss ice age at least 33% of the mainland, while at present only c. 10% is ice-covered (see Figure 1).

Würm ice age

Because of the short interval and the combined best preservation of glaciogeomorphological- and -geological evidences, the Last Ice Age, the Würm ice age, is best known. It is dated to MIS (Marine Oxygen Isotope Stage) 4– or 3–2 (cf. Ehlers and Gibbard, 2003). There existed a north-European inland ice sheet that reached down from the Scandes, the High Mountains of Scandinavia, up to the northern Middle Europe to the south (Ehlers et al., 2004). The glacier ice flowed down to the northwest, to the Norwegian coast forming fjords there. To the south, the inland ice filled and crossed the basin of the Baltic Sea up to north Germany, Poland, and Russia (among others, Boulton et al., 2004). During the Brandenburger Stage, that is, about 20–18 Ka, the Würm, that is, Weichsel ice reached its greatest extent in the north-German lowland. For comparison: on its S-margin, the Riss ice (= Saale ice age) in Germany was still further extended, namely up to the low mountain ranges (among others, Liedtke, 1981). In the basin of the current North Sea, there existed a controversial glacier confluence of the Scandinavian inland ice with that of the British Isles, built up from the mountains of Scotland, Great Britain, Ireland, and Wales (Clark et al., 2004). In the east of Scandinavia, the exact measurement of the extent of the North-Siberian inland ice was still in progress. It was connected through the Barents Sea part of the Kara ice sheet. Thus, it stretched from the Kola Peninsula in the west up to approximately the Wrangel Isle and the Bering Strait in the east (Arkhipov, 1998; Astakhov, 1998; Grosswald, 1998) (see Figure 1). In the older literature before 1984, only mountain glaciations, for example, in the Verkhoyansk



Ice Age, Figure 1 Maximum extent of glaciated areas during the LGM, based on an equal-area projection. Continental ice is indicated by a dense, marine ice by a sparse signature. Based on Broecker and Denton (1990), modified after Kuhle (among others, 1974, 1987, 2004a, b).

mountains (Kolpakov and Belova, 1980), the Koryak highlands, and the eastern Chukotka (Degtyarenko, 1984), were considered as being certain (Zamoruyev, 2004). From the North Cape in Scandinavia, a uniform ice surface across a connected ice shelf up to the ice cap of Spitsbergen at 80°N is under discussion (Svendsen et al., 2004) (see Figure 1). In several European high mountains, as, for example, the Alps, valley glacier systems have developed that converged into ice stream networks. Their lowest ice margins even left the mountain valleys and – for example, in the north- and west-foreland of the Alps – formed a connected, lobe-shaped piedmont glaciation (Penck and Brückner, 1901–1909; Fiebig et al., 2004; Buoncristiani and Campy, 2004). But also, other lower mountains of Europe showed ice caps or valley and single glaciers, for example, the Pyrenees and further mountains of the Iberian Peninsula, the Cévennes, Corsica, the Durmitor Mountains, the Vosges, the Black Forest, the Harz, the Riesengebirge, and many others.

From south Siberia at c. 53°N, with the Sayan and Transbaikal Mountains, a bridge of mountain glaciations existed in Central Asia, for example, in the Altai and Tienshan, as well as greater ice caps in Mongolia and on the Tienshan Plateau between Kungey Alatau and Terskey Alatau as far as high Asia (Kuhle, 2004a; Sheinkman, 2004). The ice stream networks of Pamir, Hindukush, Altun Shan, and Nanshan were connected to the Tibetan inland ice. In the north, the Tibetan ice sheet was connected over a length of c. 2,000 km with the ice stream network of the Kuenlun. In the south up to the southwest, it was fringed by the 2,500 m-long cornice of the connected ice stream networks of the Himalaya and Karakorum. On this highest and largest global mass uplift that currently shows permafrost and the still today greatest non-arctic glaciation, a subtropic glacier face of c. 2.4 million km² existed during glacial times (Kuhle, 1987, 2004a; Zhou et al., 2004).

In North America, the Laurentide ice sheet was built up from Labrador facing southwest. This inland ice merged with the ice stream network of the Rocky Mountains situated to the west and reached c. 37°30′N with the S-margin (see Figure 1) (among others, Dyke, 2004; Hughes, 1998). From the Greenland inland ice – which was not enlarged compared to the current ice on a large scale (Funder et al., 2004) – a broad ice bridge led via Ellesmere Island to the North American ice sheet (see Figure 1).

Numerous mountain systems in the tropics and subtropics, for example, the Andes, wore ice caps or had ice stream networks and dendritic valley glacier systems, for example, the Aconcagua group and adjacent massifs in the Mendoza Andes (Kuhle, 2004b); but in addition to the larger glaciers, there were also hanging glaciers, for example, in Ecuador, Peru, Bolivia, Colombia, Costa Rica, Guatemala, Chile, and México (Mark et al., 2004; Heine, 2004; Lachniet, 2004; Helmens, 2004; Harrison, 2004; Vázquez-Selem and Heine, 2004). Also glaciated were Malaysia and Indonesia (Hope, 2004), Papua New Guinea (Peterson et al., 2004) as well as the Iraq mountains (Wright, 2004), and the southeast Iranian mountains in the Zagros (Kuhle, 1974, 1987, 2007). In spite of semi-arid conditions, even a small piedmont glaciation occurred there. Smaller valley glaciers and larger and smaller hanging glaciers developed in the northwest- and east-African mountains, as, for example, in the Mount Kenya massif (Mahaney, 2004), on Kilimanjaro, Ruwenzori (Osmaston, 2004), and in the

Ethiopian mountains (Umer et al., 2004). Apart from those cited above, large LGM-ice faces of the outer tropics (ektropics) have been reconstructed in Patagonia (Coronato et al., 2004), on Iceland (Geirsdóttir, 2004), and on South Island in New Zealand (Suggate, 2004). Also important is the strong Ice Age valley glaciation of the Caucasus with glaciers up to 70 km in length and an ELA-depression of 1,200–1,300 m (Gobejishvili, 2004). Mountain glaciations up to the dimensions of valley glaciers are also reconstructed for Japan (Sawagaki et al., 2004). Obviously, the Antarctic Last Glacial Maximum ice sheet was much larger and the peripheral domes were 500–1,000 m thicker than at present. The grounding line positions during the LGM and later in the initial ice retreat during the Late Glacial were probably eustatically controlled (Ingólfsson, 2004).

Glacier traces as evidences of a past ice cover

The glacier cover left a lasting effect that has changed and modified the surface forms of the respective sections of continents and mountains. The whole glacier reconstruction and evidence of the Ice Age extent of glaciation is based on this observation. In many places, the debris abraded in the catchment, and source areas of the Ice Age glaciers were transported far away and deposited at a great distance from the place of erosion as accumulation of clast, that is, as moraine. In the areas of removal that in many places are mountainous, cirques, trough valleys with polishings (smoothings and glacier striae), and other characteristic traces of exaration in the rock can be observed; also, polish basins and polish thresholds, roches moutonnées, and glacially streamlined hills, as well as truncated spurs etc., are key forms of glacial erosion. As for the accumulation areas far below the snowline (ELA), flat plates of ground moraine (influenced by permafrost) or drumlins and drumlin fields (in ground moraine areas in the permanent thawing layer) are characteristic; further key forms are tongue basins lined by lateral and end moraines in which dead ice kettles (Sölle) may occur. The development of meltwater that already sets in subglacially led to meltwater channels and eskers (osar), as well as outside of the glaciers to meltwater lakes. In the lateral valleys between glacier margins and valley flanks, kames have been heaped up and within them, between lateral moraines and valley flanks, lateral sanders were accumulated. Marginally, as well as downward and increasingly outside the lowest glacier margins and end moraines, sanders have accumulated and Pleistocene watercourses (Urstromtäler) formed by the meltwaters coming out of the glacier snouts. The sanders canalized by the mountain valleys, as well as those accumulated on a large scale in form of a fan in the mountain forelands and flat lands, developed during the climax of the ice ages when the precipitation was less prevalent, because at that time the meltwater rivers were overloaded by the supply of moraine debris. Towards the end of the Ice Age, in the Late Glacial, the meltwaters cut up the sanders, whereby terrace landscapes were developed. In many places of the High Glacial glacier tongue basins, lakes formed in the still water of which the meltwaters from the already back-melted Late Glacial glacier tongues deposited rhythmically layered banded clays (varved clays). All of these indicators can unambiguously be diagnosed and are arranged in a compelling physical-functional position to one another (Kuhle, 1990). Only the isolated instances, as well as their spatial connection could render the reconstruction of the Ice Age glacier cover possible.

Characteristic of the further vicinity of the Ice Age glaciers and inland ices are phenomena that can be classified as periglacial occurrences, such as permafrost, frost debris, patterned (polygonal) grounds, cryoturbation, rock glaciers, block fields, solifluction (gelifluction) etc. The development of eolian forms as, for example, loess is also typical of the fringe area of Ice Age glaciers.

The Cold Ages in the non-glaciated areas of the earth

The subtropic arid areas, as well as the varying-humidity tropics were more extended than today, so that the areas of the tropic rainforest were heavily reduced. Only in a few regions such as North Africa, was precipitation clearly higher than nowadays. In the Sahara, this led to pluvial periods.

In contrast to the terrestrial deposits, which due to discordances are full of gaps, absolute datings by means of deep-sea sediments have been attempted. According to at least some regions, a complete sequence exists to which the variations of the $^{16}O/^{18}O$-relation in the calcareous shells of sedimented marine fossils can be assigned. It is not so much the life conditions of those organisms (sea animals) that allow us to draw conclusions as to the accompanying climate conditions, but rather the temperature-dependent abundance ratio of the stable oxygen isotope ^{16}O and ^{18}O in the sea water and in the calcareous shells of mostly foraminifers according to the Emiliani-curve. In connection with other dating techniques, evidence for the change of more than 20 interglacial and glacial ages have been obtained from this isotope relation. For the inland ices of the Antarctic and Greenland, comparable courses of the temperature have been extracted for the last c. 100 Ka by means of bore samples. Today, however, they can only partly be parallelized with the global terrestrial incidents.

During the Würm Ice Age, the development of terrestrial ice masses led to a eustatic depression of sea level of 80–130 m (among others, Flint (1971). For the Riss Ice Age, up to 200 m are quoted. The interference of eustatic uplift of the sea level during the Late- and Postglacial with a glacio-isostatic, as well as primarily tectonic elevation of land, led to the emergence of various high shore terraces on the graded shores and river deltas, as well as steep coasts worldwide.

Ice Age climate

The lowering of the average annual temperature on the continent compared to today was 4–15°C, but also values of 18°C – and in extreme continental regions still higher values of lowering – are indicated. The surface temperature of the oceans was about 4–7° lower. The depression of the snow-line (ELA) reached c. 1,000–1,200 m worldwide and locally, as in the today arid areas of the Andes, for example, in the Aconcagua massif, or on the northern hemisphere in the Zagros mountains and in the Karakorum (Kuhle, 1974, 2004a, b; Wright, 2004), and also in the European Alps 1,300–1,500 m (Penck and Brückner, 1901–1909). On the Himalayan south side, the Würmian ELA-depression even amounted up to 1,630 m. According to the specific humid conditions of that time, this corresponds to a depression of the average annual temperature of c. 8–10°C (Kuhle, 2005). For the Last Glacial, the temperatures of January at the Ice Age sea level in Central Europe have been calculated to be −14 to −22°C; for the temperatures of July, between +5°C and +10°C have been deduced. The basis of reconstructions like these is the shifting of the northern limit of forest growth to the south of the European Alps. Between the Alps and the southern margin of the inland ice, there existed the dwarf shrub vegetation of a frost debris tundra. It was occupied by the typical cold-accustomed Ice Age fauna with mammoth, woolly rhinoceros, bison, cave bear, Arctic fox, and lemming (among others, Woldstedt, 1961–1965; Kahlke, 1994). According to the vegetation, the interglacial climate largely corresponded with the current conditions. In the course of the Quaternary, however, it became somewhat cooler and drier.

Homo sapiens

The influence of the Ice Age on the Paleolithic (Old Stone Age) man and its cultures is evident. The deterioration of the climate led to a shifting of his habitat. While in northern Europe the ice cover restricted the usable land, the depression of sea level and the dewatered shelf areas widened the possibilities of man to use sea-animals near to the coast-like mussels and sea mammals, but also fishes. Due to the land bridges created by the depression of sea level, the settlement of America via the Bering-Street and of the southeast-Asian islands, as well as Australia was made feasible.

Pre-quaternary Ice Age eras

The oldest traces of glaciation evidenced by glacier polishings and abrasions, as well as tillites date from the older Precambrian system (c. 2.3 billion years BP) from North America and South Africa. c. 2 billion years ago (Eokambrium), a further longer glaciation period existed with a greater extent of ice. Again for South Africa but also in North Africa (Sahara), an Ordovician-Silurian glaciation has been proved. Known by the largest glaciation surfaces that have been evidenced is the Permo-Carboniferous glaciation (among others, the Dwyka-group), which coincided with the beginning breakage of the Gondwana-continent.

Beginnings of the history of research

About 1815 J.-P. Perraudin, a Swiss mountaineer from the Val de Bagnes, expressed his conviction that in past ages the alpine glaciers were extended up to clearly beyond their current termini. About 1818, the highway engineer I. Venetz, whom Perraudin met in the Val de Bagnes (Imbrie and Imbrie, 1979), and later on also J. G. de Charpentier during a mountain trip in the Walliser Alps (Kahlke, 1994), heard about Perraudin's interpretation of an earlier glacier extent reaching at least 5 km further down-valley. On a meeting of the Swiss Society of Natural Sciences in Luzern, 1834, de Charpentier reported about the opinion of Perraudin, which he had completed in the meantime (Kahlke, 1994). In 1836, during field excursions from the Alps up to its forelands, Venetz and de Charpentier convinced L. Agassiz that numerous forms in the field must have been shaped by past glaciers, even in the flatland. In 1937, Agassiz lectured on "The Theory of a Great Ice Age" during the meeting of the Swiss Society of Natural Sciences in Neuchâtel (Imbrie and Imbrie, 1979). In his publication 3 years later (Agassiz, 1840), he extended this theory to all regions in which erratic boulders had been observed, thus postulating an Ice Age for northern Europe. Later, he postulated an ice filling of the Amazon basin.

Summary

The (Quaternary) Ice Age was a period of global cooling of the climate with large areas of glaciation that were approximately three times more extended on the continent than the current terrestrial ice areas. Due to the chronological nearness and the modification of older glacier traces during the Last Glacial, the reliable state of knowledge as to the Last Ice Age is the most extensive, so that the findings of the Würmian glacier extent provide a valid example for the Ice Age glaciation on the whole. The geomorphological and Quaternary-geological method, that is, the decoding of the arrangements of the positions of landforms (topography) and sediments caused by glacier ice and its dynamics, is the scientific basis of Ice Age reconstruction. The Ice Age climate has been primarily deduced from the reconstructed past glaciation. The climate changes associated with synchronous cold ages in the non-glaciated areas of the earth are also understandable by the secondary global cooling that was strengthened by the feedback of the glaciations.

ICE AGE CYCLES: DATA, MODELS, AND UNCERTAINTIES

Donald Rapp
South Pasadena, CA, USA

Definition

Measurements that indicate the occurrence of alternating cycles of heavy glaciation and deglaciation on Earth, theories that attempt to explain such occurrences, and uncertainties remaining in these explanations.

This chapter is based on the book by Rapp (2009), which includes several hundred relevant references.

Introduction

Polar ice core data and ocean sediment data provide convincing evidence that Earth has experienced periodic heavy glaciation (ice ages) a number of times over the past few million years. While we tend to think of the present

climate as "normal" and ice ages as deviant, the data suggest that over the past million years, ice ages had longer durations than interglacials. Hence, it might make sense to think of the ice age as a "normal" climate for Earth at this juncture, and an interglacial as a deviation from normalcy.

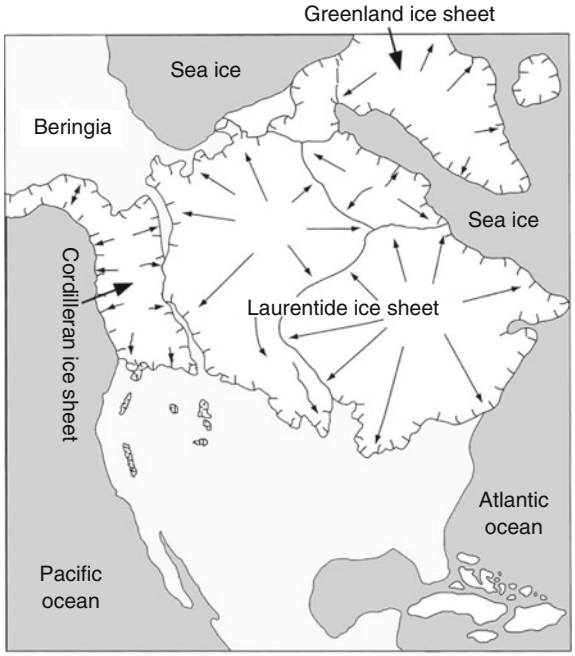
During the last glacial maximum some 20,000 years ago, Canada and the Northern U.S. were blanketed by huge ice sheets up to 4 km in thickness. In addition, there was a large ice sheet covering Scandinavia that reached down into Northern Europe. The Antarctic ice sheet was somewhat more extensive than today. Local glaciations existed in mountainous regions of North America, Europe, South America, and Africa driving the tree line down by up to 700–800 m. The temperature of Greenland was lower by up to 20°C, but the climate was only a few degrees colder than normal in the tropics.

These ice sheets tied up so much of the Earth's water that the oceans were as much as 120 m shallower. As a result, the shorelines of the continents moved outward by a considerable distance.

The sharp temperature discontinuity at the edges of the ice sheets created convection currents producing violent vertical winds that swept up dust and dirt from dry regions, filling the atmosphere with dust.

This ice age began to wane around 15,000 years ago, and dissipated through a series of gyrating climate oscillations, ending in a comparatively benign period that has lasted for the past ~10,000 years, called the Holocene.

Evidence indicates that the ice sheets did not originate near the North Pole. Formation of ice sheets requires moisture and a land base on which snow and ice can accumulate. Thus the centers of ice sheet generation occurred at upper-middle latitudes, typically around 60–70°N (see Figure 1).



Ice Age Cycles: Data, Models, and Uncertainties, Figure 1 Formation of ice sheets at upper latitudes during the last ice age (Rapp, 2009).

Data

Geological evidence

A few geologists of the nineteenth century noted the presence of large boulders with characteristic scratch marks in the Swiss Alps, as well as scratch marks on the walls of rock in mountains, and suggested that these may have been generated by huge ancient glaciers that covered the mountains. The three main sources of evidence were: (1) grooves and scratches on rocks in place, and on boulders shoved along under the ice, (2) extensive unstratified deposits known as "till" traceable to glacier action, and (3) transported material (typically large rocks) that could only have been delivered by ice (not water).

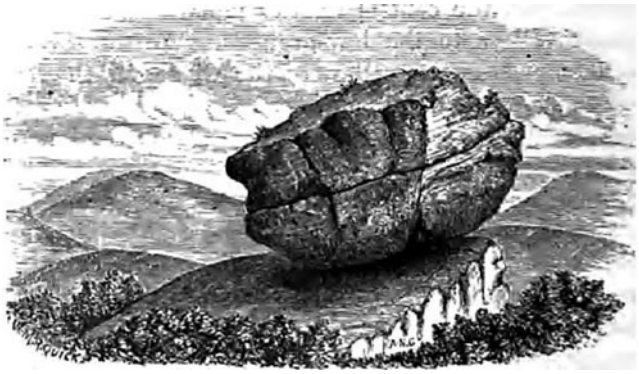
Louis Agassiz was the principal proponent of the ice age theory, but it took many years to gain acceptance. Imbrie and Imbrie (1979) described this history in their classic book. Prior to the implementation of ice core drilling and use of sediments to infer historical temperatures tens or hundreds of thousands of years ago, geologists had to rely on their observations of rocks and strata for guidance. Wright (1920) discussed the geological evidence for ice ages in great detail. He provided Figures 2 and 3 that are just two of many examples of the effects of the gigantic ice sheets. By the latter part of the nineteenth century, it was well established that ice ages had occurred, and scientists were already conjecturing on possible causes.

Polar ice core isotopic evidence

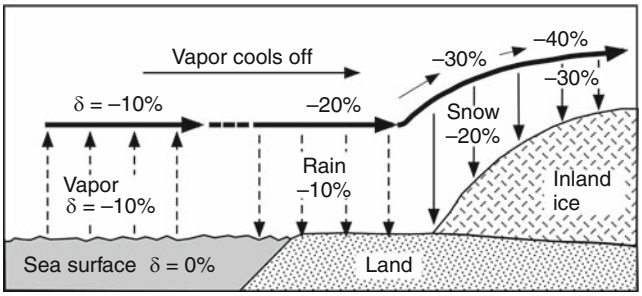
Willi Dansgaard is a Danish scientist who is credited with the original idea for using ice cores for probing temperature changes over the past thousands of years. His book provides a very interesting history of the early evolution of this technique (Dansgaard, 2005).

While 99.99% of water is $H_2{}^{16}O$, other forms, particularly $H_2{}^{18}O$ and the $HD^{16}O$ occur in concentrations of about 2,000 and 320 ppm (parts per million), respectively. When water evaporates, a higher concentration of the lighter form of water appears in the water vapor, and conversely, when water vapor condenses, there is an increase in the concentration of the heavier form in the product liquid compared to the original vapor. These processes are temperature-dependent.

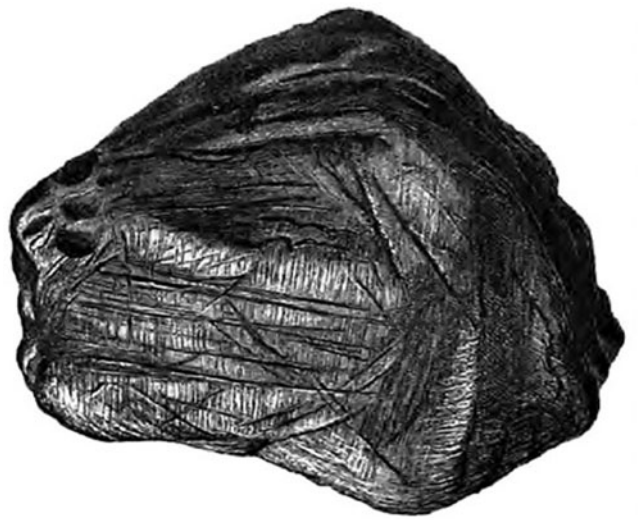
Dansgaard developed the model shown in Figure 4 for northern climes. Water evaporates from the sea with depleted ^{18}O. As the clouds move toward the shore they cool, and as rain continues to fall, the remaining water vapor in the clouds is further depleted in ^{18}O. Thus as the water-bearing clouds move inland, they cool ever



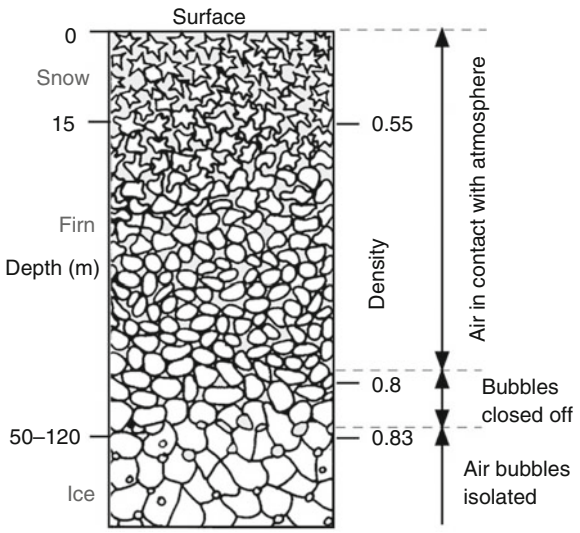
Ice Age Cycles: Data, Models, and Uncertainties, Figure 2 Erratic stone (Wright, 1920).



Ice Age Cycles: Data, Models, and Uncertainties, Figure 4 δ-changes (isotopic fractionation) in vapor and precipitation by evaporation from the sea and precipitation from a cooling air mass during its move toward higher latitudes and/or higher altitudes (adapted from Dansgaard, 2005).



Ice Age Cycles: Data, Models, and Uncertainties, Figure 3 Scratched stone (Wright, 1920).



Ice Age Cycles: Data, Models, and Uncertainties, Figure 5 The sintering process as snow is converted to firn and then on to ice with bubbles of air entrapped (Adapted from: http://www.csa.com/discoveryguides/icecore/review.php).

more, and the depletion of ^{18}O continues. The snow that accumulates on the ice sheet above the land is depleted in ^{18}O in proportion to the general climatic temperatures prevailing.

The accumulated past snowfall in the polar caps and ice sheets provides a basis for paleoclimatic reconstruction. These are referred to as ice cores even though strictly speaking there is typically a combination of snow and ice. Somewhat compressed old snow is called a firn. The transition from snow to firn to ice occurs as the weight of overlying material causes the snow crystals to compress, deform, and recrystallize in a more compact form. When firn is buried beneath subsequent snowfalls, the density is increased as air spaces are compressed due to mechanical packing, as well as plastic deformation. Interconnected air passages may then be sealed and appear as individual air bubbles. See Figure 5. At this point, the firn becomes ice. Paleoclimatic information derived from ice cores is obtained from four principal mechanisms: (1) analysis of stable isotopes of hydrogen and atmospheric oxygen; (2) analysis of other gases in the air bubbles in the ice; (3) analysis of dissolved and particulate matter in the firn and ice; and (4) analysis of other physical properties such as thickness of the firn and ice. The firn-ice transition usually occurs at a depth of around 70–100 m, typically deeper in Antarctica than in Greenland.

The ice presently buried at depth in polar caps and ice sheets was once water vapor that condensed out and became incorporated into the firn, and ultimately the ice core of the ice sheet. The isotope ratios contained in this buried ice contain an implicit historical record of the

temperatures prevailing when precipitation occurred, perhaps many thousands of years ago. In addition to the relative heavy/light isotope ratios, the trapped bubbles in ice cores provide a record of atmospheric concentrations of trace gases including greenhouse gases such as carbon dioxide, methane, and nitrous oxide. Furthermore, the ice cores contain records of aerosols and dust content resulting from volcanic eruptions and other changes in particulate content in the atmosphere. The relative atmospheric concentrations of greenhouse gases, as well as aerosol and particulate content coupled with other climate information can provide insight into both the importance of these as causes and the effects of temperature change.

A series of ice core studies at Greenland has provided a wealth of information on historical temperatures. Ice cores from Greenland have the advantage that annual layers are relatively thick due to relatively high precipitation, and can be visually observed in many cases. However, the Greenland ice cores only cover a maximum time range of up to about 150,000 YBP. Antarctica cores comprise up to 800,000 years.

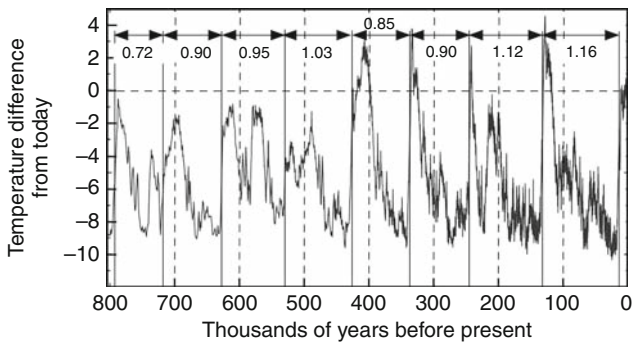
Two major issues in deriving historical data from ice cores are:

1. Developing date-to-depth relationship that provides a chronology of the ice core measurements at any depth.
2. Developing algorithms for proxies contained in the cores (typically based on isotope ratios) that reveal temperature, ice accumulation, or other historical climatological data.

The actual procedures used in dating ice cores typically involve a number of intricately woven factors. Dating of Greenland ice cores is greatly enhanced by the ability in many cases to visually discern annual layers, although these tend to blur below a moderate depth. Visual layers are not discernible at Antarctica.

Typical long-term ice core data are shown in Figure 6.

As polar snow is transformed to ice, atmospheric air is trapped in bubbles. By extracting the gases contained in ice cores, data can be obtained on the composition of the atmosphere in the past. Closure of ice pores proceeds at a slow pace: in Central East Antarctica, this process may take as much as 4,000 years, during which time some exchange of air between the pores and the free atmosphere takes place. Consequently, the air extracted from polar ice cores is younger than the accompanying snow. Present-day analytical procedures enable us to extract some gases from the ice – carbon dioxide (CO_2) and methane (CH_4) – and measure them with great accuracy.



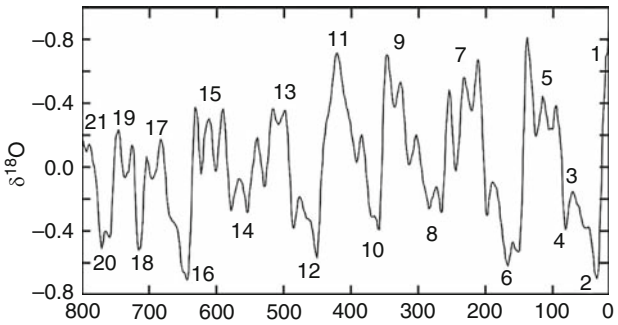
Ice Age Cycles: Data, Models, and Uncertainties, Figure 6 Temperature history (°C) derived from Antarctica ice cores (EPICA, 2004).

Ocean sediment data

Forams are shelled microorganisms found in aquatic and marine environments. There are both planktic (floating in the water column) and benthic (bottom dwelling) forms. Foram shells are made up of calcium carbonate ($CaCO_3$). These organisms record evidence of past environmental conditions in their shells. Remains of foram and diatom shells can be found by taking sediment cores from lakes and oceans, since their shells get buried and preserved in sediments as they die. The chemical makeup of these shells reflects water chemistry at the time of shell formation. Stable oxygen isotope ratios contained in the shell can be used to infer past water temperatures. Warmer water tends to evaporate off more of the lighter isotopes, so shells grown in warmer waters will be enriched in the heavier isotope. Measurements of stable isotopes of planktic and benthic foram and diatom shells have been taken from hundreds of deep-sea cores around the world to map past surface and bottom isotope variations. Planktic (surface dwelling) forams provide estimates of sea temperature, whereas Benthic (bottom dwelling) forams provide estimates of global ice volume. Water that evaporates from ocean is about 4% depleted in ^{16}O. At a glacial maximum, about 2.6% of the former oceans are stored as glacial ice. The remaining ocean waters are thereby enriched in ^{18}O by $0.04 \times 0.026 = 0.1\%$. Benthic forams provide a means of estimating the historical variability of ice volume. A great deal of analysis has focused on benthic data. However, deriving the chronology of this data presents significant challenges.

Initially, objective dating of sediment cores was limited to radiocarbon dates on the sediments younger than about 30,000 years. In addition, a notable marker point in the records was the last interglacial high temperature, which other evidence now suggests was about 135,000 YBP. An additional time marker point was added by measuring the position of a polarity change (due to reversal of the Earth's geomagnetic field) in deep-sea cores and assigning an age to this point based on radiometric (K/Ar) age estimation of the polarity change in lava flows as 780,000 years. Ice core data discontinuities have been used to provide "markers." However, most chronological assignments have been made on the basis of comparison with solar variability to high latitudes – assuming the astronomical theory is correct; this process is known as "tuning." This has led to some circular reasoning in testing astronomical theory. In a few cases, the deposition rate appears

to be constant in time – linear dependence of time on depth. In most cases, reports of ocean sediment data combine data from many oceanic sites, in which the belief is that there is a common temperature signal obfuscated by differing amounts of noise at various sites. By averaging the data over many sites, the hope is that the noise will cancel out, leaving a truer signal. Such a combination of sediment site data is known as a "stack."



Ice Age Cycles: Data, Models, and Uncertainties, Figure 7 Ocean sediment stack data (Rapp, 2009).

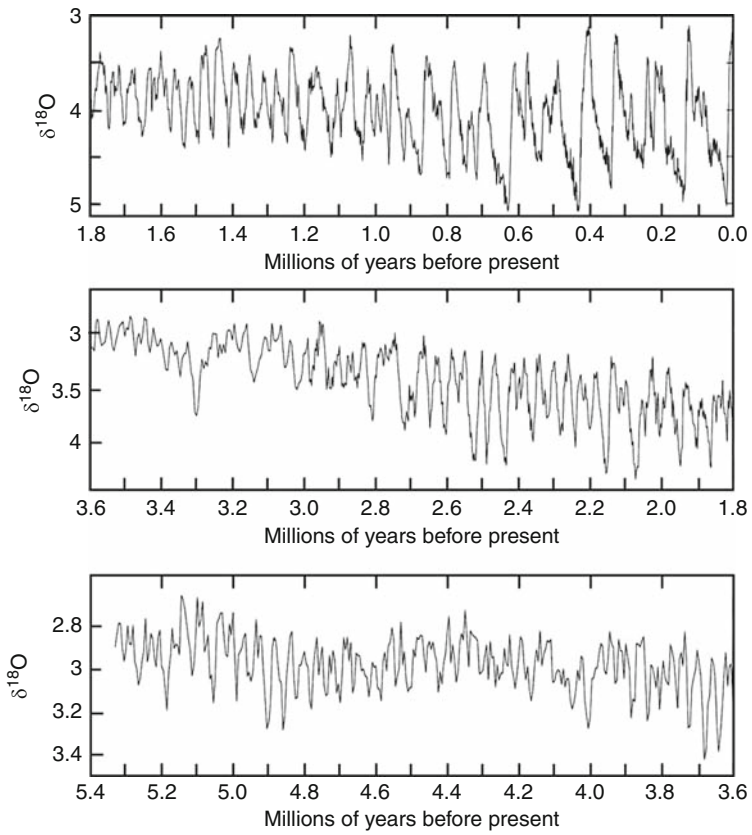
End results of stack data are shown in Figures 7 and 8. The data suggest that over the past few million years, the amplitude and period of climate oscillations has increased significantly.

Comparison of ocean sediment data with ice core data

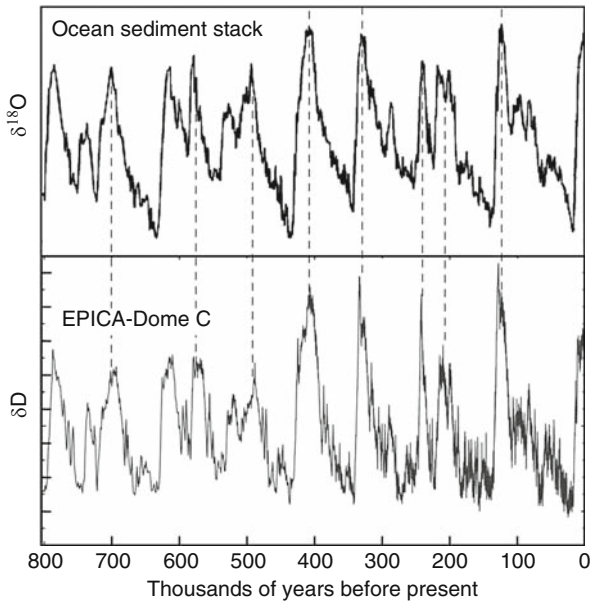
There are some striking parallels between ocean sediment data and ice core data as shown in Figure 9. However, it appears that the chronologies of these data were "fudged" to some extent and may not be independent of common assumptions, particularly regarding tuning. If the ice core data represent regional temperatures and the ocean sediment data represent ice sheet volume, presumably there should be a sizable time lag in the ocean sediment data. The fact that the two sets of data appear to have common timescales is a problem, not a virtue. It is also noteworthy that the ocean sediment data show less short-term variability, since they are more dependent on slowly varying global ice volume than rapidly fluctuating regional temperatures.

Other data sources

There are a number of other sources of data on the past climate over several hundred thousand years. Devil's Hole,



Ice Age Cycles: Data, Models, and Uncertainties, Figure 8 Ocean sediment data over several million years (Rapp, 2009).



Ice Age Cycles: Data, Models, and Uncertainties, Figure 9 Comparison of ocean sediment data and ice core data (Rapp, 2009).

Nevada calcite deposits provide a 500,000-year temperature estimate with good chronology based on the ratios of radioactive isotopes of uranium and thorium. While these results qualitatively resemble those from ocean sediments, there are several important discrepancies between the Devil's Hole data and the predictions of astronomical theory. This generated considerable controversy in the literature. Since the dating of the Devil's Hole data was independent of the astronomical theory, it provided an independent check without the concern that "tuning" might have led to circular reasoning.

Other sources of data include speleothem formed in limestone or dolostone caves, pollen acting as climate proxies, ice sheet moraines, mountain glacier markings, Red Sea sediments, and coral terraces.

Theories on the cause of ice ages

They were pretty smart in the nineteenth century

More than 100 years ago, G. Frederick Wright (1896) asked: "What were the causes of the accumulation of the ice sheets of the Glacial period?" and concluded that "Two classes of theories have been presented in answer to these questions."

> In one class, ... are the explanations of the climate of the ice age through astronomic or cosmic causes, comprising all changes in the Earth's astronomic relationship to the heat of space and of the Sun.
>
> The second class embraces terrestrial or geologic causes, as changes of areas of land and sea, of oceanic currents, and altitudes of continents, while otherwise the Earth's relations to external sources of heat are supposed to have been practically as now, or not to have entered as important factors in the problem.

Wright identified nine possible causes of ice age cycles. These included shifting of the polar axis, a former period of greater moisture in the atmosphere at higher latitudes, depletion of carbon dioxide in the atmosphere, variations in the heat radiated by the Sun, changes in the Earth's orbit, and changes in the distribution of land and water, as well as changes in land elevation.

Potential causes of ice age cycles

The following list summarizes the major concepts that have been suggested as a possible cause of ice ages:

1. *Solar*: Variability of the Sun – variations in the innate solar intensity due to structural variations within the Sun.

Unfortunately, there are no reliable estimates of historical solar variability, and there is no reason to suspect a quasi-periodic pattern in such variability, even if it occurs.

2. *Astronomical Theory*: Variability of Earth orbital parameters – quasi-periodic variations in eccentricity, obliquity, and precession of the equinoxes produce changes in sequencing of solar intensity to higher latitudes.

This is the most favored theory of ice ages. We shall discuss this theory further in the section on Astronomical Theory given below.

3. *Volcanism*: The occurrence or absence of high levels of volcanism cause temporary changes in the Earth's response to the Sun that may trigger initiation of longer-term glacial-interglacial cycles.

Volcanic eruptions have had a significant, but not sustained effect on climate – their effects tend to die out in less than 3 years. The gigantic Toba eruption of $\sim$ 71,000 years ago may be an exception – models suggest that this may have significantly amplified the budding ice age that was forming at that time.

4. *Greenhouse Gases*: Variability of concentrations of greenhouse gases (particularly CO_2 and CH_4) induced by unspecified forcings have been conjectured to be a cause of glacial-interglacial cycles via changes in the greenhouse effect.

There is no innate reason why greenhouse gas concentrations should change on their own according a quasi-periodic timetable. Furthermore, the data suggest that changes in greenhouse gas concentrations lag temperature changes during ice age cycles by about 1,000 years. Thus, changes in greenhouse gas concentrations are likely to be an effect, not a cause of ice ages.

5. *The Oceans*: Variability in the thermohaline circulation of the oceans producing large changes in heat delivered to higher latitudes.

It has been theorized that variability of the thermohaline circulation (which delivers heat from equatorial regions to higher latitudes) might be involved in ice age cycles, and indeed, there is evidence that such variability does occur. However, there is no basis for the observed long-term quasi-periodic variability. In addition, 90% of heat delivered to polar areas is from the atmosphere, not the oceans.

6. *Extraterrestrial Interactions*: Several models are based on effects due to quasi-periodic accretion of extraterrestrial dust or penetration of cosmic rays in the Earth's atmosphere as the primary forcing that induces changes in cloud cover that in turn, affects the climate.

This topic is discussed in greater detail in the section on Extraterrestrial Interactions given below.

7. *Ocean–Atmosphere Interactions*: In this model, the primary factor that controls large-scale variations in the Earth's climate is the albedo of the Earth, which in turn, is controlled by the degree of cloudiness which is hypothesized to go through repetitive cycles due to ocean–atmosphere interactions.

This topic is discussed in greater detail in Ocean–Atmosphere Interactions Theory.

Ocean–atmosphere interactions theory

Bell and Eng (2007) expounded their theory on the origin of ice ages and interglacial cycles as an alternative to the astronomical theory. Orbital variations have been around for many millions of years, but ice ages have only been around for about 3 million years – which suggests that the origin of ice ages does not lie in orbital variations.

In their model, the primary factor that controls large-scale variations in the Earth's climate is the albedo of the Earth, which in turn, is controlled to a considerable degree by the amount of cloudiness. Cloudiness affects the Earth's albedo, and since the average solar input to Earth is about 342 W/m^2, a change of only 1% or 2% in overall albedo can produce an effective forcing of 3.4–6.8 W/m^2, which would produce a significant impact on the climate. Actually, the solar input to the tropics is considerably higher, and variability of cloudiness in the tropics could have a dramatic effect on net solar input to Earth.

Consider a cold glacial period. With the Earth colder than average, cloudiness is assumed to be subnormal because the vapor pressure of water is reduced. As a result, solar penetration to Earth increases above normal, instigating a warming trend in the atmosphere. Gradually, this heat is transferred to the oceans, but that may require many thousands of years. As the Earth warms up and enters an interglacial period, the oceans slowly warm up with a considerable time lag. By the time the Earth is well into the interglacial period, the oceans have warmed up enough to significantly increase world cloudiness by evaporation. This process reduces the net solar input to Earth, instigating a cooling trend. Now the process reverses. High levels of cloudiness cool the atmosphere quickly and the oceans follow slowly. By the time the Earth has entered a glacial state, the oceans have not lost all their excess heat. As the glacial state persists, the oceans eventually cool off, reducing cloudiness. Now, the warming cycle begins again.

This theory has some attractive features. A cyclic climate history falls out naturally from the facts that the warming or cooling of the oceans lags the warming or cooling of the surface, and warming produces clouds, which in turn, produces cooling via increased albedo. However, Bell and Eng did not seem to include the greenhouse effect of water vapor, which is likely to be very significant, in opposition to the putative cloud effect. Furthermore, when one traces out multiple cycles of surface temperature, ocean temperature, cloud formation, and ice formation, it is difficult to obtain a result with long glacial periods and comparatively short interglacials.

Extraterrestrial interactions

As we pointed out in the previous section, cloud cover is an important factor that controls the way that radiation is absorbed and reflected by the Earth. Increases in cloudiness enhance global albedo, thus cooling the surface but increased cloudiness also traps thermal radiation leading to warming. Overall, the cooling effect is believed to be dominant but this is a function of cloud height and type with thin high clouds causing a net warming. Any factor tending to modify cloud cover will thus have an impact on climate so that it is important to understand the natural variability in cloud climate forcing.

If there are forces acting on the Earth that produce quasi-periodic changes in cloud cover, these forces could produce alternating periods of glaciation interspersed by deglaciation periods. Two such models have been developed. One model has to do with interplanetary dust acting to affect the stratospheric conductivity, and thereby affecting cloud formation via a complex process. Another is based on quasi-periodic changes in cosmic ray penetration of the Earth's atmosphere producing ions that act as nuclei for cloud formation.

Benestad (2005) provides an extended discussion of a theory that cosmic rays, controlled by the Sun's magnetic field, produce changes in cloud formation that affect the Earth's climate. He provides many references. Only a brief report is given here. The theory here is that as variations in solar activity take place, the solar wind changes, and the solar wind controls the amount of galactic cosmic rays from deep space that enter our solar system and penetrate the Earth's atmosphere. The solar wind thus acts like a control grid on an old-fashioned triode vacuum tube where the cosmic rays provide the "current to the anode." The theory then claims that cosmic rays enhance cloud formation by producing charged atmospheric aerosols that act as nuclei for cloud formation. Thus, according to this model, an increased flux of cosmic rays due to lower solar activity produces a cooling effect on the Earth. So, it is claimed that a putative correlation of solar activity with climate is an indicator of solar wind effects that in turn

affect cosmic ray penetration, which affects cloud formation, which in turn produces cooling. Several versions of this concept have been proposed.

Svensmark (2000) showed that the production of radiocarbon-14 in the Earth's atmosphere was inversely related to the pattern of Earth temperature over the past 1,000 years, with low production of ^{14}C during warmer periods and high production during cold periods. The production of ^{14}C decreased sharply in the twentieth century as the Earth warmed. Svensmark said:

> In 1900 the cosmic rays were generally more intense than now and most of the warming during the 20th Century can be explained by a reduction in low cloud cover. Going back to 1700 and the even higher intensities of cosmic rays, the world must have seemed quite gloomy as well as chilly, with all the extra low-level clouds.

Lockwood and Fröhlich (2007) published a rebuttal to Svensmark's theory. Svensmark and Friis-Christensen (2007) published a response to Lockwood and Fröhlich (2007).

Most recently, the world experienced a significant downturn in global temperature in years 2007–2008. At the same time, there was a serious diminution of sunspot activity accompanied by a notable lack of solar magnetic activity. Archibald (2009) presented an interesting analysis of solar cycle 23 and its comparison to earlier sunspot cycles. Solar cycle 23 has been a very long cycle with low sunspot numbers at its tail end, and it appears to be a progenitor of a period of reduced solar activity. A number of papers have predicted an era of low solar activity after sunspot cycle 23.

In a recent prediction update released May 8, 2009, a NOAA panel of experts predicted a peak of about 90 sunspots in May 2013 for solar cycle 24, which would make it the weakest cycle in a very long time. If low solar activity is associated with enhanced cloud formation, this could suggest a cooling effect.

Astronomical theory

The astronomical theory of ice age cycles originated in the nineteenth century and has evolved over the past century and a half. Quasi-periodic variations in the Earth's orbital parameters change the solar energy input to higher latitudes with periods of multiple tens of thousands of years. The fact that solar inputs to high latitudes and data on past climate variations are both subject to quasi-periodic variations over similar time periods suggests the two may be coupled. Spectral analysis supports this viewpoint to some extent.

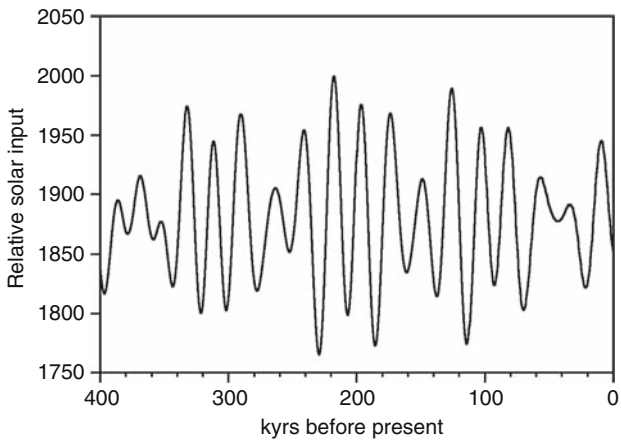
This variability of solar input to higher latitudes has a significant effect on the ability of surface and sea ice at higher northern latitudes to withstand the onslaught of summer. Thus, according to this theory, variability of the Earth's orbit about the Sun is a primary factor in determining the timing of glacial–interglacial cycles.

The three key factors in the Earth's orbit that affect solar input to higher latitudes are the eccentricity (*elongation*, period ~100,000 years), the obliquity (*tilt of the spin axis*, period ~41,000 years), and the precession of the equinoxes (*the change in season when the Earth is closest to the Sun*, period ~22,000 years). As a result of variability of these parameters, the solar input to high northern latitudes changes with time as shown in Figure 10. The variation of the precession acts like a "carrier wave" whose amplitude is modulated by the eccentricity and obliquity.

According to this concept, ice will spread at high northern latitudes during years with low summer solar input, and retract when summer solar input is high. Despite the many published papers on the astronomical theory, there is an appalling lack of modeling of specifically how solar variations produce extreme climate change. Perhaps that can be excused to some extent because of the extreme complexity of the problem, but that being the case, how can so many scientists reach firm conclusions on the veracity of the astronomical theory? In actual fact, the astronomical theory is basically a high-level intuition that solar variations affect climate. Exactly how these variations affect climate remains uncertain. A few models have been developed but none of these are very detailed.

While credible mechanisms for the processes by which solar variability affects climate are not available, nevertheless one may hope to gain wisdom by comparing the solar curves (from Figure 10) with isotope data from ice cores and ocean sediments. Here, the situation is somewhat akin to that of a detective trying to solve a crime by examining clues. Two approaches have been taken.

In one approach, the solar variability and the isotope data are both analyzed spectrally, and to the extent that the two have important frequency components that agree, there is an implication that the two are coupled. That is somewhat in the realm of "circumstantial evidence" – for example, the suspect was known to be in the vicinity where the crime was committed – but it does not lead to direct cause-effect conclusions.



Ice Age Cycles: Data, Models, and Uncertainties, Figure 10 Calculated yearly solar input (kWh/m^2) to 65°N over 400,000 years (Rapp, 2009).

The second approach involves comparing the detailed time series of isotope data with the solar data over hundreds of thousands (or even millions) of years to determine consonance between trends in the two datasets. However, there is a difficulty here because it is obvious that solar variability due to precession of the equinoxes involves more rapid variations than the long-term trends in global ice volume.

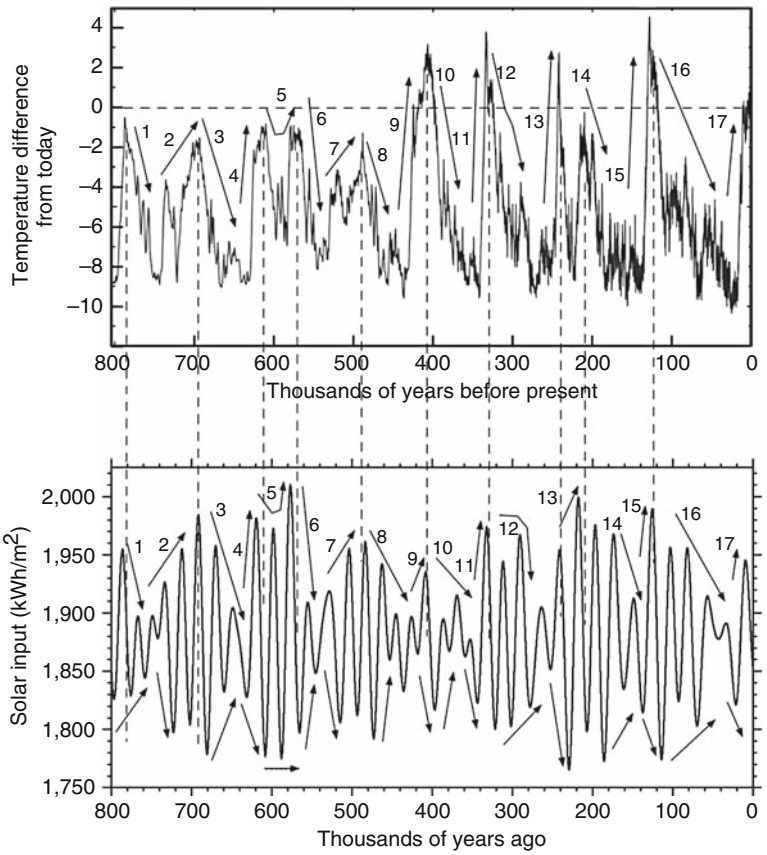
Assuming that the astronomical theory is fundamentally sound, it seems likely that the buildup and decay of gigantic ice sheets is a slow process that depends on the integral of solar variations over long periods – perhaps tens of thousands of years. Therefore, an integrative model is needed to estimate the slow buildup and decay of ice sheet volume as a function of more rapidly varying solar input. One can then compare either the rate of change of ice volume with the solar variations, or an integral of solar variations with the measured time series for ice volume versus time. There does not seem to be a single a priori model based entirely on physics that has no adjustable parameters, that allows unequivocal comparison of theory with data. Unfortunately, all models developed to date have been limited by their simplicity, as well as the obvious bias of many scientists determined to "validate" the astronomical theory via curve fitting. The combination of fixing the chronology of isotope data fixed by "tuning" to astronomical theory and using adjustable parameters to fit simplistic models to the "tuned" data raises questions of circular reasoning. However, one could argue that the models provide a framework for connecting theory with data, and the curve fitting process fills in quantitative parameters that are too difficult to estimate from fundamental principles in the real world. But the degree of elasticity in the models creates doubt as to where such procedures fit between the extremes of determination of physical parameters, or mere mathematical curve fitting.

The "bottom line" seems to be that the astronomical theory may well be correct to some extent in principle – that is, there appears to be a solar influence on glacial/interglacial cycles – but translating this into a detailed quantitative comparison of theory and experiment is not simple.

Comparison of theory and experiment

Comparison of astronomical theory with data

In Figure 11, we compare the solar input to high latitudes with the estimated temperature from an Antarctic ice core over 800,000 years. There is considerable agreement with



Ice Age Cycles: Data, Models, and Uncertainties, Figure 11 Comparison of the solar input to high latitudes with the estimated temperature from an Antarctic ice core over 800,000 years (Rapp, 2009).

trends if we ignore rapid oscillations of the solar input and concentrate on the envelope of the solar variability. However, Trend #9 is a major difficulty ("the 400 kyr problem").

One possible interpretation of Figure 11 (perhaps amongst many) is this:

According to this interpretation, the Earth naturally tends toward an ice age (at least over the past several hundreds of thousand years). Ice sheets build more slowly than they disintegrate. The "natural" state of the Earth's climate may be glacial. During those periods of the order of perhaps ~50,000 to 60,000 years, when oscillations in solar input are minimal, the solar input never gets high enough to melt summer ice, the climate cools, and ice sheets build up. However, during those periods when oscillations of solar input are large, the solar input gets high enough during the up-lobes of the oscillations to melt summer ice, the ice sheets diminish, and the climate warms. Even though there are also steep downward oscillations in solar input, the down lobes are insufficient to rebuild ice sheets lost in the previous upward oscillation, probably due to albedo effects and the likelihood that ice sheets build slowly and disintegrate more rapidly. When the amplitude of the solar oscillations is high, there is a tendency toward reducing global ice and heading into an interglacial period. When the amplitude is small, ice volume tends to increase and the ice age deepens. However, the warm period around 400,000 years ago remains a contradiction.

In order to compare the astronomical theory with ocean sediment data that represents ice volume, we require a model that relates ice volume to solar input to higher latitudes. Imbrie and Imbrie (1980) developed a simple model as described next.

During ice sheet decay, the rate of change of volume of the ice sheet is given by

$$\frac{dy}{dt} = -\frac{1+B}{T}(x+y) \qquad \text{if}(x+y) > 0$$

and during ice sheet buildup, the rate is given by

$$\frac{dy}{dt} = -\frac{1-B}{T}(x+y) \qquad \text{if}(x+y) > 0$$

in which

y = ice volume

x = solar input to high northern latitudes

T = time constant for lag between solar and ice volume buildup

B = constant to assure ice buildup is slower than ice decay

It is not immediately clear why y should appear on the right side of equation – this term reduces the rate of ice volume growth as the ice sheet volume increases.

Integration of the Imbrie's equations leads to a consistent timeline but the amplitude of oscillations can be adjusted with parameters. The Imbries chose $B = 0.6$ and $T = 17{,}000$ years to get a "best fit" to ocean sediment data over 600,000 years. Time constants for buildup and decay of ice sheets are then 42,500 years and 10,600 years, respectively (ice sheet decay is four times faster than ice sheet buildup when $B = 0.6$). More recently, Raymo adjusted B and T to be time-dependent to fit data over wider time span (3 million years) – T must decrease as the data go back further in time. The comparison of the model with data is shown in Figure 12. The degree of agreement lies in the eye of the beholder.

The primary cycle periods that characterize variability of the precession of the equinoxes, obliquity, and eccentricity are roughly 22,000, 41,000, and ~100,000 years, respectively. The spectral analysis of the Vostok and ocean sediment data indicate a strong peak with a period of roughly 100,000 years and a smaller spectral peak at 41,000 years. This should be tempered by the fact that since some tuning was used to assign the chronology for Vostok data, one might expect that elements of the astronomical model will appear in the spectrum for Vostok temperatures.

Summary

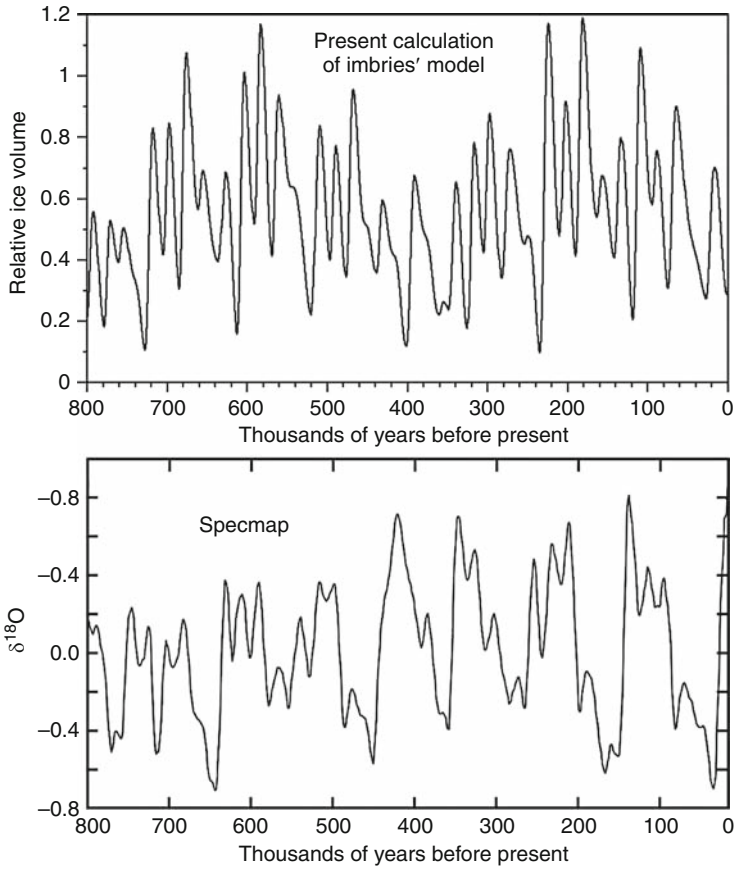
About 2.7 million years ago, the Earth entered an enhanced cooling phase that has continued unabated to the present day. Since then, the Earth has undergone a large number of climate cycles ranging from ice ages with large ice sheets in the northern hemisphere and a general cooling of the entire Earth, to interglacial periods that were comparable or perhaps warmer than the present climate. These cycles have become lengthier and of greater amplitude in the most recent million years.

Data are available from ice cores and ocean sediments, as well as other sources that reveal aspects of past climates dating back hundreds of thousands and even millions of years. These data indicate that there has typically been a long-term secular pattern of very roughly repeatable cycles, whereby great ice sheets have slowly built up over many tens of thousands of years culminating in a glacial maximum, followed shortly by a rather abrupt end of the ice age with rapid global warming leading to an interglacial period of perhaps 10,000 or more years.

The interglacial periods seem to end with abrupt climatic cooling to start a new ice age that gradually expands over many tens of thousands of years. This pattern is actually quite variable, but the outline described here seems to roughly describe the last four ice age cycles.

Ice core and ocean sediment data are couched in terms of isotope ratios. Converting these data into specific climatological variables (e.g., global average temperature, global ice volume, etc.) is not straightforward. Greenland and Antarctic isotope ratio data are believed to represent regional temperature conditions even if the absolute conversion to temperature is uncertain.

Ocean sediment data from benthic sources are believed to represent mainly global ice volume, although Lisiecki, Raymo, and Curry (2008) recently concluded: "Generating a robust age model for benthic $\delta^{18}O$ or ice volume without the assumptions of orbital tuning remains an important, unsolved problem."



Ice Age Cycles: Data, Models, and Uncertainties, Figure 12 Comparison of Imbries' model with ocean sediment data.

In attempting to compare the astronomical theory with data, one must first clarify what the data represent.

- Isotope ratio data at Greenland and Antarctica are believed to represent local temperatures. These interpretations of isotope ratios are far from ironclad, and involve a number of uncertainties. Nevertheless, accepting these assumptions regarding the interpretation of ice core data, we still face the problem of how to compare ice core data with variability of solar intensity from year to year.
- If increased solar intensity raises temperatures, is there a time lag and does it depend on other factors as well?
- If the main driver for climate change is Northern Hemisphere solar intensity, how does this relate to Antarctica climate and temperature?
- Isotope data from marine sediments are typically believed to primarily represent ice volume – however, ice volume models are notoriously simplistic. Comparisons of theory with data are often compromised by use of "tuning" to set chronology.

In most cases, the time periods with higher amplitude solar oscillations appear to be associated with higher temperatures, and the periods during which solar oscillations are weak seem to be associated with lower temperatures. This would be the case if

- There is a fundamental tendency toward glaciation.
- Ice sheets grow slowly and disintegrate rapidly.

In that case, ice sheets would disintegrate and not recover when solar oscillations were large, but would grow when solar oscillations were small. All of this is very tenuous and represents a somewhat subjective interpretation of the data. However, the fact that the frequency spectrum shows the frequencies for eccentricity and obliquity but not precession, suggests that it is the amplitude of solar oscillations that matters, and the precession frequency does not directly contribute to climate change but rather, only the eccentricity and obliquity determine the amplitude of precession oscillations.

There are problems with this interpretation:

- The change from ~41,000 years spacing to ~100,000 years spacing of ice ages
- The occurrence of an ice age around 400,000 YBP when solar oscillations were minimal

And while there are innumerable books, reports, and published articles claiming that the astronomical theory is proven, the basis for such claims is not ironclad.

Onset of the Pleistocene Ice Age Era and its rhythmic glaciations

Definition

Theory on the development and course of the Quaternary ice ages.

Introduction

Several theories on the development of ice ages are under discussion. They state extraterrestrial causes or the CO_2-household, ocean currents, and the closure of the Panamanian seaway.

The $\delta^{18}O$ records of planktonic foraminifera (Shackleton et al., 1988; Tiedemann et al., 1994) have shown that the Quaternary ice age began at about 2.75 Ma BP; from ~1 Ma BP onwards, its intensity (ice volume) and the length of its glacial phases approximately doubled (Figure 2b). It is now recognized that the explanation of these events cannot be fully exhausted by the variations of the Earth's orbital parameters (Berger et al., 1999). Insolation variations (Figure 2a) – which have displayed the same patterns for tens of millions of years (Berger and Loutre, 1991) – account for the waxing and waning of global ice volumes to a limited degree (Hays et al., 1976), but to explain why ice ages occur at all and why they increased so rapidly during the past 1 Ma, we must look for an additional, terrestrial cause.

In recent years, the continuous decline in levels of the greenhouse gas CO_2 in the atmosphere and a concomitant global cooling have been considered to be the most likely cause (Broecker, 1995; Ruddiman et al., 1997). Computer simulations by Berger et al. (1999) show that, to trigger ice ages in this way, atmospheric CO_2 must have decreased from more than 320 ppm by volume (ppmv) to 200 ppmv during the past 3 Ma. However, the latest alkenone-based CO_2 estimates (Pagani et al., 1999) have shown that, in spite of high temperatures, CO_2 levels during the Tertiary were by no means higher – sometimes even lower – than the preindustrial value of 270 ppmv in postglacial times or >300 ppmv during the Eem Interglacial (Fischer et al., 1999). So there is still no evidence for a general decrease in atmospheric CO_2 concentration since the Tertiary/Quaternary transition that may have caused temperatures to fall. Furthermore, the fine-scale records of the GRIP ice core confirm that during the last three glaciations the decrease of the CO_2 values lagged climatic change by as much as several thousands of years (Fischer et al., 1999). This reverses the previously accepted causal nexus: evidently, atmospheric CO_2 concentrations decreased in the wake of glacial-interglacial transitions, rather than promoting them.

The hypothesis that the closure of the Panamanian seaway and the resulting North Atlantic deep water formation were responsible for the onset of the ice ages (Haug and Tiedemann, 1998) is still inconclusive. Closure occurred 4.6–3.6 Ma ago, that is, 1 Ma too soon. The argument that increasing obliquity amplitudes between 3.1 and 2.5 Ma BP caused the ice to build up contradicts the fact that the decrease in obliquity amplitudes between 1 and 0.8 Ma does not coincide with ice retreat; on the contrary, it corresponds in time with an intensification of global glaciation (Figure 2a, b). Long-term global climatic changes may also have been caused by Cenozoic plateau uplift (especially of the Himalaya-Tibetan and the North American plateaux), inducing a change of zonal wind and precipitation patterns and a steepening of the climatic south-north gradient (Ruddiman and Kutzbach, 1992). However, uplift of the Tibetan plateau started 20 Ma BP

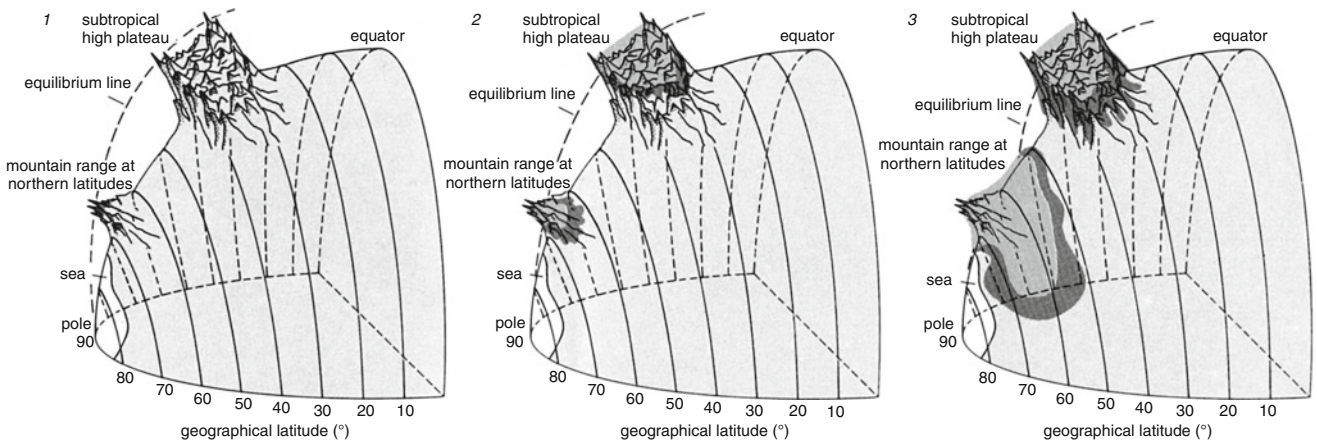
ago (Harrison et al., 1992) and, as the onset of the summer monsoon suggests, it began to act as a climate-effective barrier some 8 Ma ago (Prell and Kutzbach, 1992; Tiedemann et al., 1994; De Menocal, 1995) – too early for the start of the ice ages.

As an alternative a terrestrial Ice Age development theory will be introduced here. It is the relief-specific model of the Ice Age on the basis of uplift-controlled glacier areas in Tibet and the corresponding albedo increase as well as their positive climatological feedback by means of the global radiation geometry. It explains the onset of the Pleistocene glaciation as an autocycle on the basis of a 2.4 million km² ice sheet on the Tibetan Plateau (Kuhle, a.o., 1985, 1987, 1988, 2002).

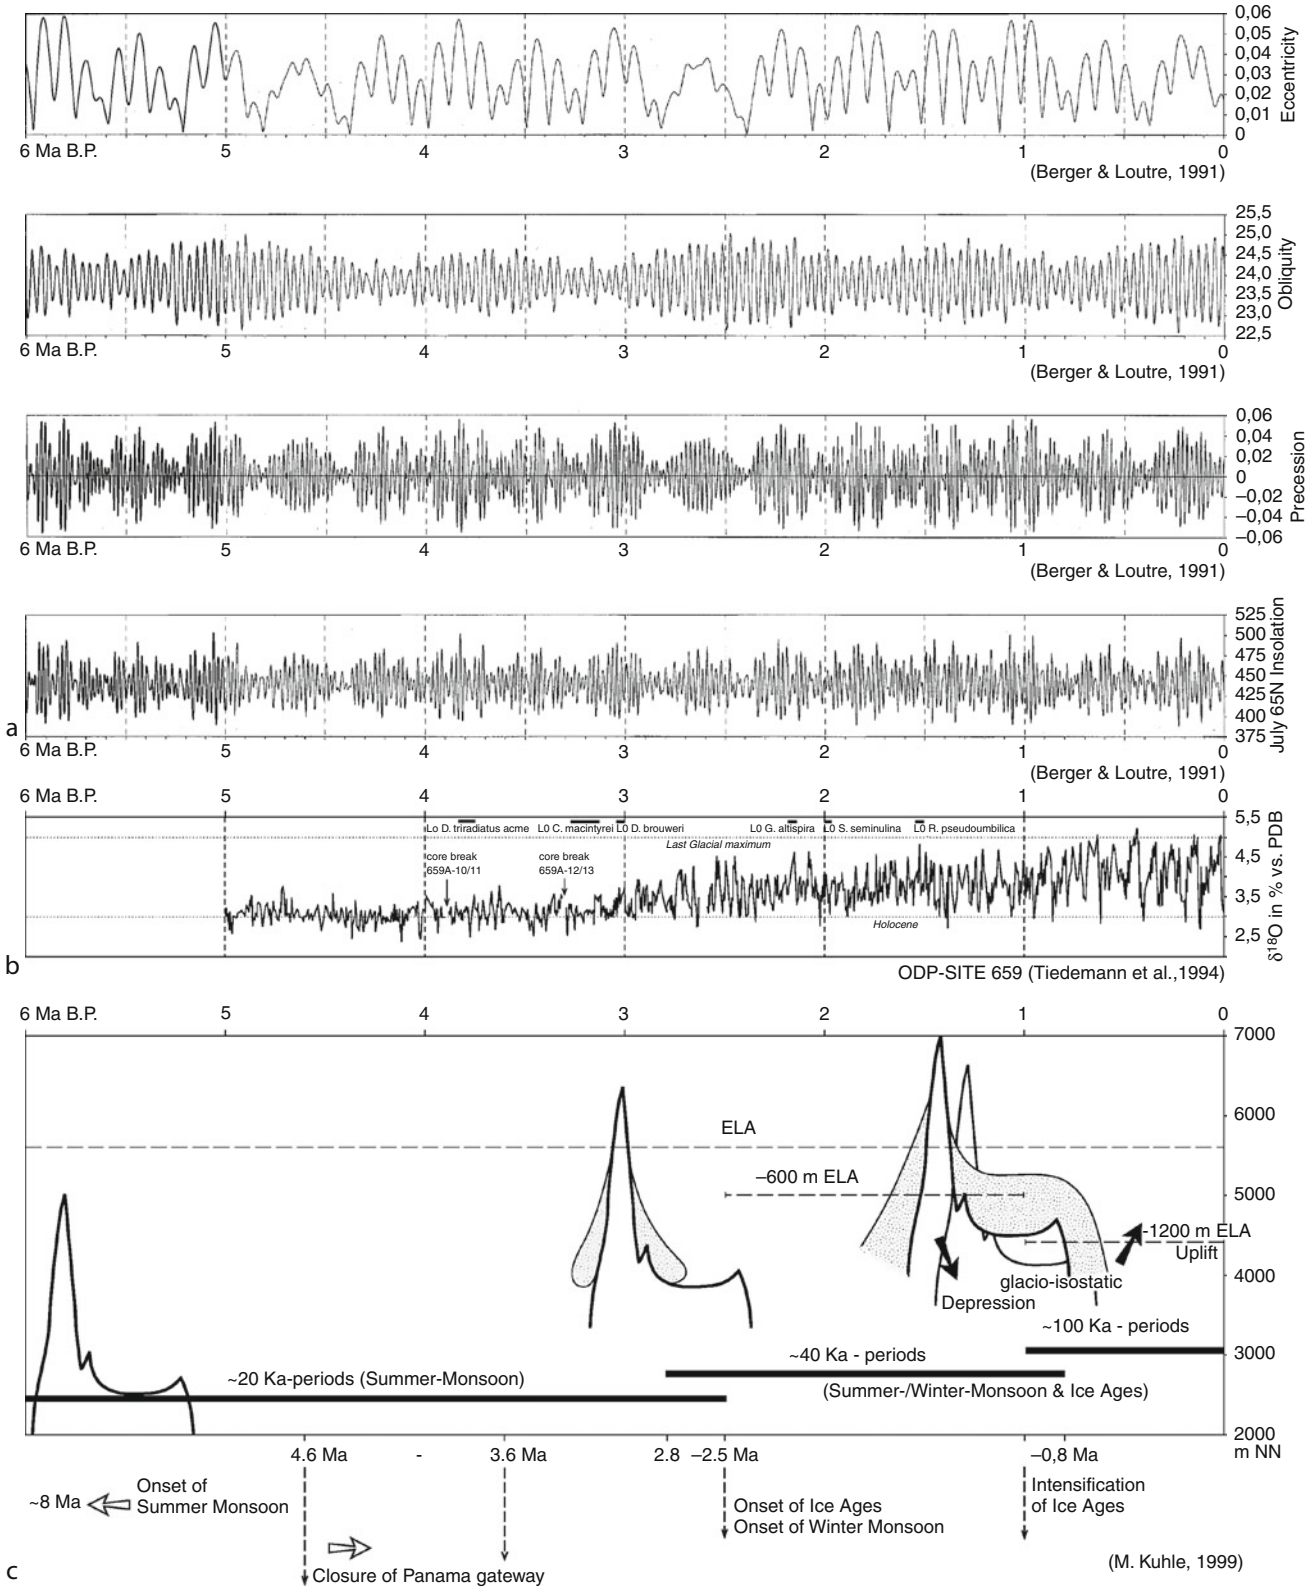
The beginning of the winter monsoon c.2.75 Ma BP ago is evidence of the start of a restricted glaciation on the Tibetan Plateau, i.e., the height of the plateau reached the snow-line (ELA) for the first time. At that time the global cooling began. Since c.1 Ma BP Tibet has exceeded the ELA on a large scale and the distinct stages of glaciation led to the breakdown of the summer monsoon. The alternation with intercalated interglacials results from glacial-isostatic lowerings and rebounds. It overlaps with the amplifying or weakening efficacy of the variations of the Earth's orbital parameters.

Empirical induction

1. Observations of standard forms of glacial accumulation and erosion are evidence of a large-scale Pleistocene glacier cover of the Tibetan highland. Marginal sites at 2,000–2,460 m a.s.l. in all of the surrounding mountains of Tibet are evidence of an equilibrium line



Ice Age Development Theory, Figure 1 Schematized presentation of the principle of the relief-related origin and termination of ice ages. The causative intensification of the cooling-down process emanates from a subtropical high plateau (such as the Tibetan Plateau) due to the fact that the initial lowering of the equilibrium line by approximately 500 m leads to the glacier's descent by 1,000 m from the mountains, thus suddenly glaciating large plateau areas (*step 1 to 2*). Mountain chains at higher latitudes experience the same amount of equilibrium line lowering as a result of the cooling down by 3.5°C during a change in the parameters of the earth's orbit. Since the altitudinal distance of the present glaciation to the height of the foreland areas is too great, glaciation has had little effect on area and thus on reflection (2). As the subtropical high plateau has undergone large-scale glaciation, with the transformation of a formerly very effective "heating panel" into an area of reflection, the further cooling down of the atmosphere caused in this way leads to a renewed lowering of the equilibrium line. The consequence is a chain-reaction-like worldwide enlargement of glacier areas. This advanced particularly fast in all those places where the lowering of the glaciation line reaches the flat mountain forelands (*step 2 to 3*). The sequence of additions of mountain foreland glaciation depends on the particular altitudinal distance of pre-ice-age hanging glacier ends from the altitudinal level of the foreland. Although, due to the conditions of radiation, the cooling effect per glacier area is greatest in the subtropics, the areal gain of glaciers increases significantly with the decreasing equilibrium line at higher latitudes (3). The reason for this is the fact that the equilibrium line dips toward the polar regions, and that the starting point of equilibrium line heights becomes progressively lower toward the lowlands. In the end the ice areas of the high latitudes outnumber those of subtropical high plateaus and mountains by approximately 8:1, by which time their cooling effect has increased around twofold. Nonetheless, such far-reaching glaciation would not have occurred without the impact of the subtropical inland ice. The cooling, which reacts upon the impact of the subtropical plateau ice as well, can hardly result in any further increase of the area of ice there because the glaciers cannot reach the lowlands when flowing over the edge of the plateau (*step 2 to 3*). In a reverse process (*steps 3 to 1*) the end of the Ice Age begins in the N and S lowland plains: on the return to normal values of solar radiation and a rise in temperatures by those initial 3.5°C the corresponding rise in the equilibrium line by 500 m with a rise in the glacier ends by 1,000 m becomes particularly effective for areas of flat lowland glaciation (*step 3 to 2*). Whilst lowland ice areas experience extreme reductions, thus forcing a global warming, the surface areas of the subtropical highland ice will remain almost constant, because only the steeply descending outlet of glacier tongues on the margins will become shorter on the initial upward move of the equilibrium line, whereas the reduction in glaciation is far from reaching the flat plateau ice proper (*step 3 to 2*). Only when the further warming of the earth has been initiated and has progressed through the disappearance of lowland ice, will the subtropical highland areas also be freed from ice (*step 2 to 1*); (Kuhle, 1987).



Ice Age Development Theory, Figure 2 (Continued)

depression of 1,100–1,660 m to 4,720–3,250 m a.s.l. The Ice Age equilibrium line thus ran up to 600 m below 85% of the Tibetan surface. This resulted in a 2.4 million km² inland ice mass with a thickness of 700–2,000 m (up to 2,700 m), (cf. Last Glacial Maximum Glaciation (LGM/LGP) in High Asia (Tibet and Surrounding Mountains), in this volume). Its volume was the equivalent of an approximately 5.4–6.5 m drop in sea level.
2. 14C ages substantiate the formation of inland ice at a date more recent than ∼50 ka and older than 9 ka (MIS 3–2, Würm).
3. Amounts of uplift of Central Tibet of more than 10–521 mm per annum are far in excess of the tectonically younger Himalaya, and are consequently interpreted as glacio-isostatic.
4. Presently consisting of 99% rock and scree, the Tibetan surface reflects only 15–20% of the high subtropical radiation coming from space. This results in a global heating effect of the atmosphere. Covering 97% of Tibet and reflecting 85–90% of the radiation, inland ice achieved a global cooling effect that is four times greater than at the latitudes of Nordic inland ice.

Theoretical deduction

1. Even an uplift of the Tibetan Plateau of 500 m or an equilibrium line depression of 500 m (=3.5°C drop in temperature) as a result of cyclical changes in the parameters of the earth's orbit was bound to lead to the formation of larger glacier areas in Tibet. According to this the highland necessarily was a pacemaker for the Ice Age (Figures 1, 2). The initial glacier cover of one third of Tibet caused further autocyclic equilibrium line depressions, aided by the 85% albedo of high subtropical incoming radiation. The resulting ice increase in Tibet aided global cooling and led to an approximately 46 million km² global High Ice Age glacier area, 26.3 million km² of which is Nordic inland ice (Figure 1), without the uncertain Siberian ice.
2. Milankovic radiation anomalies operated during the Pre-Pleistocene, without giving rise to an ice age (Figure 2). The glaciation of a subtropical energy-effective high plateau appears to trigger the Ice Age proper (see above).
3. In accordance with insolation being four times higher than at Nordic glaciated areas, the Tibetan ice was a much more influential global climatic body. Only 15% of the energy that previously heated the atmosphere before glaciation remained available for ablation. The reversal from a heating to cooling surface was also four times more effective and implies a corresponding increase in the self-intensification of glaciation from high to low latitudes.
4. In Tibet even a net precipitation of 200 mm/year would lead to an ice cover having an average thickness of 1,100 m within a little less than 10,000 years. This shows that in terms of time – from 90 to 60 ka, for instance – Tibetan ice would have been able to fulfill its role as a pacemaker.
5. An alimentation model is based on an analogy for the Antarctic ice: a depression that drew in humidity lay above a cold and shallow anticyclone situated over the ice cap.
6. With four times less cloud cover in the subtropics than at high latitudes, a subtropical inland ice sheet was bound to exert a particularly large global cooling effect.
7. The termination of the ice age cycle originated from the Nordic lowland ice. The end of extraterrestrial cooling (Milanković cycle) led to a rise of the equilibrium line by 500 m. The marginal and steep high plateau ice was initially not reduced during this ELA rise. By contrast, the vast lowland ice was bound to undergo an extreme loss of area. A lowland albedo loss led to global rewarming and an interglacial period.
8. In their role of pacemakers the uplift of a subtropical plateau above the ELA as well as its glaciation were triggers of the Ice Age on condition of the relief-specific Ice Age mechanism. This mechanism is

Ice Age Development Theory, Figure 2 (**a**) Astronomical parameters of the earth's orbit and rotation and corresponding insolation values for 65°N for the last 6 Ma according to Berger and Loutre (1991). (**b**) Benthic oxygen isotope records from Ocean Drilling Program Site 659 according to Tiedemann et al. (1994). The fluctuations in the $\delta^{18}O$ content of the foraminifera reflect the fluctuations of the global ice volume, with high values corresponding to the glacials and low values to the interglacials. Neither the beginning nor the intensification of the Quaternary glaciation period is correlated with the insolation (**a**). (**c**) Synopsis of the uplift and glaciation of the Tibetan plateau in their relation to other geoecological events. Comparison between (**a**) and (**b**) shows that an additional factor apart from orbital variations is required to explain both the start of the ice ages about 2.8 Ma and their increasing intensity from 1 Ma onwards. The closure of the Panama gateway occurred too early to be the terrestrial cause. The uplift of the Tibetan plateau, as far as it can be reconstructed from the onset of the summer- and winter monsoons, and, derived from this, the begin of an autochthonous glaciation of Tibet from ∼2.5 Ma BP onwards, were synchronous with the onset of the global ice ages. Evidence that variations of the summer- and winter monsoon intensity documented by marine dust flux records and loess-palaeosol sequences on the Chinese loess plateau occurred in phase not with the insolation variation but with glacial-interglacial cycles (40 ky and ∼100 ky periods) is a strong pointer to the existence of a Tibetan glaciation. Gradual uplift of the Tibetan Plateau toward the ELA (equilibrium line) level enabled an ice sheet of 2.4 million km to grow from ∼1 Ma BP onwards; the resulting cooling effect permitted a maximum expansion of the Nordic lowland ice sheets (−1,200 m ELA). The now beginning glacio-isostatic depression, deglaciation, and following rebound of the plateau were responsible for the occurrence and duration of interglacial-glacial cycles (∼100 ky periods).

based on global radiation geometry. The spherical geometry of the earth and the position of the Earth's axis are the necessary requirements for the formation of large lowland ice sheets at high latitudes, while subtropical glaciers occur at extreme elevations and are therefore restricted to small areas. Their small extent is compensated by a very high radiation energy, so that a minimal area of ice cover triggers the Ice Age (Figures 1, 2). A small rise in the equilibrium line is all that is needed to begin global rewarming through loss of glacier surface area. Proven moraines from that time, plus the reconstructions of their positions, will certainly permit a later corroboration of the kind of orogeny that extended up into the vicinity of the equilibrium line during the Permo-Carboniferous glaciation, for instance.

9. Extraterrestrial cooling is not needed to trigger the ice ages. The Tibetan Plateau would only require an uplift of an additional 500–1,000 m for a glaciation to occur without this cooling. An uplift of this kind could occur within 50–100 ka, so that a renewed Ice Age – accelerated extraterrestrially – might take place in a few dozen millennia. The denudation of the Tibetan High Plateau will terminate the Ice Age of the Pleistocene Era.
10. The uplift of Tibet came to its Early Pleistocene end as a result of the loading of inland ice. This ensured the deglaciation of the plateau as a continuation of the wasting begun by the lowland ice. The present extreme uplifts in Tibet are to be regarded as compensatory glacio-isostatic movements. Altitudes of plateaus and highlands of earth are climatically controlled by the position of the equilibrium line. The greatest possible plateau altitudes are found in subtropical latitudes.

Confirmations of the relief-specific ice age theory

The central role of the Tibetan plateau for the understanding of the Quaternary climatic changes is undeniable (Hughes, 1998). This is also derivable from the increasing importance of a Tibetan inland ice for all climate simulations (cf. Last Glacial Maximum Glaciation (LGM/LGP) in High Asia (Tibet and Surrounding Mountains), in this volume). The ecological consequences of a subtropical inland ice of c.2.4 million km² are of utmost importance (Lautenschlager and Santer, 1991). The albedo of snow-covered ice surfaces reaches from 75% to 95%. This means that this portion of global radiation is reflected and thus lost for the atmosphere. Regionally the ice cover of the plateau is especially important, because today (interglacially) Tibet is one of the most significant heating faces of the Earth. Energy balance calculations suggested that during the LGM/LGP 70.5% of the albedo-induced energy loss was caused by the Nordic lowland ices, but solely 20.5% was due to the ice on the Tibetan plateau (Bielefeld, 1997).

Sensitivity experiments with a general circulation model (Felzer et al., 1998) show that the Nordic lowland ices caused a cooling of −2.8°C of the altogether −6.5°C ice age decrease in GMT (Global Mean Temperature), whilst the Tibetan ice caused a GMT drop of at least −0.8°C. This is a minimum value, because the energy loss due to the Tibetan glaciation amounts to even 32% instead of 20.5% when the changed infra-red emission is taken into account (Bielefeld, 1997).

Synchronism of Tibetan uplift and the ice ages

In the opinion (Kuhle, 1987, 1988, 2002) that the reaching of the plateau's elevation of 4,600–5,000 m a.s.l is the cause of the intensification of global glaciation between 1 and 0.8 Ma before today along with the change to a 100,000 years rhythm (Shackleton et al., 1988; Tiedemann et al., 1994), geological indicators confirm the Tibetan uplift during this interval at the beginning of the Pleistocene (Ding et al., 1995; Chen Zhiliang, 1999). This chronology of Tibetan uplift and start of the High Glacials is proved by the change of the intensity of summer- and winter monsoon (Figure 2) which sets in. Under modern orographic conditions the intensity of monsoon circulation is controlled by insolation in low latitudes (Prell and Kutzbach, 1992; Felzer et al., 1998) and thus should follow the 21,000 years rhythm of precession. However, there is only evidence for a dominant 20,000 years rhythm prior to 2.8 Ma before today (De Menocal, 1995). Afterwards, up to c.1 Ma before present, a 41,000 year rhythm followed and then the current glacial 100,000 year rhythm where glacials have a weak summer- and strong winter monsoon, and interglacials vice versa (Tiedemann et al., 1994; De Menocal, 1995; Emeis et al., 1995; Xiao et al., 1995; Ding et al., 1995) (cf. Last Glacial Maximum Glaciation (LGM/LGP) in High Asia (Tibet and Surrounding Mountains), in this volume.)

Development of loess

The worldwide most important loess sedimentation on the Chinese loess plateau as a secondary deposit of glacial genesis is a hard indicator for the rhythmical inland glaciation of the Tibetan plateau since 2.75 Ma with a maximum extension since 1 Ma. This cannot be explained by an insignificant mountain glaciation but is dependent on inland ices (Kuhle, 1985, 1987, 1988, 2007).

Summary

The onset of the ice age era at ∼2.75 Ma BP and its increasing intensity from ∼1 Ma BP onwards cannot be explained by variations of the Earth's orbit. Evidence

supporting a 2.4 million km² ice sheet on the Tibetan plateau during the Last Glacial Maximum has led to the hypothesis that the resulting albedo-induced heat loss in the Earth's atmosphere may have triggered global ice ages. Recent data obtained from marine and terrestrial sediment records now confirm the climatic ecological impact of a Tibetan glaciation; they also show that the development of Tibet's ice sheet was synchronous with the onset and intensification of global ice ages.

ICE APRON

Mahendra R. Bhutiyani
Hazard Assessment and Forecasting Division, Snow and Avalanche Study Establishment, Chandigarh, India

Definition

Ice aprons are small accumulations of snow and ice masses that stick to the topography of the glacierized basin (Figure 1). They are generally found above the equilibrium line.

Ice Apron, Figure 1 Ice aprons in the cirque of a glacier in the Karakoram Himalaya.

Origin

Ice aprons are formed in snow-bound glacierized basins as some parts of the snowcover stay put in smaller depressions on moderately inclined slopes, even after avalanches have brought down most of the snow. With accumulation of residual snow, these ice patches grow in size and undergo metamorphism with each passing year. They may undergo movement by internal plastic deformation due to shear stresses imposed by a component of gravitational force.

Significance

Ice aprons at some places develop into smooth icy slopes, which may facilitate triggering of loose snow avalanches. At a few places where conditions favor their growth into comparatively larger ice patches, they may develop into overhangs as a result of ice-deformation and may become potential sites of dangerous ice avalanches.

ICE CAPS

Mahendra R. Bhutiyani
Hazard Assessment and Forecasting Division, Snow and Avalanche Study Establishment, Chandigarh, India

Definition

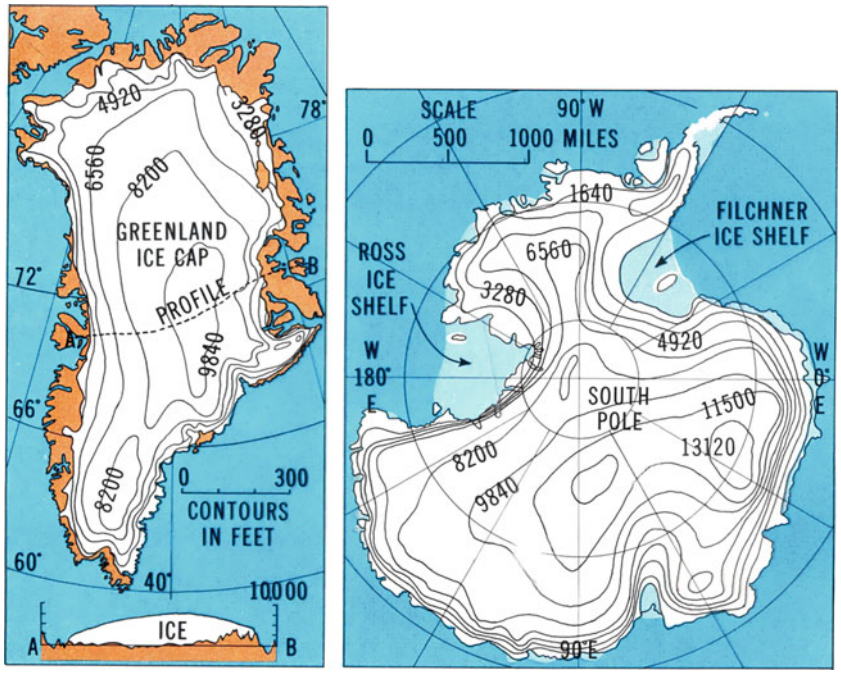
Ice caps can be defined as large masses of ice covering the Polar Regions with a surface area less than 50,000 km^2. They are essentially the huge glacier masses that almost submerge the topography beneath. At places the peaks of the covered terrain protrude through the ice mass, giving rise to the formation of "nunataks." On the periphery, the ice caps spread out into number of polar glaciers occupying the valleys. These glaciers, being at subzero temperatures, unlike their counterparts in the temperate regions, do not generate high amount of runoff. The examples of ice caps are the high-latitude continental ice sheets covering Antarctica and Greenland (see the Figure 1), where their growth is limited by the surrounding oceans. They are also found in regions such as the Canadian Rockies and Patagonia where altitudes are higher.

Origin

Ice caps generally form in regions where polar to subtemperate climatic conditions prevail throughout the year. Accumulation generally exceeds the ablation as subzero temperatures inhibit melting and the glaciers grow on the tops of individual mountains. They may merge together, forming an icy band around the mountain. If the conditions favor, this may grow until it covers the mountain's summit. Ice caps from nearby mountains can merge to form really big ice caps.

Significance

The ice caps served as the cores of many continental ice sheets that formed during Ice Ages in the past. When the ice sheets melted, the core ice caps may have survived.



Ice Caps, Figure 1 Ice caps of Greenland and Antarctica(From Ward's Natural Science Establishment, Inc. 1964).

ICE CAVES

Mahendra R. Bhutiyani
Hazard Assessment and Forecasting Division, Snow and Avalanche Study Establishment, Chandigarh, India

Definition

Caves formed within the glacier body or at its base (ice-rock interface) are often called ice caves or glacier caves. They are generally found in those glaciers where temperatures remain subzero for large parts of the year.

Origin

They are mostly formed by surficial melting on the glacier surface during ablation season. The supraglacial meltwater channels thus formed (Figure 1) enter the glacier body either through the crevasses or vertical shaft like holes called "moulins" or "mills" (Figure 2). Full-depth crevasses or moulins may guide this water to the base of the glacier. Subglacial cavities or channels are thus formed due to hydrostatic pressure exerted and enlargement of cavities facilitated by heat transfer from the water by its whirling action and the air to the ice mass. These meltwater channels ultimately exit at the glacier snout (Figure 3). Some subglacial ice caves are formed by geothermal heat from the earth and also from volcanic vents or hot springs beneath the ice. Sometimes, water falling through half-depth crevasses or moulins may carve its own englacial meltwater cave and a channel by similar process.

Ice Caves, Figure 1 Supraglacial meltwater channel on the glacier surface.

The ice cave thus formed may get enlarged through melting in summer. They are very dynamic and change from year to year. They may disappear as glaciers melt and retreat in response to the rising temperatures.

Ice Caves, Figure 2 A typical glacier "mill" or "moulin."

Ice Caves, Figure 3 Ice cave of Zemu Glacier in Sikkim Himalaya, India.

Significance

These ice caves help the glaciologists to study the interior of glaciers. The study of glacier caves themselves is sometimes called glaciospeleology.

ICE CORE

Nancy A. N. Bertler
Joint Antarctic Research Institute, Victoria University of Wellington and GNS Science, Wellington, New Zealand

Definition

An ice core is drilled from glaciers or ice sheets. It represents, like tree rings, an often sub-annual record of snow accumulation through time. Geochemical analyses of the ice, gas bubbles, and particulates can be used to reconstruct a detailed view of environmental conditions at the time of the snow precipitation. This includes reconstruction of local temperature, snow accumulation, humidity and temperature at the source region of the moisture, as well as atmospheric circulation pattern and vigor, storminess, sea-ice extent, ocean productivity, and greenhouse gas concentrations.

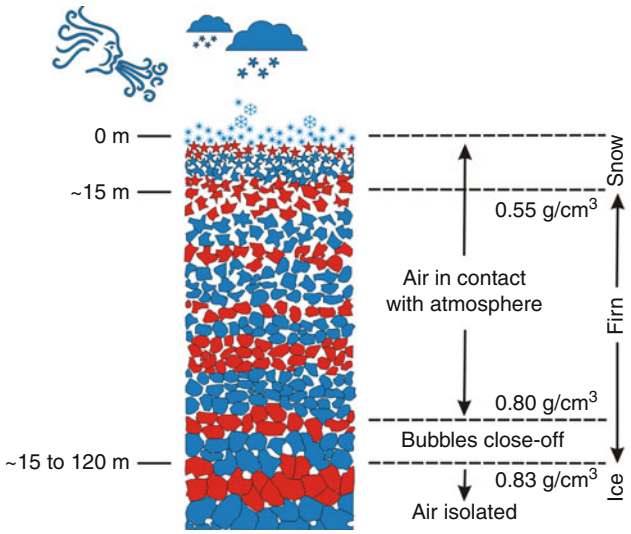
Introduction

As snow precipitates and accumulates to create glaciers and ice sheets, it captures and preserves a realm of information on the climatic and environmental conditions at the time of precipitation. As the snow is buried by subsequent snow fall, it forms isochrones (layers of same age) that can be read like pages of a detailed diary of past climate variability with near instrumental quality (Alley, 2000; Mayewski and White, 2002). Depending on annual snow accumulation and the seasonal distribution of snow fall, ice cores can provide climate records with sub-annual to decadal resolution for hundreds of millennia. The longest ice core record to date has been recovered by the European Programme for Ice Coring in Antarctica (EPICA) at Dome C in East Antarctica and spans almost 1 million years (EPICA Community Members, 2004). The deepest ice core record is 3,623 m long and has been recovered from Russian Vostok Station in Antarctica, which contains a record of the past 460,000 years (Petit, 1999) and lies above the largest lake in Antarctica, Lake Vostok. However, ice cores have been recovered from many places, including Greenland (Mayewski et al., 1993; O'Brien et al., 1995; Sigfus J. Johnsen et al., 2001; Steffensen et al., 2008) and Antarctica (EPICA Community Members, 2004; Jouzel et al., 1987; Mayewski et al., 2004; Mayewski et al., 2005; Petit et al., 1999; Wolff et al., 2009), and also from mountainous regions outside the polar regions, such as the Himalayas (Kang et al., 2004; Kaspari et al., 2008), Rocky Mountains (Osterberg et al., 2008), European Alps (Preunkert et al., 2000; Schwikowski et al., 1999), South American Andes (Aristarain and Delmas, 1993), and even the tropics (Stager and Mayewski, 1997; Thompson et al., 2003), such as Mt Kilimanjaro (Thompson et al., 2002) (Figure 1).

Structure of an ice core

As snow is compressed under the weight of new snow accumulating above, snowflakes turn into firn and eventually ice (Figure 2). The transition between those stages is defined by density. Snow is defined as lighter than 0.55 g/cm^3, while ice has the density of 0.83 g/cm^3, and firn lies in between. While snow and firn is permeable to air, below the bubble close off depth that lies between 0.80 and 0.83 g/cm^3, the ice becomes impermeable and the crystals trap pockets of atmospheric gases in tiny bubbles between crystal boundaries. As the bubbles are not closed off above the firn-ice transition, the gas in the bubbles is younger than the surrounding ice by the time it takes the ice to reach the bubble close off depth from the surface. This age difference depends on annual snow

Ice Core, Figure 1 Danish Hans Tausen Drill containing an ice core from Greenland from about 400 m depth. (Picture taken by Nancy Bertler.)



Ice Core, Figure 2 Schematic model of snow densification to firn and ice as defined by density. The depth of these transitions is highly dependent on site-specific characteristics such as average annual temperature and snow accumulation.

accumulation (the higher the annual snow accumulation the smaller the age difference) and annual average temperature (the warmer the temperature the smaller the age difference). For this reason the age difference does not stay constant even at a particular site, but is larger, for example, during glacial than during interglacial periods.

Resolution and length of an ice core record

In general, three types of ice cores are distinguished: shallow, intermediate depth, and deep ice cores. While shallow ice cores are in the order of a few meters to perhaps 100 m depth (e.g., the ITASE project), intermediate depth ice cores can be up to ~1,500 m deep (e.g., Berkner Island and Law Dome ice cores), and deep ice core projects have recovered cores of 3–4 km length (e.g., Vostok, EPICA, Dome F, Byrd, NGRIP, GISP2, GRIP ice cores). The logistical challenge of drilling intermediate or deep ice core limits the number of projects to a few, very large international efforts. While intermediate drilling projects might require 10–20 personnel on site, deep drilling projects are multi-year deployments with ~50 or more personnel on site. These projects often target long ice core records for many millennia in both high (WAIS, Greenland) and low snow accumulation (Vostok, EPICA) sites. Shallow ice cores can be obtained by a small team of 2–5 people and are often used for site reconnaissance, to reconstruct the recent past (perhaps the last 50–200 years), and to quantify geographical variability by obtaining a large grid of ice cores from different places, such as achieved by the International Trans Antarctic Scientific Expedition (ITASE) programme in Antarctica (Mayewski et al., 2005).

Types of information derived from ice cores

Ice cores provide three general types of proxies: (a) geochemical characteristics of the ice, (b) content and isotopic composition of gas bubbles enclosed in the ice, and (c) particulates.

Geochemical characteristics of ice

The ice is routinely measured for stable isotopes signature and geochemical composition.

Stable isotopes: The melted water of ice cores is commonly analyzed for stable isotope ratios of oxygen ($\delta^{18}O$) and hydrogen (δD) and measured against an international standard (V-SMOW – Standard Mean Ocean Water supplied from Vienna office of the International Atomic Energy Agency). Either isotope record (oxygen or hydrogen) can be used to reconstruct past temperature variability at the sampling site (Jouzel et al., 1997). Depending on the time resolution and length of the record, the data can reflect the seasonal change and/or longer-term temperature variability, such as glacial–interglacial cycles. To convert the stable isotope record into a temperature record, the data require site-specific calibration, which takes into account potential changes in moisture source, precipitation height over the surface (e.g., inversion layer), and site elevation changes (e.g., as ice sheets grow and shrink) (Jouzel et al., 1997). Over longer time periods (glacial/interglacial time scale) changes in the ocean composition have also to be taken into account, as the ice core record combines the signal of two effects (a) cooler temperatures and (b) a trend toward isotopically heavier ocean water during glacial time periods as

preferentially more and more isotopically lighter water is stored in the expanding ice sheets.

When both isotope ratios are measured, deuterium excess (d excess) can be calculated using the formula:

$$\text{d excess} = \delta\text{D} - 8 \times \delta^{18}\text{O}$$

Dansgaard (1964) observed for the first time that deuterium excess, or the deviation of the measured sample from the global meteoric water line, is sensitive to the sea surface temperature and absolute humidity at the moisture source region. When plotting global stable isotope measurements of meteoric water creates a linear correlation between oxygen and hydrogen isotope data, with a graph that intercepts with a value of 10 and a slope of approximately 8. While the slope is a result of the different diffusivity of deuterium and hydrogen, the intercept of 10 represents a global mean of deuterium excess. Deuterium excess is sensitive to kinetic fractionation of the water isotopes, which is primarily sensitive to phase changes such as evaporation and snow formation, providing a powerful proxy for sea surface temperature and humidity over the ocean, as well as air mass origin (Petit et al., 1991; Vimeux et al., 2002).

Geochemical analyses: The melted water is commonly measured for concentration of major ions, in particular Na, Cl, K, Mg, Ca, NO_3, SO_4, and methane sulfonate (Bertler et al., 2005). Together they represent a substantial proportion of all soluble aerosols in the atmosphere (Legrand and Mayewski, 1997) and provide a comprehensive view of the geochemical composition of the atmosphere and its circulation pattern. Circulation pattern can be reconstructed by identifying sources and transport mechanism of these aerosols, which indicate, for example, marine air-mass influences (e.g., Na and Cl), stratospheric air-mass input (e.g., NO_3), and volcanic events (e.g., SO_4). In addition, Boutron and colleagues developed methods to measure extremely low concentrations of trace and rare earth elements to provide preindustrial background levels (Boutron and Lorius, 1979). Today, the focus has shifted toward understanding their source and sinks as well as transport characteristics by using concentrations as well as isotopic ratios of these elements (Osterberg et al., 2008; Rothlisberger, 2000) as well as organic acids (Legrand et al., 1992).

Gas bubbles

Since 1958 AD atmospheric measurements at Mount Mauna Loa Observatory monitor the concentration of carbon dioxide (CO_2) in the atmosphere (Keeling et al., 1976). Prior to the onset of the observational record, ice core records have been used to extend the record of greenhouse gas concentration back to almost 1 million years (EPICA Community Members, 2006; Luthi et al., 2008; Petit et al., 1999). As snow compacts under the overlaying burden of new snow precipitation, it changes into firn and eventually ice. At the firn-ice transition, tiny bubbles are closed off between the ice crystals. Those bubbles contain a sample of the atmosphere at the time of bubble close off and hence can provide a detailed record of past variability of greenhouse gas concentrations, such as carbon dioxide (CO_2), methane (CH_4), and nitrous oxide (N_2O). The available resolution of the gas records depends on the depth and age of the bubble close off layer and the mixing ratio of the gas in the firn. While the firn is permeable, it is more vented at the top than toward the firn-ice transition. The gradual capture and gravitational fractionation of the gases has to be taken into account. One of the highest available greenhouse gas records has been derived from Law Dome in Antarctica. There the age difference between the gas and the ice at the modern firn-ice transition is only 60 ± 2 years and the diffuse mixing time of the gas down to the bubble close off is 8 years (Morgan et al., 2002). At colder, lower snow accumulation sites, for example, Vostok, the age difference is well over 1,000 years; however, the records are significantly longer (Petit et al., 1999).

Ice cores have shown for the first time that greenhouse gas concentration and temperature covaried in the past. The Vostok ice core was the first core to show the close relationship between carbon dioxide and methane and temperature over the last four glacial/interglacial time periods (Petit et al., 1999). The EPICA Dome C core record extended that record and showed that carbon dioxide and methane remained in a narrow range over the past 800,000 years, not exceeding 300 ppm (Luthi et al., 2008) and 800 ppb (Loulergue et al., 2008), respectively, during past warm periods. These records provide a baseline to compare modern concentrations and show that over the past 250 years during the industrial revolution, greenhouse gas concentration in the atmosphere increased significantly – about 35% for carbon dioxide, 150% for methane, and 16% for nitrous oxide (IPCC, 2007).

Particulates

Through predominantly dry deposition, dust and other particulate material is trapped in porous snow and firn, which provides a detailed record of past atmospheric particulate loading. Dust is an important driver of global climate, and appears to be the first indicator to change over glacial–interglacial time periods (Broecker, 2000; Delmonte, 2004; Lambert et al., 2008; Steffensen, 1997; Wolff et al., 2006). Dust particulates effect the climate system through iron fertilization of the ocean (Blain et al., 2007; Boyd et al., 2000), the influence of aerosols and dust particles on nuclei formation and drop size in clouds, and on the residence time of water molecules in the atmosphere (Broecker, 2000). Global dust particulates are characterized by modal grain size between 2 and 6 μm (Delmonte et al., 2004). The transport of particulates to snow surfaces is dependent on weathering of crustal sources, the proximity of the source region, wind speed, wind turbulence, and snow accumulation (Delmonte et al., 2004). In addition, studies of black carbon particulates in ice cores provide records of past forest fires and anthropogenic pollution (McConnell et al., 2007).

Dating ice cores

The most common dating technique of ice cores is by counting seasonal variability, which can be expressed in stratigraphy (e.g., denser winter and lighter summer layers), stable isotope variance (low oxygen or hydrogen isotope values for winter and higher values for summer), geochemical differences (e.g., sodium often peaks during winter, while MS peaks during autumn), etc. (Alley, 2000; Mayewski and White, 2002). In addition, time markers from volcanic eruptions are often used to evaluate the accumulative dating error of annual layer count and to adjust the annual layer count to absolute ages back in time. Rarely is tephra found as evidence of the volcanic eruption, instead sulfate or SO_4 is used, which shows large peaks for many eruptions, such as Tambora and Krakatau (Dixon et al., 2005; Kurbatov et al., 2006; Zielinski et al., 1997). In addition, radioactive isotopes such as 10Be, 14C, 36Cl, and Tritium are used as radioactive clocks (Beer et al., 1988; Muscheler et al., 2005; Petrenko et al., 2006). Long ice core records, covering many glacial–interglacial records, are often dated using age models which are based and tuned to Milankovitch cycles (Parrenin et al., 2004; Schwander et al., 2001).

The future of ice core research efforts: the International Partnership on Ice Coring Sciences (IPICS)

To coordinate the science efforts of the ice core community of the next decades, the International Partnerships on Ice Coring Sciences, or IPICS, was established. IPICS is a group that represents 18 nations (Australia, Belgium, Brazil, Canada, China, Denmark, Estonia, France, Germany, India, Italy, Japan, Korea, Netherlands, New Zealand, Norway, Russia, Sweden, Switzerland, United Kingdom, and the United States) and is composed of ice core scientists and drilling engineers. IPICS identified four scientific and one technical focus area for the ice community for the next 10–20 years. These are (http://www.pages.unibe.ch/ipics/documents.html):

- The Oldest Ice (at least 1.4 million years and beyond)
  This focus group investigates the characteristics and cause of the transition from 40,000-year cycles to 100,000-year cycles in the late Pleistocene. One of the main contributions of such an ice core would be to reconstruct greenhouse gas concentrations during the 40,000-year cycle period in comparison to the last 1 million years that was dominated from 100,000-year cycles.
- The IPICS 40,000-year array: A bipolar record of climate forcing and response
  The behavior and timing of the last deglaciation shows large geographical variability in the available ice core records. This focus group aims to obtain more intermediate deep ice cores that will help to understand these geographical differences and correlate records from the Northern and Southern Hemispheres.
- Northwest Greenland Eemian
  The extent of the Greenland during the last interglacial, the Eemian, is still unknown. The North Eemian Ice Core Project, or NEEM, is anticipating to find Eemian ice in Greenland, which will provide proof that the Greenland ice sheet existed during this warmer-than-today time period, and will provide new insights of the climate and environmental conditions in Greenland and globally.
- The IPICS 2,000 year array
  This focus group investigates the geographical variability of ice core records from Antarctica and Greenland to help interpret deeper records and to understand current climate variability, such as interhemispheric relationships and the timing and expression of the Little Ice Age. The suggested work is based on the efforts of the International Trans Antarctic Scientific Expedition, or ITASE, programme, which focuses on the past 200 years.
- New Drilling Technology
  Ice core research is a rapidly growing science branch that necessitates new technology to cater for new sampling requirements, such as directional drilling, drilling of the ice-bedrock interface, clean drilling technology, etc. This focus group provides a platform to share new developments and to prioritize technological needs.

Summary and conclusions

"Ice Cores provide the most direct and highly resolved records of (especially) atmospheric parameters for the last 1,000,000 years" (EPICA Community Members, 2004). Major scientific contributions of ice core research linked atmospheric temperature and greenhouse gas concentrations (Petit et al., 1999), and provided evidence that major climate swings can occur within less than 2.5 years (Steffensen et al., 2008). Large international collaborations, such as ITASE and IPICS, started to integrate ice core records from across the world and to prioritize the most important work for the ice core community. With new drilling and analytical technological developments and ever more new proxies and higher resolution records, ice cores have yet big stories to tell for the decades to come.

ICE COVERED LAKES

Lars Bengtsson
Department of Water Resources Engineering, Lund University, Lund, Sweden

Definition

Ice on lakes grows in a static way. Ice is produced as black ice, when heat is lost to the cold atmosphere from the water underneath the ice, or as snow ice, when the ice is suppressed under the water surface by heavy snow and water freezes in the slush layer in the snow on top of the ice.

Lakes at high latitudes or high altitudes are ice covered part of the year; typically from November through April and in the very north sometimes from October to early June. Arctic lakes may be ice covered throughout the year. When there is a regular ice cover for several months, the ice thickness reaches more than ½ m, as shown in the example in the figure from Luleå, Sweden. At mid-latitudes, occasional ice cover may appear for short periods several times during a winter. Where there is a stable ice cover, ice roads are prepared. Fishing is done also at commercial scale. Ice covered lakes are used for recreation.

Ice on a small lake is formed rather quickly after the surface water is cooled down to the freezing point – most often after a cold night with no wind. It takes much longer time for a large lake to freeze over than a small lake, since relatively warm water is brought to the surface during the more intense mixing in a large lake. Once ice is formed, it grows rather quickly the first weeks until the ice cover insulates itself and snow on the ice insulate the water from the atmosphere and the rate of ice growth is slowed down. The heat lost from the water to the atmosphere must be taken from the latent heat released when ice is formed, since the water just below the ice is at the freezing point. Balancing the ice formation at the underside of the ice cover and the heat conduction through the ice leads to the degree-day method, which well determines the ice thickness:

$$h = CS^{1/2}$$

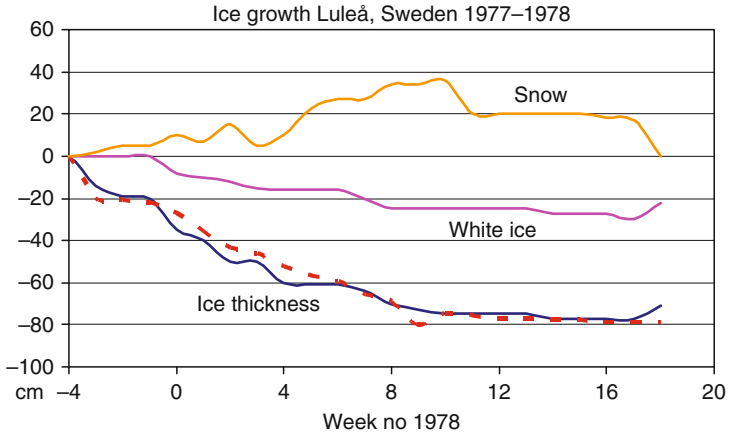
$$S = \text{accumulated negative degree} - \text{days after the first thin ice is formed}$$

where the coefficient C is about 2 cm/(°C-day)$^{1/2}$, when there is snow on the ice and 3.5 cm/(°C-day)$^{1/2}$ for snow-free ice. As an example, after 1 month with −10°C and snow on the ice, the ice thickness should be 35 cm, and after 5 months with −10°C, 77 cm. The snow thickness on the ice is limited by the lifting force from the ice. From Archimedes' principle, the maximum snow cover is seen to be one third of the ice thickness, when the snow density is 0.3 relative that of water (common on ice some time after the snowfall) and half the ice thickness when the relative snow density is 0.2.

An example of ice growth is shown in Figure 1 from a bay in the Luleå archipelago (almost fresh water). The computed ice thickness using a degree-day approach is also shown.

Ice formed from the underside of the ice sheet has crystals with columnar structure; it is possible to see through the ice. Such ice is called black ice. Ice can also be formed in a slush layer between the snow and the top of the ice. When the weight of the snow is more than the lifting force from the ice, the ice cover is forced under the water surface and water enters into the snow, which becomes saturated with water. When this slush layer freezes, snow ice or white ice is formed. The crystals in this kind of ice are randomly distributed. The ice is like milk; it is not transparent.

The ice on a lake has ecological consequences. The water is insulated from the atmosphere. Due to heat flux from the sediments, the heat content of the water in an ice-covered lake slowly increases during winter. A warm bottom layer of close to 4°C is becoming thicker and



Ice Covered Lakes, Figure 1 Observed ice growth in the inner archipelago in Luleå, Sweden. Snow depth on the ice is shown and, separately, the snow ice growth. The *dotted line* is the computed ice thickness using a degree-day approach. Measurements by the author.

thicker. Since there is no exchange with the atmosphere, the oxygen content of the water decreases and the bottom layers may be completely depleted. The circulation in an ice covered lake is very much reduced as compared to ice-free conditions. There is no wind-driven circulation. However, slow back and forth seiche movements are initiated by the wind acting on the ice cover giving rise to some dispersion near the ice. The heat flux from the sediments causes large-scale very slow convection. In spring, when the ice is free from snow, solar radiation may penetrate through the ice and induce convective mixing of the top few meters.

Man's impact on lake ice is mainly from release of oxygen consumption substances, which increases the rate at which the lake water is depleted in oxygen. All releases from industries and waste water treatment plants and also the increased winter flows in regulated rivers have local effects on the ice cover.

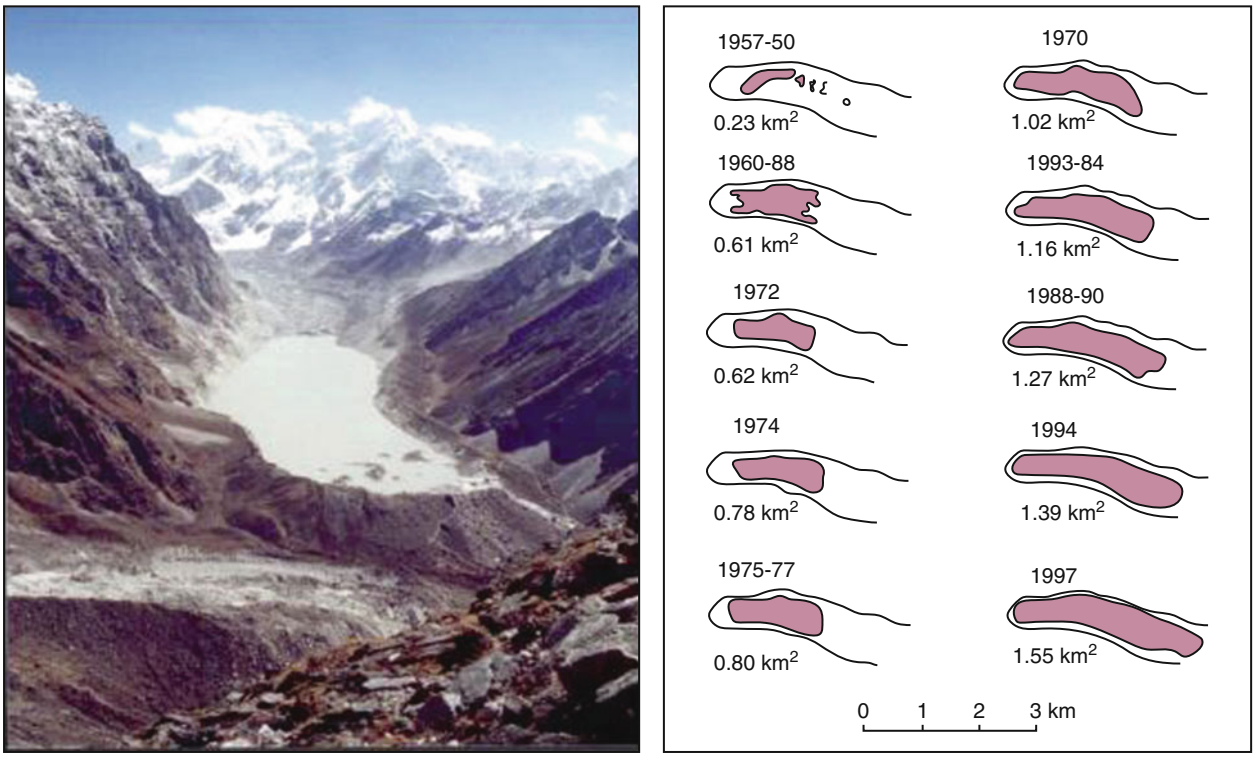
Definition

Ice dams are the temporary reservoirs of impounded meltwater formed in glacierized river basins.

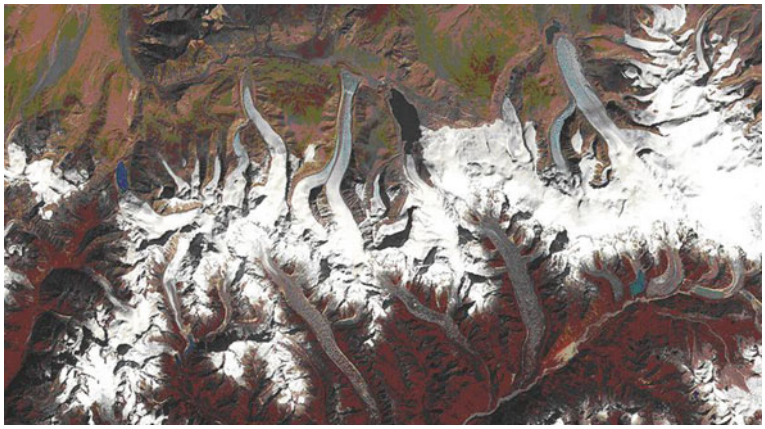
Origin

They owe their origin to either the "retreating" glaciers or the "surging" glaciers (with abnormally high velocities). Smaller glaciers with narrow valleys while retreating in response to warming climate leave behind large mounds of inactive end or terminal moraines in the valley. They act as a barrier or a wall resembling a dam to the flow of the glacier stream. Meltwater accumulates and gradually a reservoir builds up in the upstream direction (Figures 1 and 2), exerting significant hydrostatic pressure on the structure. Failure of such fragile dams may sometimes lead to disastrous flash floods (Figure 3). Depending upon the situation, such floods are also known as glacier lake outburst flood (GLOF). There have been many incidences of such floods in the Himalayas. Similar dams are also formed when smaller "surging" glaciers in the transverse valleys move rapidly to such an extent that they block the main longitudinal valley and obstruct the flow of its meltwater stream (Figure 4). An ice dam thus formed is also subjected to large hydrostatic forces due to the buildup of a large reservoir upstream.

Ice Dams, Figure 1 A typical retreating glacier with a formation of an ice dam.



Ice Dams, Figure 2 This NASA image shows the formation of numerous glacial lakes at the termini of receding glaciers in Bhutan Himalaya.



Ice Dams, Figure 3 Growth of potentially dangerous ice dam in Nepal Himalaya.

Ice Dams, Figure 4 Google Earth (2007) slanted view of Thangman Glacier – a "surging" glacier in the Karakoram Himalaya with a potential to form an ice dam upstream.

Significance

Failure of these dams has given rise to number of disastrous glacier meltwater flash floods in the Himalayas, the Alps, and the Rocky Mountains.

ICE SHEET

Alastair G. C. Graham
Ice Sheets Programme, British Antarctic Survey, Cambridge, UK

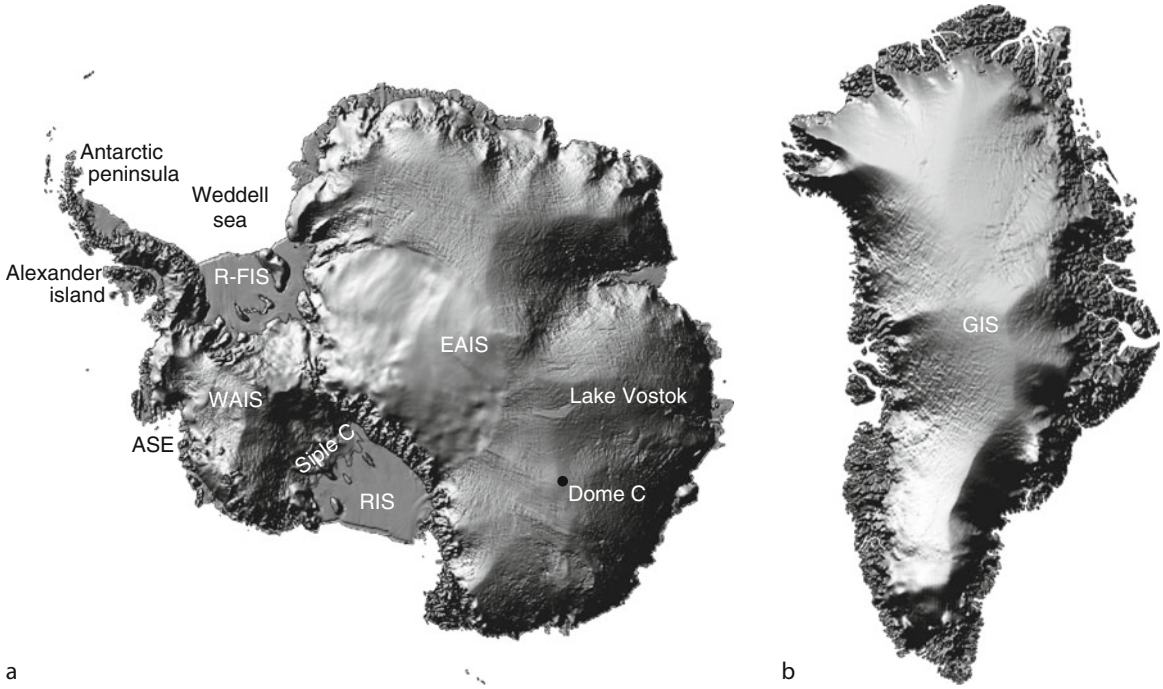
Definition

Ice Sheet. A perennial mass of glacier ice, and snow, that covers surrounding terrain and that has an area greater than 50,000 km^2 (19,305 miles^2) (after Armstrong et al., 1973).

Introduction

The two remaining polar ice sheets are the largest single bodies of ice and snow on the planet, covering 3% of the Earth's surface – the surface areas of Greenland and Antarctica measure 1,710,000 and 14,000,000 km^2, respectively (Figure 1). They act as important stores for over 80% of the world's fresh water (Bamber et al., 2007). The water trapped in Antarctica's ice sheet alone would fill Lake Superior 2,000 times over, and has the capacity to raise global sea level by up to ~61 m, if it were to melt fully.

Both the Antarctic and the Greenland ice sheets have, however, a longevity that belies their fragile composition. Ice has been present in some form at the poles for at least 5 Ma, with a year round ice cover on East Antarctica since at least 14 Ma, and has survived many periods of global change – even periods when the Earth was



Ice Sheet, Figure 1 Digital elevation models (DEMs) of the two remaining polar ice sheets, shaded to highlight their topography and form. (**a**) Antarctic surface topography DEM from Liu et al. (1999). (**b**) Greenland surface topography DEM extracted from the ETOPO2v2 2-min gridded global relief dataset (http://www.ngdc.noaa.gov/mgg/fliers/01mgg04.html). warmer than it is at present. Despite this proven resilience and their truly "glacial" rates of response, ice sheets are surprisingly dynamic on the geological-timescale, responsive to their external environment over both long timeframes; for example, the tens of thousands of years over which the orbit of the Earth around the Sun alters; and the rather shorter timescales; for example, the daily cycles manifested in the tides of Earth's oceans. Ice sheets are important features within the global climate and ocean systems and with the potential to produce widely felt impacts well outside the polar regions. An improved understanding of their behavior and interactions is, therefore, urgently required by those scientists involved in trying to predict the future climate of Earth.

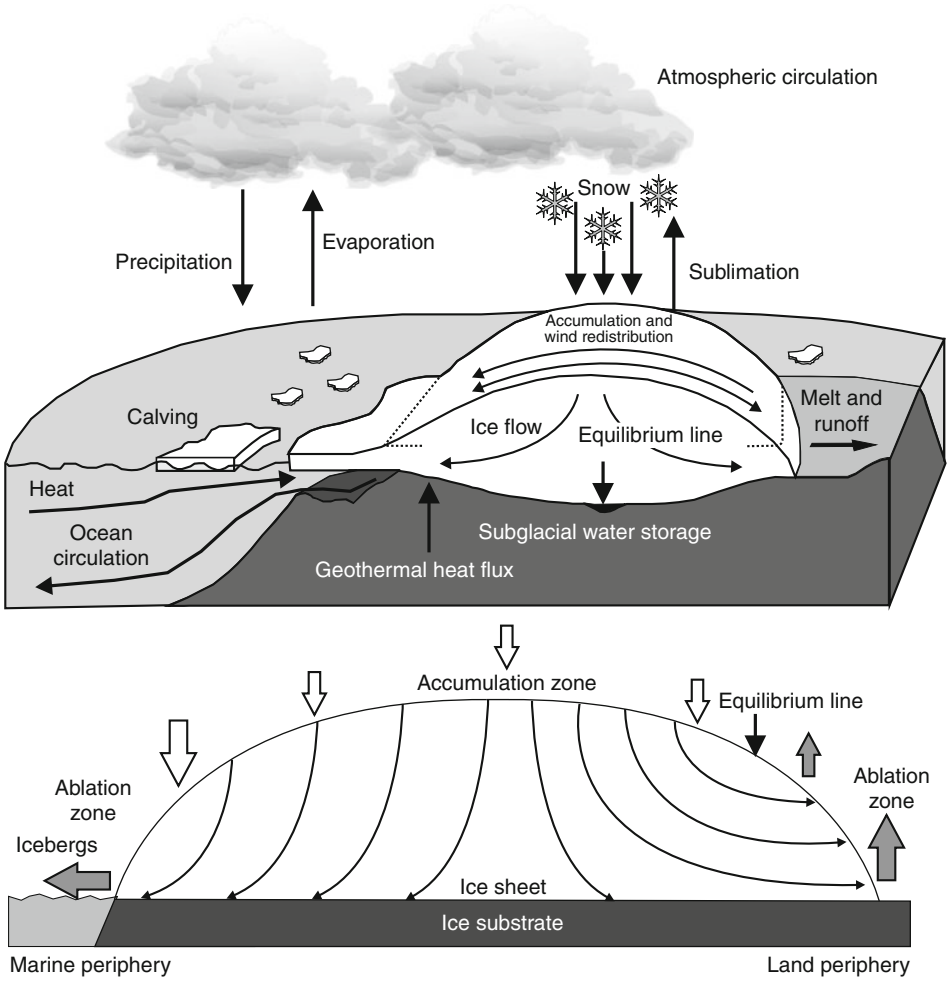
Indeed, in the last decade, observations of change in both ice sheets, made possible by a new generation of sophisticated Earth-observing satellites, has demonstrated that ice sheets may be more sensitive to change in their surroundings than previously thought. This implies that particularly vulnerable parts of both ice sheets may be threatened by even relatively small perturbations in climate. The future increase in mean global temperature, caused by anthropogenic warming, which is projected to rise an average of 3°C by the end of the twenty-first century (the Intergovernmental Panel on Climate Change [IPCC], 2007), may have severe and irrevocable consequences for polar ice masses. Indeed, the past 30 years have already seen major and apparently rapid changes occurring in the polar ice sheets, perhaps as a consequence of the "greenhouse effect." In response to this warming, the demise of polar ice sheets would have damaging repercussions, not only for the environment, but for society and the economy (Stern, 2006). As a result, understanding the physical processes in polar ice sheets, their geological setting, the potential for their future change, and possible collapse, have become leading questions for climate policymakers (IPCC, 2007), the media and society (e.g., Gore, 2006), and polar scientists alike.

This entry provides an overview on the subject of ice sheets and ice sheet change, offering an introduction to their physical and glaciological character from an Earth Science perspective. This entry introduces some concepts of growth, flow, and loss, before describing the form and features of ice sheets. We consider the shift in focus of ice sheet research over the years, and illustrate some of the changes underway in the polar ice sheets today. We frame these against evidence for changes in former ice masses from the geological record, and conclude by discussing the future of the modern ice sheets on the planet.

Physical and glaciological character

Ice sheets describe the vast, contiguous masses of ice that form the Earth's two largest glacial bodies (Figure 1): the Greenland Ice Sheet (GIS), and the Antarctic Ice Sheet, which in itself comprises three unique provinces: the West Antarctic Ice Sheet (WAIS), Antarctic Peninsula Ice Sheet (APIS), and East Antarctic Ice Sheet (EAIS). In their broadest context, the ice sheets are linked to the climate of Earth through a complex and intricate ice–ocean–atmosphere circulation system, which regulates the movement of heat, water, and ice in both hemispheres, and at both poles (Figure 2). Our understanding of the physical changes in ice sheets (and indeed in any glacier or ice cap) is built around these climate systems and specifically the concept of steady-state ice flow (see also *Atmosphere-Snow/Ice Interactions*).

Each year, ~7–8 mm of water from the surface of the world's oceans enters the polar ice sheets as snowfall. If this buildup of ice was not returned to the ocean in some way, sea levels would fall by ~8 cm every decade, while the ice sheets would continue to grow to impracticable sizes. Glacial flow is the mechanism that regulates the size of the ice sheets, ensuring the amount of ice gained is compensated by ice lost. A "steady state" is achieved, in principle, where the input and output of ice is exactly equal. The fine balance that exists between this input and output – known as mass balance (see also *Glacier Mass Balance*) – ultimately influences whether an ice sheet grows or shrinks (Figure 2). In today's polar ice sheets, the repeated growth and loss of ice has resulted in the ice sheets achieving a sensitive balance between their input and outflow; almost to the point of "steady" equilibrium. However, the many billions of tons of ice that enters and leaves the AIS and GIS each year results in parts of the ice sheets being surprisingly responsive, and to even the smallest of imbalances. Assessments of the state of the ice sheets, both now and in the future, are important because mass balance and thus



Ice Sheet, Figure 2 Schematic illustrations of the Earth's ice–ocean–climate system, and the various components involved in determining ice sheet mass balance. *Top* schematic redrawn and modified from US Global Change Research Program (http://www.usgcrp.gov; last visited 20/04/2009), *bottom* schematic redrawn and modified from Siegert (2007).

ice volume is a major control on global sea level. The growth, flow, and loss in ice sheets are the fundamental mechanisms for understanding how imbalances may occur.

Ice sheet growth, flow, and loss

An ice sheet builds mass at its surface by deposits of snowfall and frost, which, because of the persistent cold environment, do not melt but amass year-on-year in the accumulation zone (Figure 2). Gradual compression and packing of surface snows, as they are buried by the weight of new snowfall, eventually transforms them into solid ice, at depth (see *Transformations of Snow at the Earth's Surface and its Climatic and Environmental Consequences*). At a critical mass, gravitational forces lead the ice sheet to move, which it does so as an ultra-viscous fluid. The general domed topography of ice sheets dictates that most of this ice is driven toward the ice sheet exterior, where it is lost in the ablation zone, or at the ice margin where the ice sheet meets the ocean (Figure 2). The flow of ice is initiated because of differences in pressure caused mainly by the ice-surface slopes, which result in the ice sheet being held under permanent strain, in response to applied stress. Normal and shear stresses cause motion in the ice sheet, through a combination of deformation of the ice, deformation of the ice substrate, and sliding at the ice-bed interface. Other conditions impart a resistance against ice flow, and include physiographic factors such as roughness at the bed, as well as glaciological factors; for example, through buttressing from floating ice shelves.

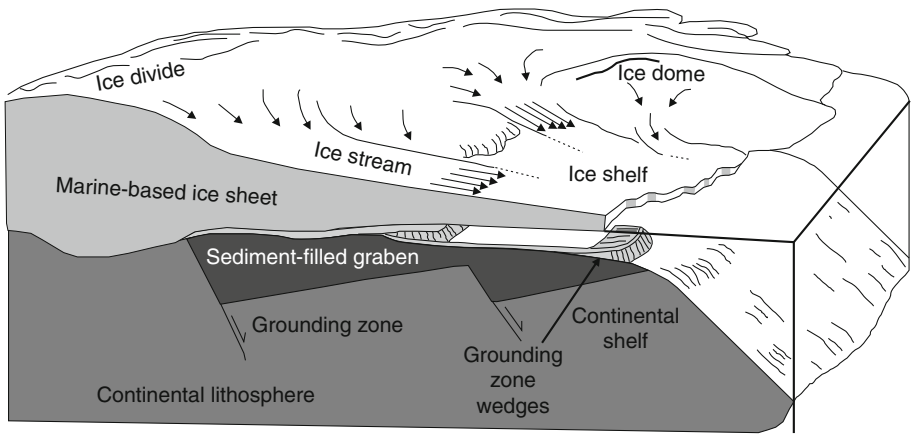
The Equilibrium Line Altitude (ELA) is the boundary dividing the areas of net growth and net loss in the ice sheets (Figure 2). Its position is an important gauge of ice sheet balance and therefore "state." Ice accumulates in the area of the ice sheet above the ELA, where the precipitation rates, elevation, and surface area of the ice sheet determine net growth. The great size, cold conditions, and overall form of the ice sheets help create unique microclimates in their inland centers, which allow them to continually regulate their mass balance. In contrast, expanses of the ice sheet beneath the ELA are exposed to greater melting and to net loss. Forced changes in the position of the ELA, whether natural or human-induced, can tip the balance in favor of ice growth or decay accordingly.

In both polar ice sheets, fringing glaciers provide the main outlets for ice flow to drain to the exterior, and most mass loss can be attributed to these arterial drainage components (Figure 3). In marine ice sheets such as the WAIS that have margins terminating straight into the ocean, when the flow of glacial ice eventually reaches the sea it either calves off as icebergs or melts directly into coastal waters (Figures 2 and 3). Melting at the ice sheet fringes can be enhanced externally, by the heat transfer from ocean waters feeding the underside of the floating portions of the ice sheet (ice shelves), and delivering warmer water to the ice sheet grounding line (the line or zone at which an ice mass entering a water body begins to float). The contrasting example is a terrestrial ice sheet, like that of Greenland, where most of the ice is grounded upon dry land, and where most ice loss occurs by a combination of melt-out, runoff, and surface ablation (Figure 2).

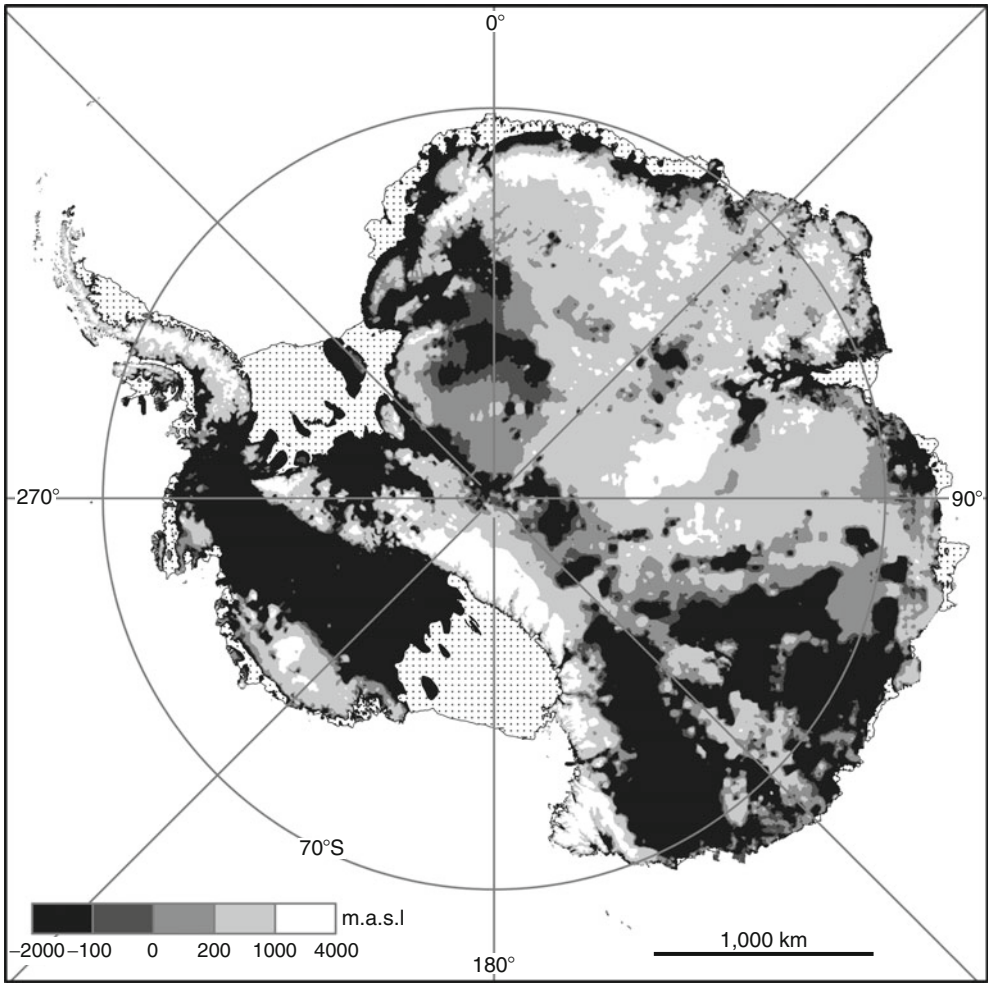
Marine and terrestrial ice sheets

The way mass balance changes are manifested in an ice sheet, and the resulting dynamics of that ice, are both strongly influenced by the physiography of the bed buried beneath several hundreds of meters or kilometers of ice. Indeed, the flow and stability of an ice sheet grounded in a marine versus a terrestrial setting is quite different e.g., (Figure 2).

The beds of the WAIS and parts of the EAIS lie well below sea level today, meaning the ice sheet above is marine-based (Figure 4). With a base below sea level, the WAIS is anchored to its sole only because it is too thick to float off. Marine ice sheets are thus inherently unstable



Ice Sheet, Figure 3 Schematic illustration of the geological setting and glaciological components of a marine-based ice sheet, such as the West Antarctic Ice Sheet. Note the ice centers and ice domes drained by well-defined ice streams, which in turn, feed floating ice shelves at the ice sheet periphery. After http://icesat.gsfc.nasa.gov/science.php (last visited 20/04/2009).



Ice Sheet, Figure 4 Map of the bed topography beneath the Antarctic Ice Sheet in relation to modern-day sea level. The basins of West and East Antarctica shaded black have a bed well below sea level and are therefore susceptible to rapid deglaciation. M.a.s.l. (meters above sea level). Drawn from the BEDMAP dataset (Lythe et al., 2001). Ice shelves are denoted by stippled shading.

as they come into direct contact with the ocean, and because changes in their mass can effect their buoyancy.

Marine ice is especially unstable where the ice sheets have beds that slope inland. On a back-sloping base, even small amounts of ice thinning or increases in outlet-glacier velocity can trigger a positive feedback in retreat of the grounding line. Initial retreat inevitably leads to further flow enhancement and loss because, while the ice sheet may be retreating, the thickness of the ice at the grounding line and the gradient of its surface profile both increase inland (Schoof, 2007; Vaughan and Arthern, 2007). The increasing negative imbalance resulting from this feedback far outweighs the ability for the ice sheet to be replenished by new snowfall, and runaway "collapse" (i.e., rapid deglaciation) of the marine parts of the ice sheet is therefore possible under these conditions.

A terrestrial ice sheet has few areas of ice grounded below sea level at its margins meaning the ice sheet is essentially buffered against a similar marine collapse. Instead, warming from the atmosphere above, or from the substrate beneath the ice sheet, are the most important controls on terrestrial ice sheet balance. These factors influence the position of the ELA on the ice sheet, and the conditions of ice flow within it. Unlike marine ice, rapid deglaciation of terrestrial ice sheets is really only achievable where warming raises the ELA sufficiently so that growth of the ice sheet is no longer possible without significant global cooling.

Form and features

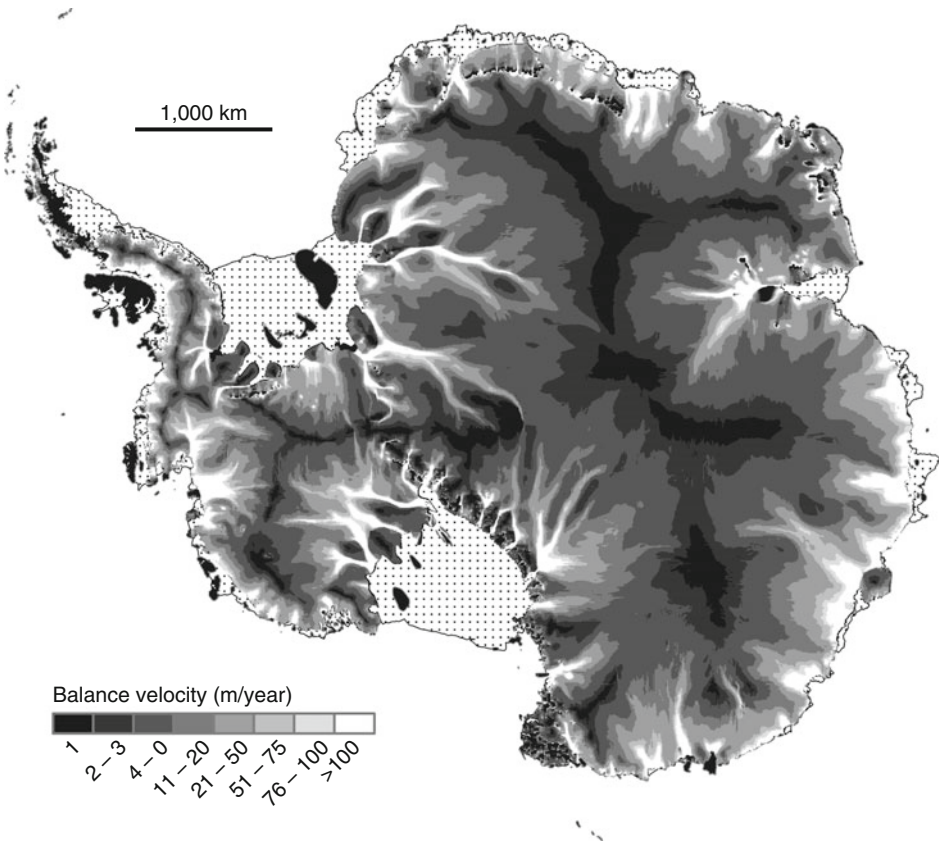
Whether marine- or terrestrial-based, ice sheets can usually be considered in terms of a number of unifying glaciological components. The drainage characteristics described herein are important for ice flow and form, and for assessing ice sheet changes (Figure 3).

Inland ice sheet: slow-moving centers

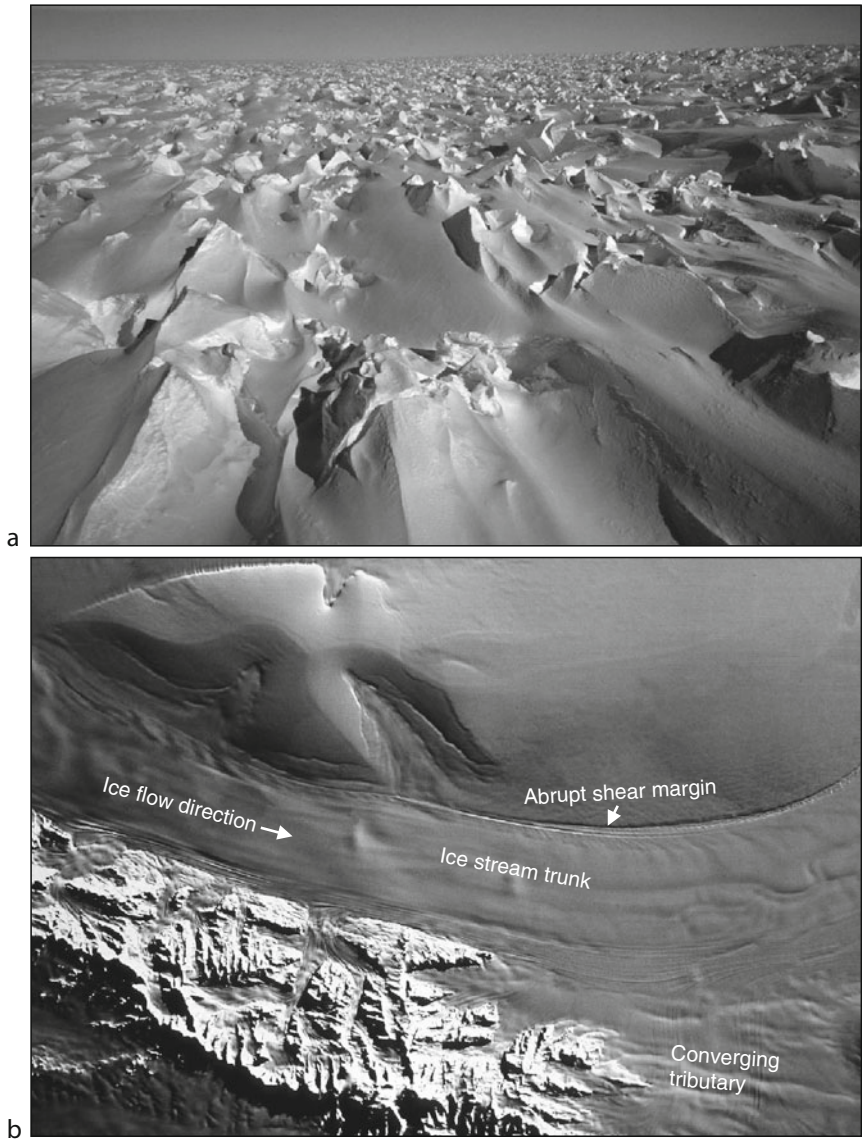
The centers, or inland parts of the polar ice sheets are amongst the driest, coldest, and most inhospitable places on Earth. They are also the slowest moving and most stable parts of an ice sheet. Major ice divides characterize this zone, segregating individual ice domes, and delineating the first-order ice drainage basins (see also Figure 5). The surface character of the inland ice sheet is generally flat and featureless over vast expanses, although in places wind-blown dunes (sastrugi) form ridge-troughs in the direction of prevailing winds, causing small-scale roughness elements in the upper layers of the snow cover (Figure 6a).

Beneath parts of the Antarctic interior, vast mountain ranges have been imaged and mapped (e.g., the Gamburtsev mountain range), which serve as major obstacles for ice flow, and which strongly influence the broad-scale ice dynamics of the overlying ice sheet. These ranges offer insight into how the ice on Antarctica was first conceived, and have been the targets of recent pioneering, multidisciplinary survey campaigns in inland East Antarctica.

Recent observations beneath these interior zones have also identified the importance of ice sheet centers for subglacial hydrology. Pools of trapped water beneath the ice – subglacial lakes – imaged by radar, exist toward the center of ice sheets, often near to ice divides, and exploit topographic lows or tectonic boundaries. These form key components within an interconnected network of channels and isolated basins that make up a complex subglacial hydrologic system. Water is now known to move between these pools and along ice-flow pathways abruptly and in massive quantities, demonstrating a dynamic side to ice sheets that was previously unknown. More important to ice sheet change perhaps, is the recent realization that subglacial lakes can significantly alter the dynamics of overlying ice by enhancing ice flow in the upstream reaches of ice sheet drainage outlets (e.g., Bell et al., 2007). The lakes can instigate acceleration in downstream ice because, above the lake, the basal stress of the ice sheet is reduced to zero. Lakes can also alter the subglacial thermal regime of ice sheets by warming the ice over the lake, due to the heat released during processes of accretion. Both processes may cause ice to remain unfrozen to its bed downflow.



Ice Sheet, Figure 5 Balance velocity map for the Antarctic Ice Sheet inferred from satellite datasets (after dataset in Bamber et al., 2000). The map shows the distribution of ice divides as areas of low velocity (black to dark-gray), and inter-fingering networks of high-flux, faster-flowing ice streams (light-gray to white). Ice shelves are denoted by stippled shading.



Ice Sheet, Figure 6 (**a**) Photograph of the inland part of the Antarctic Ice Sheet, showing wind-blown dunes (sastrugi) on the ice surface (image from BAS photo database), (**b**) A Landsat image of the Rutford ice stream, illustrating its fast-flow trunk, distinct shear margin, and converging tributaries at onset (image from BAS photo database). Width of the main ice stream trunk is c. 26 km.

The largest known subglacial lake, today, is Lake Vostok in East Antarctica (Figure 1; c. 14,000 km^2 in area). Vostok lies beneath one of the thickest parts of the ice sheet – as thick as the largest peaks of the Rocky Mountains are high. The lake is associated with a rather prominent morphological surface feature in that the ice sheet surface over the lake is flat and featureless, resembling the upper plain of an ice shelf. Up to 280 subglacial lakes have now been recognized beneath the AIS based on similar surface observations (Siegert et al., 2005; Wingham et al., 2006; Smith et al., 2009), as well as detailed characterization and classification of the ice sheet bed from airborne and satellite datasets. It is likely that many more subglacial lakes remain to be discovered at the poles.

Ice streams: outlets of fast flow

Whether enhanced by an underlying subglacial lake, or simply driven by the force of gravity, the transfer of ice from the "static" interior to the ice exterior is a key process in all ice sheets. Calculations of the polar ice sheets' balance velocity – the velocity required to maintain ice sheet steady state at each given point on the ice sheet – show

that this process is not uniform around ice sheet edges (Figure 5; Bamber et al., 2000). Indeed, more than 50% of the outflow from the AIS passes through just 40 of its largest outlets – pathways of restricted, faster glacier flow, termed ice streams (Figures 3, 5, and 6b). These streams represent the transition from interior flow to marginal or ice-shelf spreading, and serve to focus ice drainage (as well as water and sediment drainage) toward the coasts or ice sheet periphery, acting as large conveyer belts that deliver ice from centers of accumulation to areas of loss (Figures 3, 5, and 6b).

Maps of the balance flux of the ice sheets also show that ice streams originate from the ice sheet cores, and gradually increase in velocity downstream along their length (Figure 5). Flow speeds in the main trunks of some of the major Antarctic ice streams have been measured in a range from about 100 to more than 2,000 m year^{-1} (e.g., Pine Island Glacier), faster than the surrounding ice in which they are emplaced by a factor of 100 or more (Truffer and Echelmeyer 2002). As a result, the highest ice flux rates focus along these pathways (Figure 5), and it is of little surprise that they have been described as the arteries of an ice sheet (Figures 5 and 6b; Bennett, 2003). Accountable for 90% of drainage in the AIS, ice streams are, therefore, inextricably linked to the amount of ice lost and thus an ice sheet's mass balance.

Ice flow within ice sheets, let alone within their ice streams, cannot be explained by gravitational force alone. The flow of ice streams is therefore made possible, and enhanced, by their flow within sediment-filled subglacial valleys or across regions of subglacial meltwater (Bell et al., 1998; Studinger et al., 2003; Peters et al., 2006). The latest observations have demonstrated that many of the changes in ice sheets originate in, and radiate from, channelized ice streams or outlet glaciers. Hence, ice streams have received a lot of recent attention as the regulators of flow in ice sheets. A case in point are the extensive field campaigns that have taken place, in recent years, along the Siple Coast of West Antarctica (Figure 1; Alley and Binschadler, 2001), aimed at better understanding the role of ice streams in ice sheet change. Ice streams in this region appear to be capable of rapid changes, including migration within the ice sheet (Fahnestock et al., 2000), and abrupt "switch off," as observed in the case of Ice Stream C (Rose, 1979). An interesting conclusion stemming from the Siple coast studies is that ice stream behavior may be nonlinear, in so much that ice streams may be difficult to predict and more prone to rapid change than current estimates suggest.

Borne out of these detailed studies, much of the nonlinearity observed in ice streams in recent times (e.g., rapid changes) may have its roots in the operating conditions at the ice-bed interface. Investigations into the rheology of ice stream beds and the basal conditions beneath ice streams have become major research emphases because our current knowledge of subglacial processes and drainage is poor.

Through methods of bed characterization (e.g., from seismic data), direct sampling (e.g., from boreholes), and state-of-the-art computer modelling, there is now a general consensus that ice streams flow via a combination of traction and sliding over a thin (meters-thick) layer of deformable debris, which is water-saturated at the bed. Physical measurements on the till – the mixed carpet-like layer of mud and debris commonly found at the base of glaciers – beneath Antarctica's ice streams, showed low yield stress associated with a high pore pressure in the sediments (Boulton and Hindmarsh, 1987; Kamb, 1991). The physical character of this "weak" dilated subglacial layer is now known to enable the ice to flow faster in ice streams than over surrounding terrain, and may also contribute to their unstable behavior.

Ice shelves: floating margins

A final component of flow occurs exclusively at the mouths of marine ice streams or outlet glaciers, where it is common to find an adjoining tongue of floating ice, an ice shelf, that remains permanently attached to the grounded ice sheet (Figures 2, 3, and 5; see *Ice Shelf*). Vast plateaus of flat, floating shelf ice are well developed today in Antarctica, in the Ross Sea and Weddell Sea, while smaller ice shelves fringe the glaciers that drain much of East Antarctica, and along both coasts of the Antarctic Peninsula (Figure 5, stippled shading). While physically dissimilar to much of the grounded part of the ice mass, ice shelves are best considered as part of this system, because they play an important role in an ice sheet's flow configuration. We shall examine the exact reasons for this a little later.

History of measuring change in ice sheets

The interiors, ice streams, and ice shelves of the polar ice sheets have not always been so well understood however. Although ice sheets have been centers of scientific investigation since the late eighteenth century, the early explorers of the high latitudes were intent on exploration, and it is only the more recent generation of targeted survey and measurement that has led to a better understanding of ice sheet processes and their ability to change.

A scientific focus on the polar territories did not emerge until the 1957–1958 International Geophysical Year, which directed science questions at ice sheets for the first time. Even so, up until about 30 years ago, measurements on the ice sheets themselves were still few, confined to only a limited number of traverses across the ice interiors. Even in the 1970s, large parts of the poles remained uncharted and still appeared as empty white space on maps.

The major difficulty in filling these white spaces was that the ice sheets could still only be mapped using in situ data and represented local measurements at single points in time (e.g., seismic shots for ice-thickness soundings; Behrendt, 1998). In monitoring the ice itself, these methods offered little in the way of appreciation for

how the ice sheets might be changing over the years. Furthermore, with a ground perspective rather than a continent-wide view of the ice sheets, it remained virtually impossible to connect observations in one part of an ice sheet with those in another.

Recent improvements in the way ice sheets and their various changes can be measured, both upon and within the ice sheets today, and offshore from the geological records of the past, have vastly improved knowledge of ice sheets and their climate links. The last decades, in particular, have witnessed the birth of new technologies, which allow remote sensing of ice sheets from the air and from the space (Figure 7). Coupled with rapidly improving logistical access to the poles, this capability has revolutionized our understanding of ice sheets and their response to future change.

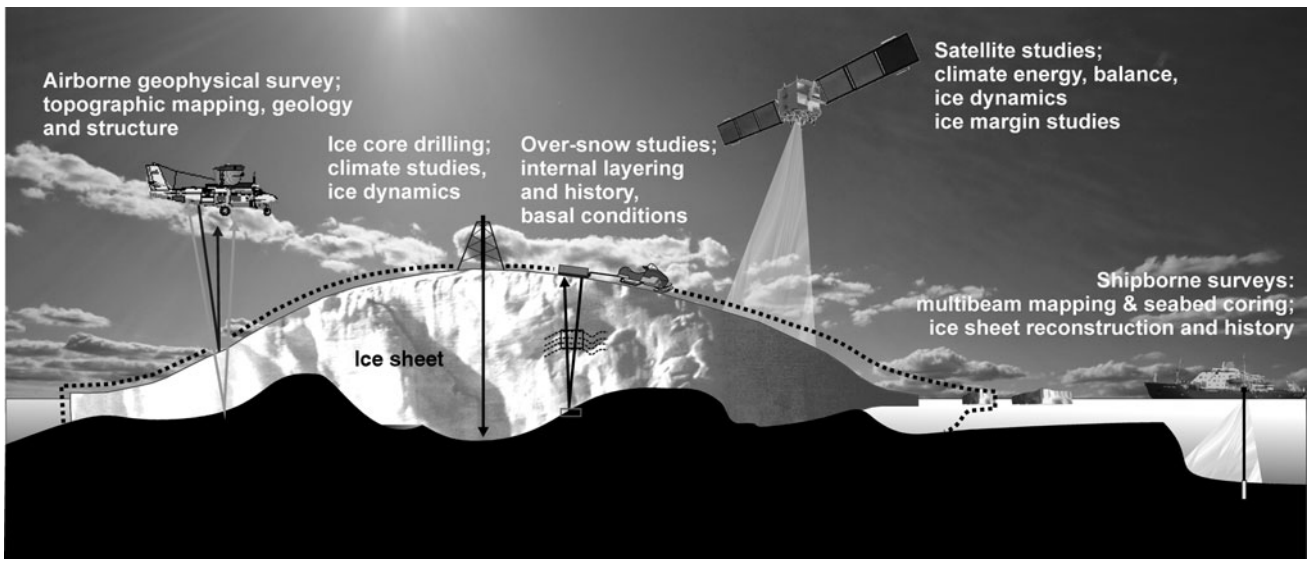
New technologies for studying ice sheets

Satellite radar interferometry is perhaps the most surprising and innovative tool that has been directed toward ice sheet understanding. It has revolutionized knowledge of ice motion in the polar regions (Figure 7) and is capable of detecting ice-flow rates, and even the subtle transition from grounded to floating ice. With the launch of ERS-1 in 1992, ERS-2 in 1995, and Radarsat-1 in 1997, maps of ice motion on Greenland and Antarctica have been produced with a coverage that makes ice-sheet-wide interpretations now possible. Similar to interferometric technology, satellite altimeters, which measure changes in the surface elevation of the ice sheets, are now so precise that they can yield maps of even the very small changes in ice-surface profile, to as little as 1 cm year^{-1}. By tracking changes in both elevation and dynamics over time, changes in the "state" of the ice sheets can be measured in detail.

Prior to these satellite capabilities however, and as late as the early 1990s, assessments of input versus output of ice from the polar ice sheets, based on direct measurements of snow accumulation and rudimentary calculations of ice loss, revealed no measurable "imbalance" in their state. In other words, until very recently, the ice sheets did not appear to be changing appreciably – if anything, the ice sheet in Antarctica appeared to be slowly gaining net mass (Bentley, 1993). However, these older assessments contained some significant uncertainties, with the smaller coastal systems of the ice sheets specifically understudied.

More recently, near-complete maps of the velocity of Greenland glaciers were assembled using Radarsat-1 data, and employed to calculate ice discharge and mass balance of the entire GIS. Results were surprising, indicating that the mass loss from the GIS had actually doubled in the decade between 1996 and 2006 (Rignot and Kanagaratnam, 2006). In Antarctica, both ERS-1/2 and Radarsat-1 data were also used to map ice velocity across ~85% of the coastline. A picture of dynamic and rapidly changing sectors of Antarctica emerged, revealing slow rates of thickening in some parts of the ice sheet, as predicted, but unexpected rapid rates of thinning in others. Particular focus in these studies was directed at the coastal areas, and it is here where the ice sheets' changes now appear to be most significant (Pritchard et al., 2009).

As well as satellite datasets of surface change and flow rates, advanced over-snow and airborne methods have made it possible to quickly and accurately derive a range of detailed ice-flow parameters, including ice thickness and flow velocity (Figure 7). These methods have offered a new way to analyze the bed of ice sheets that were impenetrable by more conventional methods, and have led to a much-improved understanding of processes



Ice Sheet, Figure 7 Cartoon illustrating the various technologies employed in modern-day ice sheet surveys.

occurring at the ice-bed. Radio-echo sounding (RES) constitutes a main technique by which glaciologists have investigated the subsurface properties of the polar ice sheets (Bingham and Siegert, 2007). Using RES, the internal layering of the ice sheets can be imaged to resolve local dynamics, helping to understand englacial and subglacial processes, and the histories of change in flow configuration. Ice-penetrating radar and seismic data have also been used widely to derive information on basal mechanics in different parts of the ice sheet, showing the presence of water or saturated sediments at the bed, and characterizing the mechanics of ice motion over its substrate (e.g., Smith and Murray, 2009). These are important components in understanding the processes of ice flow and the mechanisms that might lead to ice sheet change, at the scales witnessed by the satellites.

Better shipboard mapping and sampling techniques have also revealed a greater understanding of the history of ice sheets, from the offshore geological record. Shipborne multibeam echo sounders have replaced single depth-soundings as the most effective way of mapping the seafloor (Figure 7). These sonars measure bathymetry from a large footprint of the seabed allowing now-submerged former ice-beds to be mapped in near real-time, and at a high resolution. Coring of seabed deposits from ships capable of breaking sea-ice in areas once covered by, or which lay adjacent to, past ice sheets enables archives of glacial change to be obtained from the stratigraphic records of sediments that have accumulated slowly through time (Figure 7).

Around Antarctica, geomorphological features generated by ice sheets and sediments deposited at their base provide insights into former ice-bed conditions and flow directions. They act as indicators of past ice retreat that show how paleo-ice sheets once behaved and how they have changed through geological history.

Recent advances in the dating methods applied to samples and sediment sequences recovered from these environments have also significantly improved our ability to date long-term, geological-timescale changes in ice sheets. These include new radiocarbon techniques on marine sediment cores, designed to date histories of ice retreat while removing the problems that commonly arise from the reworking of older carbon-bearing sediments by glaciers (Schrum et al., 2006; see *Dating Glacial Landforms*). Independent records of relative paleomagnetic intensity are also being used to date stratigraphic sequences that lack carbonate material suitable for radiocarbon analysis. Most recently, land-based cosmogenic isotope dating has emerged as a key tool in calculating the length of exposure time since glacial erratics and regions of bedrock last became ice-free. Cosmogenic dating is now an essential technique for assessing rates of long-term thinning in presently glaciated areas. Importantly, the information from paleo-records has been influential in framing the recently observed twentieth- and twenty-first-century ice sheet changes against a picture of long-term geological rates of ice sheet retreat; the two are clearly at odds with one another, as we will go on to show.

Ice-age theory to polar meltdown: the shift in rationale

The rapid progress in these methods, and the growth in knowledge that has inevitably followed, has led to some recent notable changes in the foci of ice sheet investigations. The last 30 years, in particular, has witnessed a complete reversal in the rationale for investigating the polar ice sheets – shifting from one focused previously on "ice-age theory" to one centered on the possibility of future ice sheet collapse.

During the 1970s, the imperative for most ice sheet research revolved around the Earth descending into a "new ice age," with the polar ice sheets growing to their former large extent, and new ice sheets forming in the mid-to-high latitudes. More recently, this idea has been dispelled by predictions from the eccentricity of Earth's orbit, which suggest that interglacial conditions (i.e., natural continued warming) will persist over the next 5–50 kyr (Loutre and Berger, 2000). Moreover, the impact of anthropogenic warming is such that it may drive further widespread warming over a number of decades to come (IPCC, 2007). Worryingly, this warming may be contributing to or even instigating some dramatic changes that are currently taking place in the AIS and GIS, as hinted at by the satellites, and particularly in their fringing outlet glacier systems where fast ice margin recession, thinning of parts of the ice sheets, and rapid acceleration of glaciers have occurred. Recent changes in ice sheets and the potential for their future retreat have therefore become a focus for the large majority of modern-day ice sheet investigation.

These same recent observations have also led to a general consensus that ice sheets are able to operate over timescales that were once not thought possible for large ice masses. Within the observational window afforded by continuous satellite monitoring, glaciers along the WAIS, Antarctic Peninsula, and Greenland margins have displayed ever-greater change year-on-year. Some changes have been abrupt, and with clear triggers, demonstrating the short response time of ice sheets to external conditions. Together, they support a general picture of ice sheets being complex and dynamic landscapes with changes taking place much faster than previously anticipated.

The corollary of a future characterized by both increased warming and rapidly responding ice sheets is such that, rather than renewed onset of glacial conditions, further glacial retreat in the major ice sheets seems likely – and may be possible over the timescale of only a few lifetimes. Sea-level rise, estimated at 7.2 and 61.1 m for a "polar meltdown" (a complete rapid deglaciation of the GIS and AIS) is the obvious hazard associated with such retreat (IPCC, 2007) and thus forms the imperative for a large majority of today's polar science.

Drivers of ice sheet change

Before examining some specific recent changes in the Antarctic and Greenland ice sheets, we first consider

why ice sheet changes occur – be they the extremes of a polar meltdown or simply a minor thickening over a number of years – and the processes driving ice sheet variations.

The dominant controls on mass balance, and the climate systems discussed previously, are external to the ice sheets and operate at varying timescales. They dictate that ice sheet equilibrium – we have referred to it as "steady state" – is never truly reached.

The most important of these relates to the Earth's orbit around the Sun. Climate records of the past 2 million years attest to periods of past warming: interglacial periods; separated by lengthy times of cooling: glacial periods, with changes in global ice volume correlating with sea level, with oceanic and atmospheric conditions, and global temperature changes. The generally accepted view is that large fluctuations in ice sheet size, in the form of expansions during glacials and deglaciations during interglacials, are forced by orbital variations – the Milankovitch cycles – and that the polar ice sheets therefore pulse to a "natural" (geological) rhythm over tens of thousands of years (see *Glaciations and Groundwater Flow Systems*; *Ice Age*).

Other ice sheet drivers operate subordinately to the Milankovitch cycles leading to local or short-term deviations from steady-state conditions that are a perpetual characteristic of the "changing" ice sheets. The range of these is vast and complex, including, for example, tidal oscillations, which influence diurnal to fortnightly velocities in Antarctica's glaciers, through to seasonal solar forcing effects that exert a strong control over ice flow and discharge in the GIS. Sea-level changes, variations in surface albedo, ice sheet elevation, and ocean salinity are just a few of the many other drivers and feedbacks that help to comprise sensitive ice sheet systems, and that cause ice sheets to be, naturally, predisposed to change (Siegert, 2007).

But it is not only the natural drivers that effect changes in the ice sheet state. There is now a growing body of literature, which suggests that the past ~200 years of human activity is being reflected, indirectly, through ice sheet changes at the poles.

In the Amundsen Sea region of West Antarctica, late-twentieth-century changes in glacier flow appear to be connected to ocean warming, where Pacific waters bathe the marine outlet glaciers. There, the process of warm Circumpolar Deep Water upwelling onto the continental shelf is probably responsible for the thinning of the ice sheet and its ice shelves, the advanced rate of retreat in the grounding line, as well as a marked increase in glacier acceleration in the sector (Jacobs et al., 1992; Thoma et al., 2008). High basal melt rates noted at the fringes of other parts of West Antarctica in recent decades are also likely to be linked to oceanic warming where the warmer ocean comes into contact with the grounding line. We can be certain that ocean circulation and heat transfer are linked to the atmospheric climate (Figure 2). As a result, it is quite plausible that the changes seen in places like the Amundsen Sea, and elsewhere across the marine parts of polar ice sheets are in fact the result of warming through increased anthropogenic greenhouse emissions.

Another example comes from Greenland, where the ice margins are predominantly terrestrial, so that the effects of ocean warming on ice sheet change are not as apparent. However, even in the GIS, mechanisms exist whereby small climate perturbations are still observed to influence ice motion. One particular study by Zwally et al. (2002) showed that meltwater, pooled in lakes on the Greenland ice surface, periodically drained through cavities in the ice sheet, infiltrating the cracks that connect the ice surface to its bed and leading to enhance rates of glacier flow only a short time later. Perhaps more significant than the process itself was the finding that periods of higher melting at the ice surface correlated positively to larger increases in flow acceleration. An indisputable link between warming and climate change at the ice surface, and motion in the ice sheet beneath, was therefore established for the first time. Such rapid feedbacks have led to a recent conclusion that the GIS is highly responsive to environmental and anthropogenic change and, like the ice in the Antarctic, is also more capable of rapid changes than once expected.

Evidence for recent changes in ice sheets

Driven by the complex cycles of the planet, or by greenhouse warming, the evidence for recent and dramatic changes in the polar ice sheets is now clear, and certainly not restricted to the two examples given above. Indeed, there is now widespread proof that major changes are afoot in all parts of the ice sheets, but particularly noticeable in two of the most sensitive gauges of their state: in ice streams, and in ice shelves.

Changes in ice streams

Recent maps of ice sheet change have successfully highlighted those areas that are fast-flowing as ice streams e.g., (Figure 5). They have also highlighted that the parts of Antarctica and Greenland where the largest changes are taking place, and which pose the greatest risk in terms of contributions to future sea-level rise, are concentrated in those areas drained by ice streams (Rignot et al., 2008).

In Antarctica, the Amundsen Sea Embayment (ASE) appears to be the one area where ice stream changes are most dramatic (Vaughan, 2008). Two major ice streams have outlets into the ASE – the Pine Island and Thwaites Glaciers. The first time-series maps of Antarctic ice-thickness change produced about a decade ago, including the Pine Island–Thwaites system, seemed to show the majority of the ice sheet at or near its expected balance. One exception, however, was noted in a prominent surface thinning of ~10 cm year^{-1} in the Pine Island and Thwaites Glaciers. While an anomaly on its own, at the same time and over roughly the same period, the grounding line of Pine Island Glacier was found to have been retreating inland at an alarming rate (~1 km year^{-1}). These early results seemed to suggest that the oceanic warming of

ice shelves noted several years earlier was leading to advanced retreat in these ice streams of the WAIS.

Since that time, other observations have revealed further evidence for dramatic changes; short-term thinning and periods of acceleration that have led to the Pine Island glacier to speed up by ~34% over the past decade. Time-series analyses of satellite images of Pine Island Glacier have shown that its ice shelf had, in one part, been thinning for almost three decades (at a rate of 4.8 m year^{-1}) up to 2002, even though the position of the ice-shelf front had not shown any clear trend over the last 50 years (Vaughan, 2008). Thinning in the main body of the glaciers has also occurred in their fastest-flowing portions, and other surveys have concluded that neighboring glaciers – the Smith and Kohler glaciers – have also been undergoing similar changes.

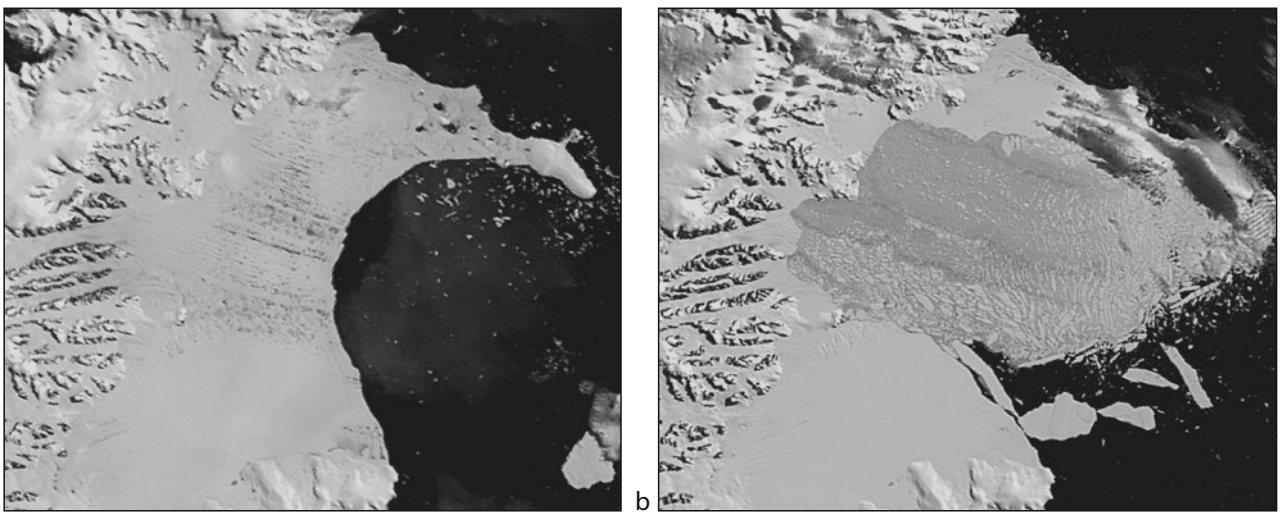
The most recent calculation of ice flux in the basins of Pine Island and Thwaites Glaciers showed the net mass balance to be -33 ± 10 km^3 ice year^{-1}, meaning the glaciers are almost certainly losing mass in response to their increased flow acceleration (Rignot et al., 2008). Surface elevation change, the rate of flow acceleration, and rate of grounding-line retreat in Pine Island Glacier are all greater now than at any time since measurements began (Scott et al., 2009). The drainage area captured by these major ice streams, alone, contains the potential to raise sea level by ~1.2–1.5 m. Fast-flowing outlets that drain the ASE therefore appear to be responding to a common forcing and are able to alter rapidly enough to make a significant addition to the rate of sea-level rise (Bamber et al., 2007; Rignot et al., 2008).

Changes in ice shelves

Seaward of the ice streams, the evidence for very recent climate changes reflected in Antarctica's ice shelves is both explicit and dramatic. Many of the Antarctic Peninsula ice shelves have been lost in recent years, during phases of rapid and catastrophic collapse: a long-predicted result of climate warming along the Peninsula spine (Mercer, 1978). The most publicized of these events occurred in 2002, involving the breakup of the Larsen B ice shelf, on the northeastern Antarctic Peninsula (Figure 8a, b). The retreat of Larsen B, and other ice shelves on the Peninsula, is understood as a devastating response to a combination of long-term thinning and decomposition, coupled with a recent trend of oceanic and atmospheric warming across the whole of West Antarctica (Steig et al., 2009).

At first, many glaciologists suspected that these types of collapses were part of a natural cycle of shelf-ice growth, evacuation, and regrowth – similar to the cyclic shedding of large icebergs from floating glacier tongues. Surprisingly however, historical records of ice-shelf conditions, as shown in sediment cores collected from areas several kilometers away from the Larsen B coast, confirmed a long-term stability of the ice shelf. The cores revealed that the 2002 collapse was actually unprecedented over the past 11,000 years, indicating that twentieth-century changes in the maritime Antarctic were adverse on millennial timescales, and without a Holocene analogue (Domack et al., 2003).

However, this picture is not so clear in the sediment archives for other ice shelves on the west of the Antarctic Peninsula. Here, ice shelves appear to have collapsed and reformed periodically over the last 10,000 years. Sediments on Alexander Island, for example, show that the neighboring George VI Ice Shelf collapsed ~9,600 years ago following a phase of climatic warming but then reformed from ~7,700 years ago, and has survived in its



Ice Sheet, Figure 8 (**a** and **b**) MODIS satellite imagery of the breakup of Larsen B Ice Shelf, Antarctic Peninsula. Full-resolution, grayscaled images: (**a**) at the start of the collapse on January 31, 2002, and (**b**) after the collapse on March 7, 2002. The area of ice lost between the two images is approximately 3,250 km^2. Source: http://svs.gsfc.nasa.gov/vis/a000000/a002400/a002421/index.html (last visited 27/05/2009).

current state through to the present (Smith et al., 2007). Some ice shelves therefore appear sensitive, not only to warming, but also to short-term, centennial-to-millennial climate cooling trends. Past influxes of warmer water and concomitant atmospheric warming are believed to be causal factors in the past collapse of Antarctica's ice shelves, and may be comparable to the conditions driving renewed ice-shelf retreat today.

In fact it may be because of this warming that over the past 20 years, ~14,000 km^2 of ice shelf has been lost along the Antarctic Peninsula. While some parts of the ice sheet have not been seen to respond to ice-shelf disintegration in terms of velocity variation, elsewhere significant acceleration has been observed in glaciers once supported by ice shelves, following their breakup (e.g., De Angelis and Skvarca, 2003; Rignot et al., 2004; Scambos et al., 2004). Ice shelves work to exert an important back pressure on the ice sheet behind it, effectively putting the brakes on the ice sheet advancing forward. Without these fringing shelves, the glaciers behind are vulnerable to the intrusion of warm oceanic waters, which may lead to increases in their flow-rate, and increased mass loss via calving at the grounding line.

The timing and duration of glacier change in response to ice-shelf breakup remains an uncertainty at present. However, new models of one Antarctic ice stream system, with a presently intact floating tongue, have shown that it would take up 150 years for the glacier's velocity and flow conditions to stabilize, if its ice shelf should collapse. While floating ice is, therefore, not a direct contributor to sea-level rise, the loss of buttressing ice shelves on the Antarctic Peninsula, and at the periphery of a warming West Antarctica (Steig et al., 2009), may serve to destabilize ice streams, leading to enhanced retreat and sea-level contributions from the ice sheet, with lasting effects felt over several centuries.

Lessons from the past: long-term records of ice sheet change

While the recent changes in ice stream and ice-shelf systems have occurred over short timeframes, the greatest changes in ice sheets occur across timescales of glacial–interglacial cycles, over tens of thousands of years. During past glaciations, ice sheets covered up to 30% of Earth's surface, extending well beyond currently glaciated terrain (Ehlers and Gibbard, 2004). A major advance in our understanding of ice sheets has therefore come from the ability to draw lessons from the disappearance of past ice masses to inform current and future scenarios of deglaciation (see Siegert et al., 2008 for a review).

Major ice sheets have existed on Antarctica since at least Oligocene times, approximately 34 million years ago. Records of ice sheet state over the last 1 million years remain the most instructive however, because these ice sheets witnessed cycles of glacial–interglacials most similar to the present, with major oscillations in climate coincident with the regular growth and decay of continental ice (see also *Pleistocene Epoch*; *Quaternary Glaciation*). The archives of change from this period are also the most well preserved in the geological record. Within this 1 million year window, in each glacial cycle, deglaciations form the most rapid events in the climate record, and are probably the most suitable analogues for present ice-climate scenarios at the poles.

For the most recent deglaciation, the short-term changes observed in ice sheets over the past decades overprint a much longer-term trend of ice retreat that began immediately prior to, and continued through the Holocene, c. 11,000 years ago (e.g., Conway et al., 1999; Anderson et al., 2002, Siegert et al., 2008). The fact that ice sheets survive within the current warm period, but appear only partially deglaciated at present, makes deciphering current-and-future natural ice retreat from human-induced ice sheet change particularly difficult. However, by understanding the size and timing of previous glacial cycles, the configuration of ice during these past glacial transitions, and the forcing behind such changes, questions regarding future ice sheet change may become clearer.

Marine and terrestrial archives of past ice sheet change

Marine sediments provide one important archive for assessing changes in ice sheet configuration through time (Figure 7). Drift accumulations resting on the continent at the ice sheet fringes (i.e., on the continental shelf, slope, or continental rise) reveal a natural succession of sediments that record the depositional environments in the deep ocean and shallow glacial seas over millions of years. The varying sediment types and structures, their organic, heavy-mineral and isotopic content, the provenance of the grains within the sediments, and the rate at which sediments were deposited, all provide useful indicators of the state of the ice sheet and the neighboring ocean at time slices through recent history. The archive of ice sheet changes held in sediment cores can be used to show environmental conditions during periods of past ice loss, and to date the speed and timing of withdrawal of ice sheets from the polar continental shelves after the last major glaciation (the Last Glacial Maximum [LGM], c. 25–19,000 years ago).

Onshore, a new and promising method for assessing how longer-term ice sheet change may be underwriting the short-term measured record of change has come from the terrestrial rock record. The abundance of cosmogenic 10Be and 26Al in quartz-bearing rocks is directly related to the duration of their exposure following the onset of deglaciation, and can be measured to give an exposure date. In this way, geological surfaces can be prescribed a minimum age indicating when an ice sheet last covered them.

One recent example of this method applied to ice sheet change was carried out by Johnson et al. (2008) who collected a small suite of glacially derived boulders for cosmogenic isotope analysis from four sites surrounding Pine Island Bay, in order to establish a geological record of ice thinning in the ASE since the LGM. Exposure ages

from these samples yielded results that suggest that the rapid ice sheet thinning rates observed in the Amundsen sector over the past decade (e.g., Thomas et al., 2004) are unusual when placed against the longer-timescale pattern of Antarctic ice retreat, by at least one order of magnitude – a thinning of ~2–4 cm year^{-1} over the last 15 kyr, compared against a thinning rate of ~3.5 m year^{-1} measured on Pine Island Glacier for 2007 (Scott et al., 2009). These ages support similar studies, which show that the magnitude and rates of current changes in some parts of the polar ice sheets are highly extraordinary in the context of the recent geological past.

Ice cores

Another archive is found in the ice cores through layers of ice that have accumulated through time (Figure 7). In Antarctica, the oldest ice core recovered dates back ~800,000 years (EPICA core at Dome C; Figure 1), but ice older than 1 million years probably exists in areas of particularly low accumulation. During the slow compaction of snowfall to ice, interconnected air bubbles in the near-surface ice remain open to the atmosphere. Over time, the air and associated impurities (dust and particulates) captured in these pockets are sealed off, and eventually pushed by the weight of the overlying ice into the crystalline structure of the ice itself. The sample air preserved within the ice structure can be released and captured for analysis by sampling ice from different levels in cores.

The history of past climates available from ice cores is one of the most important sources of information about how the climate on Earth has changed through time. The chemical composition of the air samples that can be obtained from the cores reveals how the important greenhouse gases have changed through glacial–interglacial cycles. Relative concentrations of different isotopes of oxygen and hydrogen also provide an indication of variation in the global ratio of seawater to ice volume, and serve as a "natural thermometer" that shows how the temperature of the planet has fluctuated through the past.

The most recent ice core extracted from Dome C shows that current levels of greenhouse gases in the atmosphere are higher now than at any time in the past 650,000 years. Carbon dioxide is about 30% higher than at any time, and methane 130% higher than at any time. Furthermore, the rates of increase are exceptional: 200 times faster than rates of natural change over the same period. Because variations in Antarctic temperature and atmospheric carbon dioxide follow each other closely, such changes may cause global climate and its related ice sheet systems to alter rapidly.

Ice sheet "collapse": geological precedents for future rapid deglaciation?

From the changes in the ice core and geological records, and those observed in the ice sheets themselves, it appears that a combination of natural and anthropogenic warming could trigger the future collapse of the polar ice sheets. Mercer (1978) was the first to argue the hypothesis that anthropogenic climate warming could instigate a rapid loss of much of the WAIS. Though unsupported at the time, recent ice sheet models have confirmed Mercer's original fears that even small amounts of warming could lead to positive feedback in WAIS retreat where ice is grounded on an inland-sloping base (Schoof, 2007). In particular, major evacuation of marine basins seems to be possible in situations where the ice may be close to becoming ungrounded from pinning points and where the bed slope is monotonic toward the ice interior – and several of the major Antarctic glacier catchments currently meet the criteria for this unstable situation (e.g., the Thwaites glacier).

Indeed, the instability of marine ice sheets is no mere hypothesis. The rapid and widespread collapse of former marine ice sheets is likely to have occurred in the past, such as in the rapid steps of deglaciation in the Laurentide Ice Sheet, between ~14,600 and 7,500 years ago. For Antarctica, compelling evidence for past WAIS collapse was first presented in the late 1990s, in samples recovered from the muddy bed beneath the ice sheet. In four separate samples, sediment yielded fossils of microscopic marine plants along with isotopes showing that the fossils were deposited under open water conditions. It is widely regarded that these deposits provide evidence that the ice sheet collapsed at some point during the Late Quaternary (in the last 1.3 Myrs, probably during Marine Isotope Stage [MIS] 11), and that the ice sheet interior formed a seaway where it was inundated by marine waters.

Deep-marine sediment cores recovered on the continental rise offshore of the ASE also record anomalies in the state of the ice sheet through the Late Quaternary, with one notable period dating back to about 620 to 500 ka. Sedimentological proxies for climate in the cores from this time slice display indicators for an unusually prolonged interglacial period, within an otherwise rhythmic pattern of glacial–interglacial cycles. This climate anomaly also appears to coincide with perturbations observed in paleoclimate records from both hemispheres (Hillenbrand et al., 2009); suggesting this "event" had global significance. Although further work is needed to test the hypothesis, it seems quite likely that these deposits relate to a time of reduced glacial activity, and may record a large drawdown of the WAIS during MIS 13–15.

The presence of thick diatomite sequences, interbedded with glacial diamictons, drilled from beneath the McMurdo ice shelf has also been used to argue the evidence for repeated loss of the WAIS through the Pliocene and Pleistocene (Naish et al., 2009). The criteria for a West Antarctic collapse from these deposits appear somewhat contentious at present – especially given that thick sequences of diatomaceous mud have accumulated in glacial marine basins through the Holocene, while the WAIS and EAIS have remained mainly intact. Nevertheless, ice sheet model outputs support the inferences from the rock record, predicting a dynamic oscillation of the AIS over

the past 5 Myrs, with punctuated collapse and growth. Large collapses are inferred during the early Pliocene and during the warm "superinterglacial" of MIS 31, at c. 1 Ma years ago (Naish et al., 2007).

Independent of the geological archives, sea-level "fingerprinting" has also shown abrupt rises in global sea level in the past, and there is a strong suggestion that these events must relate to massive discharges of meltwater from at least a partial collapse of the polar ice sheets (Clark et al., 2002). Taking these data alongside the above geological evidence for former ice sheet collapse, it appears that regardless of exactly when, a future widespread deglaciation of the ice sheets has at least one geological precedent.

The future of the polar ice sheets

Although the evidence for potentially rapid retreat of marine ice sheets existing in the geological archives and the record of global sea level is difficult to ignore, the general instability of marine ice sheets is not universally accepted, and several researchers have argued that complete collapse of WAIS may be unlikely within a few centuries (Vaughan and Spouge, 2002; Vaughan, 2008) – although this still allows for significant and substantial rates of sea-level rise. Indeed, the current contribution from the Amundsen Sea alone is sufficient to raise sea level by more than 0.2 mm year^{-1} (Thomas et al., 2004).

Yet, it remains to be seen how far the current changes are precursors of a major ice sheet loss, with ongoing difficultly in predicting the future of the polar ice masses (Vaughan and Arthern, 2007). The shortfall in present understanding is likely a result of a lack of knowledge in the mechanisms of ice sheet change, but also an inability for observed rapid changes to be successfully reproduced in ice sheet models (IPCC, 2007). Some areas of the science require further improvements in "skill" before qualified predictions of ice sheet response to external forcing can be made. Amongst these, the dynamics of sub-ice stream processes, their stability on back-sloping surfaces (Schoof, 2007), and the physics of grounding-line–ice-shelf interactions, remain major research emphases.

Summary

The two remaining polar ice sheets are the cornerstone of the global cryosphere and climate systems. They are sensitively balanced through processes of growth, flow, and loss, and comprise a number of glaciological components that are key to maintaining this balance (including inland centers, ice streams, and ice shelves). However, the ice sheets may be threatened by future warming of the planet, which is projected to rise significantly over coming centuries. Indeed, whether driven by humans, or by the natural cycles of the Earth, there is evidence that parts of the polar ice sheets are already undergoing major changes. Geological clues from the past hint at times when ice sheets were completely disintegrated, and demonstrate that the current rates of change are unusual in the context of longer-term ice dynamics. However, while we know much about the history of ice sheets and their present-day operating mode, their future behavior remains a continual uncertainty. Thus, many lines of enquiry form an ongoing programme of research into ice sheets, their past, present, and future changes.

ICE SHEET MASS BALANCE

Eric Rignot
Department of Earth System Science, University of California Irvine, Irvine, CA, USA
Jet Propulsion Laboratory, Pasadena, CA, USA

Definition

Ice sheet mass balance refers to the balance between additions to and losses of mass from an entire ice sheet. It is expressed as a mass per unit of time, positive if the ice sheet is gaining mass, negative if the ice sheet is losing mass. The term is often used loosely to mean either the surface mass balance or the total mass balance. Surface mass balance, however, signifies the addition of mass to the surface of the specified region. It does not include processes such as the advection of ice by glaciers and ice streams or the melting of ice at the underside of ice streams or floating ice shelves. Total mass balance or mass balance signifies the balance between all additions (snow, advection of ice from upstream, basal freezing, etc.) and all losses (ice motion, ice melt, basal melting) from the region of ice under investigation.

Introduction

Ice sheets have a large impact on global sea level. At the last glacial maximum, global sea level was 120 m lower than today. If all ice in Greenland and Antarctica were to melt to sea today, it would raise sea level by another 65–70 m. In the early part of the twentieth century, sea level was rising at a rate of 1.8 mm/year. At present, it is rising at 3 mm/year and the rate is expected to increase in the coming centuries with the melting of ice sheets, mountain glaciers, and ice caps, and the thermal expansion of the oceans. To determine the contribution to sea level rise of ice sheets, we need to determine their state of mass balance, that is, the rate at which they are gaining or losing mass to the ocean with time. For every 360 Gt/year of loss in mass of an ice sheet, sea level increases by 1 mm/year.

Until the 1990s, the state of mass balance of the ice sheets in Greenland and Antarctica was virtually unknown. Significant progress has been made since due to the advent of satellite missions and the deployment of modern instruments onboard airborne platforms. There are at present three major techniques to measure the continent-wide mass balance of ice sheets:

1. The mass budget method, comparing perimeter losses with interior accumulation, to infer the net change in mass of the ice sheet
2. The gravity method, utilizing time series of time-variable gravity data, to infer mass changes directly, except on floating ice tongues and ice shelves
3. The altimetry method, which uses repeated altimetry surveys of the ice sheet surface elevation to infer volume changes, which are subsequently converted into mass changes

All three techniques have been applied to the entire ice sheets. The mass balance values obtained from these independent techniques do not all agree perfectly, for various reasons, but the level of agreement is improving with time as processing errors and uncertainties associated with the spatial and temporal variations of the signal are more fully understood and resolved. Most important, all three techniques bring a piece of puzzle on how the ice sheets are changing and why.

Mass budget

Interior accumulation of mass is essentially equivalent to the surface mass balance of the ice sheet. It includes snow accumulation minus ablation from processes such as melting, evaporation, sublimation, and wind transport. Snow accumulation may be inferred in situ from ice cores, stake measurements, snow pits, or ground-penetrating radars, but such data are difficult to extrapolate for characterizing total snow accumulation on areas as large as Greenland (1.7 M km^2) or Antarctica (14 M km^2). Interpolation of these data has been performed using satellite passive microwave data or meteorological information or large-scale atmospheric modeling, with mixed level of success, especially along wet, coastal sectors where surface measurements are lacking. More recently, regional atmospheric climate models constrained by global climate reanalysis data have made significant improvements in estimating net snow accumulation over ice sheets. Models such as the Regional Atmospheric Climate Model 2 (RACMO2) resolve interior accumulation accurately and capture coastal gradients realistically for the first time.

These models employ in situ measurements to evaluate their absolute level of precision instead of using them for calibration (van de Berg et al., 2006; Ettema et al., 2009). The results reveal higher-than-expected accumulation along wet coastal sectors and higher total snowfall overall (Van den Broeke et al., 2006). The level of precision of these models is about 9% total accumulation in Greenland, 5% in dry sectors of Antarctica, degrading to 30% in its wet coastal sectors. Expressed in Gt (gigatons = 10^{12} kg = 10^{9} metric tons) per year, these uncertainties translate into surface mass balance known within ±41 Gt/year in Greenland and ±102 Gt/year in Antarctica.

Measurements of perimeter losses improved drastically as well. Early characterizations of perimeter losses were based on a few velocity data points and limited knowledge of ice thickness. Surface velocity of ice is now measured with satellites, mainly synthetic-aperture radar interferometry (Insert), over the entire periphery of ice sheets, with a precision of a few meters per year, at a spatial sampling of a few hundred meters. For ice flux calculations, these surface velocities must be translated into depth-averaged velocities. Because the largest dischargers of ice are also the fastest glaciers, this is not a major issue because most of these glaciers are sliding almost entirely on their bed and numerical models indicate that the difference between surface and depth-averaged velocity is typically less than 2%. Similarly, ice velocity is often measured at one time during the year, typically in winter in Greenland, hence must be corrected for seasonally variations. In Antarctica, seasonal variations are negligible. In Greenland, ice motion accelerates by 8–10% on average during the summer months, independent of latitude (Rignot and Kanagaratnam, 2006). This translates into an underestimation of the annual velocity from the winter velocities by about 2%. Overall, the underestimation from the seasonality and the approximation of depth-averaged flow nearly compensate each other, so that in Greenland the error in depth-averaged velocity is at the sub-percent level is one uses winter surface velocities instead. In Antarctica, the error should be much less than 2%.

Ice thickness is measured using airborne radio echo sounders over a growing share of the coastal sectors, at a precision of about 10 m in the interior, degrading to a few 10 m in outlet glaciers. These measurements are limited in spatial extent to the flight tracks of the airborne platform, but new techniques of two-dimensional mapping are now emerging. Historical data did not systematically cover the grounding line region, either because the grounding line position was not well known or the radar instrument did not operate well over that type of ice (in Wilkes Land, East Antarctica, for instance, historical data typically have no bed echoes over main glacier troughs) or the data were not acquired with sufficient precision (no GPS location, no digital recording of radar echoes). In Greenland, modern radars have difficulties in obtaining bed returns in warm, deeply entrenched coastal troughs occupied by outlet glaciers. In these areas, a new approach based on airborne gravity measurements at the sub-milligal level is being explored, with a precision of 100 m vertical and 3–5 km horizontal. Otherwise, ice fluxes have to be calculated farther upstream and changes in speed and thickness at the glacier grounding line are employed to estimate grounding line fluxes required in the mass budget calculation (Rignot and Kanagaratnam, 2006).

In places where such modern data are not available and ice reaches floatation in seawater, ice thickness may be deduced from ice surface elevation assuming hydrostatic equilibrium of ice with seawater (Rignot et al., 2008). Ice surface elevation is measured with satellite laser or radar or laser/radar combined altimetry (Bamber et al., 2009), that is, ERS-1 in 1994 and ICESAT-1 in the year 2000. These data yield estimates of ice shelf elevation with a submeter precision, and translate into grounding line thicknesses with a precision of 80 m, degrading to 120 m in more complex settings (Rignot et al., 2008). For small glaciers entrenched in narrow valleys, the current surface elevation data derived from satellites is difficult to use.

All thickness data must be corrected from the depth of the firn layer, so that all ice thicknesses represent an equivalent thickness of solid ice, instead of a total thickness of ice and firn. Firn depth correction may be calculated as a by-product of Regional Atmospheric Climate Models. In Antarctica, the correction varies from 0 to 10–25 m (Van den Broeke, 2006).

Quadruple difference interferometry has been used to detect the position of the grounding line of glaciers, where ice detaches from its bed to become afloat, at a horizontal precision better than 100 m (Rignot, 1996). This transition boundary is the natural boundary where to measure ice fluxes into the ocean since the resulting fluxes represent the discharge of ice, hence of mass, into the ocean, independent of the melting of floating glacier ice downstream of the grounding line. This boundary may be inferred from aerial or satellite photographs of the surface reflectance at visible wavelengths, with uncertainties of the order of 10–100 km, from radio echo sounding as a transition from a dim ice-bed interface to a bright ice-seawater interface, also with uncertainties of the order of many kilometers, or from GPS, laser altimetry, and tilt meter instruments typically at a precision of 1 km (Vaughan, 1995). In Greenland, floating extensions of glaciers are only found in the north.

The ice fluxes, obtained from the integration of ice thickness times the depth-averaged velocity across the glacier width, are converted to mass using a solid ice density of 917 kg/m^3.

The mass budget compares two large numbers, perimeter losses with snow accumulation, with large uncertainties (Rignot and Thomas, 2002). It is critical to minimize these uncertainties to below a level of about 10%. This requires complete inventories of the ice sheets with the highest precision measurements and high-quality regional atmospheric climate models. At present, the

largest source of uncertainty remains the surface mass balance component, so that current estimates of the mass balance are no better than 9% precision in Greenland or about 50 Gt/year and no better than 5% in Antarctica or 100 Gt/year. The precision of the measurements in Antarctica is largely biased by the vast extent of dry East Antarctica. In the rapidly changing sectors of West Antarctica and the Antarctic Peninsula, our knowledge of net accumulation is indeed no better than 10%.

Time-variable gravity

Since April 2002, the GRACE satellite has been measuring the Earth's gravity field and its temporal variability. After removing the effects of ocean tides, atmospheric loading, variable pressure fields, and other effects, high-latitude data contain information on temporal changes in the mass distribution of the ice sheets and underlying rock. Because of its relatively high altitude aboveground, GRACE only collects coarse-resolution measurements (200–400 km) of the gravity field and its changes with time. The chief advantage of this technique is to yield a direct measurement of mass changes that does not require knowledge of its different components, the density at which the surface elevation changes, the fluxes of ice, or the position of the grounding line. Floating ice is not influencing the gravity field because floating ice is isostatically compensated, so gravity data does not include the contribution from floating ice.

Error sources include processing errors, leakage of gravity signal from regions surrounding the ice sheets, and causes of gravity changes other than ice-sheet changes. Of these, the largest uncertainty is the gravity change associated with vertical bedrock motion. Velicogna and Wahr (2006) estimated a mass-balance correction of 5 ± 17 Gt/year for bedrock motion in Greenland, and 173 ± 71 Gt/year for Antarctica (Velicogna and Wahr, 2006). As more constraints are established on the magnitude of postglacial rebound, for instance using the GPS data collected by POLNET, the gravity technique will provide high-precision measurements of mass balance and continental-scale maps of mass changes. On the other hand, these data do not provide direct information on the components of change, that is, whether they are due to a change in snowfall, ice melt, or glacier discharge. It is an integrated method.

Another source of uncertainty affecting these data is the short duration of the GRACE mission. During that short duration, the signal is influenced not only by the long-term evolution of the mass of ice sheets but also by the seasonal, interannual to decadal variability in surface mass balance. This is especially significant in Antarctica where total surface mass balance is nearly seven times larger than in Greenland but the total mass losses are comparable in magnitude. A number of studies have examined the average mass loss over short periods. The results are biased by the evolution of surface mass balance during that time period, which may not reflect long-term changes. In addition, it is well established that the mass loss of these ice sheets is not constant, but is increasing with time. Time averages calculated over different periods of time therefore naturally disagree.

In terms of absolute mass loss, the gravity technique is capable of a precision of 20–30 Gt/year in Greenland and 70–90 Gt/year in Antarctica, which is better than the mass budget method. In terms of changes with time, or the second-order derivative of mass, $M(t)$, with respect to time, or d^2M/dt^2, it is important to note that the GRACE data is not affected by the precision of postglacier rebound since this signal is constant over the timescale under consideration. Hence the technique is even more reliable to detect changes in mass loss with time than to quantify absolute losses.

Repeated altimetry survey

Rates of surface-elevation change reveal changes in ice-sheet mass after correction for changes in depth/density profiles and bedrock elevation, or for hydrostatic equilibrium and tides if the ice is floating. Satellite radar altimetry has been widely used (e.g., Shepherd et al., 2002; Davis et al., 2005; Johannessen et al., 2005; Zwally et al., 2005), together with laser altimetry from airplanes (Krabill et al., 2000), or NASA's ICESat (Zwally et al., 2002a; Thomas et al., 2007). Modeled corrections for isostatic changes in bedrock elevation (e.g., Peltier, 2004) are small (few mm/year) but with errors comparable to the correction. Those for near-surface snow density changes (Arthern and Wingham, 1998) are larger (1 or 2 cm/year) and also uncertain. Historically, this technique has the longest time record, which is critically valuable for examining the interior regions of ice sheets, which are dominated by a strong interannual variability in surface mass balance. This is also the first technique proposed historically to monitor ice sheets.

Radar altimetry employs beams of 20 km or more, designed primarily for the surface of the nearly flat ocean. Radar returns are far more complex over the sloping and undulating ice-sheet surfaces with spatially and temporally varying dielectric properties. Radar range measurements are generally off nadir, and return-waveform information is biased toward the earliest reflections (i.e., highest regions) within the large footprint, and depends on radar penetration into near-surface snow. On glaciers and ice streams, ice flows in surface depressions that can be narrower than the radar footprint, so that elevation changes are weighted toward slower-moving ice along the glacier sides. At high elevation, climate warming affects the depth of the reflecting horizon of ice sheets, and those changes may be misinterpreted as volume change, especially Greenland (Thomas et al., 2007). This makes the interpretation of radar altimetry data on a melting surface challenging to interpret.

Laser altimetry provides data that is easier to interpret: footprints are small (1 m for airborne, 60 m for satellite)

and there is negligible penetration of laser into snow and ice. However, cloud cover, atmospheric conditions, and laser pointing errors limit the precision of the technique to 20–30 cm vertical, versus 10–20 cm vertical from an airplane platform. Existing laser data are sparse compared to radar altimetry data because of the orbit selection for ICESAT-1, and the limited range of aircrafts. Laser altimetry has been operating from 1993 on airplanes in Greenland, from 2002 in Antarctica, and from 2002 on satellites.

Both laser and radar altimetry operate in profiling mode with a narrow swath that does not allow a comprehensive survey of the entire ice sheet. This introduces biases in regions where changes are concentrated and high, for example, for a rapidly thinning glacier. Most often, this may result in an underestimation of the glacier loss or of the glacier thickening. Once this issue is solved, changes in volume must then be converted into changes in mass. This requires knowledge of the density at which these changes are taking place, for example, snow (density of 0.3) versus pure ice (density of 0.917), and corrections from temporal variations in the depth of the firn layer, or firn compaction. Overall, the issues of steep slopes in the coastal regions, coarse track spacing, unknown density, and firn compaction have limited the potential of altimetry at providing reliable estimates of total mass loss. This technique has however been important and critical to outline regions of change, to document the pattern of thinning of glaciers and ice streams, and to detect decadal trends in interior accumulation. This technique has clearly demonstrated the importance of losses from ice dynamics by mapping out areas of ice thinning corresponding to areas of fast flow. It has also revealed sharp transition in mass balance across ice divides (Krabill et al., 1999). The continuing record of altimetry data is extending in time and improving with each additional year on record.

Results

Ice locked in the Greenland and Antarctic ice sheets has long been considered immune to change, protected by the extreme cold of the polar regions. Global climate models suggested that climate warming would enhance precipitation in the interior, increased melting from coastal regions, yielding a small loss in mass from Greenland and a gain in mass from Antarctica for an overall modest contribution to sea level. Observations from the last 2 decades and recent advances in regional climate modeling however show a different story.

In terms of precipitation on ice sheets, regional climate models show no significant change in precipitation, but large interannual to decadal variability, which, taken over short time periods of a few years to a decade reveal growth or shrinkage, but analyzed over the last 25–50 years show no evidence for change, except for the western flanks of the Antarctic Peninsula where precipitation has increased (Monaghan et al., 2006; Van den Broeke et al., 2006). In Greenland, the results are similar but models and in situ data indicate a marked increase in ice melt, at a rate of 14 ± 4 Gt/year^2 in 1992–2008 (Ettema et al., 2009). As a result, the surface mass balance of Antarctica exhibits no long-term trend, while in Greenland it has decreased steadily since the 1990s.

Airborne observations indicated that the Greenland ice sheet is thinning along its edges and near balance in the interior (Krabill et al., 2000). Thinning at the coast is concentrated along narrow channels occupied by outlet glaciers and is therefore not indicative of a change in snowfall but of a change in ice dynamics. In Antarctica, changes are concentrated along the coast in narrow channels occupied by ice streams and glaciers. Glacier acceleration is confirmed using InSAR and other measurements of ice stream motion (Rignot and Kanagaratnam, 2006; Rignot et al., 2008). The dynamic response of the glaciers is complex, however, and not fully understood. Even though we know that it is affected by the geometry of the glaciers, their depth below sea level, the makeup of the glacier beds, ocean water heat fluxes, surface runoff, and other effects, the complex interactions between these processes are poorly documented, understood, and modeled.

In Greenland, the results from the three mass balance techniques do not agree perfectly in terms of absolute losses, but they all indicate a similar trend in increasing mass losses. For the mass budget method, the results will improve as the survey of glaciers becomes more complete and accurate, and regional atmospheric climate models operated at higher resolution gain in precision. For the time-variable gravity method, it is now possible to detect the increase in mass loss from ice sheets (Velicogna, 2009). For radar altimetry, we have a long record of glacier and ice shelf changes.

Some of the differences between measurement techniques are directly explainable. For instance, areas not surveyed by airborne laser altimetry were estimated using a melt model. Mass losses were therefore systematically estimated in places where losses from ice dynamics are significant. Similarly, the GRACE results do not always address the same time periods, hence includes periods where surface mass balance – the dominant term of the signal – behaves differently. For the mass budget method, recent surface mass balance has shown large disagreements with earlier estimates based on interpolation of in situ data.

To improve upon these results, more ice thickness data are needed on the outlet glaciers, regional climate models must be operated at a higher spatial resolution and compared to additional field data, and time-variable gravity, altimetry, and ice motion must be collected systematically and almost continuously for many decades to come. Such observations are critical to help numerical models of ice sheet flow become more reliable and more practical for prediction. In addition to these satellite measurements and associated field program, we need to continue

documenting surface climate with weather stations, and collect critical data about processes taking place at the bed and occluded from the view of satellites. In the case of ice–ocean interactions and their impact on ice sheet balance, multidisciplinary efforts going well beyond the field of glaciology are required to circumvent our current limitations and make great strides at improving the predictability of ice sheets.

ICE SHELF

Adrian Jenkins
British Antarctic Survey, Natural Environment Research Council, Cambridge, UK

Definition

Ice shelf. Part of an *ice sheet* that floats on the ocean while remaining attached to grounded ice.

General characteristics

Ice shelves form at the margins of an *ice sheet*, where the ice becomes thin enough to float free of a bed that lies below sea level. Ice shelf-like features also form in the interior of ice sheets where the ice floats on subglacial lakes. Most of the ice shelves that currently exist on Earth are found in *Antarctica*. In particular, ice shelves almost completely surround the *marine ice sheet* of West Antarctica. The larger ice shelves are fed by multiple glaciers, the outflows from which coalesce to form a distinct glaciological feature, but the smaller ones are generally the floating termini of single *tidewater glaciers*. Although any ice that exists between the grounding line and the calving front of a tidewater glacier is formally an ice shelf, these features are often not accorded an identity distinct from their parent glaciers.

Ice shelves range in thickness from less than 100 to over 2,000 m and individually cover areas of up to 0.5 million km^2 (Vaughan et al., 1999). In Antarctica, the combined area of all the ice shelves is only 14% of that of the grounded ice sheet, but around 80% of the snow that falls over the grounded ice drains into them before being lost to the oceans (Vaughan et al., 1999). The processes of mass loss from the ice shelves are therefore critical in determining the overall mass balance of the ice sheet. Their level and largely crevasse-free surfaces gave the great ice shelves of Antarctica historical significance as providers of relatively safe routes to the interior of the ice sheet for the earliest exploratory expeditions.

Ice shelf dynamics

Ice shelves are distinct from other parts of the ice sheet in that they rest on a frictionless substrate. The flow of an ice shelf is therefore controlled entirely by the tendency of the ice to spread horizontally and the degree to which this tendency is opposed by the lateral confinement provided by surrounding ice or land masses (see Paterson, 1994 for a review of the mathematics).

The tendency to spread is a result of the density difference between the ice and the water in which it floats. The lower density ice has a freeboard, with between 10% and 20% of its thickness being supported above the waterline. As a consequence the pressure at any point within the ice shelf, resulting from the weight of overlying ice, exceeds the pressure at the same level within the ocean, resulting from the weight of overlying seawater. Only at the level of the ice shelf base does the pressure within the ocean equal that within the ice; this is the floatation condition. The ice shelf response to the excess pressure is lateral spreading, the speed of which is controlled by the effective viscosity of the ice. The forces that drive spreading increase with the thickness of the ice shelf, so lateral spreading and the consequent thinning of the ice shelf are more rapid where the ice thickness is greater. As a result variations in thickness tend to decay over time, and this gives rise to one of defining characteristics of ice shelves; the near absence of surface topography.

For an ice shelf that is bounded on more than one side by ice or land masses, additional processes need to be considered. Spreading of the ice is restricted by the lateral barriers, so that for an ice shelf occupying an embayment with near-parallel sides the spreading is predominantly unidirectional, parallel to the bay walls. Importantly, there is also a frictional resistance to ice flow parallel to the walls. This means that even in the direction that the ice is free to spread there is a force opposing the spreading generated by the need to push all the ice downstream past the bay walls. The magnitude of this force is related to the degree of confinement of the ice and is greater for ice in the interior of the ice shelf than for ice near the seaward edge.

By a similar argument, ice flowing across the grounding line of an ice shelf must push the entire ice shelf past its confining obstructions, but how far inland this effective restraint on the flow of the grounded ice sheet is felt has been the subject of much debate. The *ice streams* feeding the ice shelves are themselves closely confined by lateral shear margins, and flow over a bed where additional frictional resistance is generated. Inland these local forces will eventually dominate, but the distance over which the restraint of the ice shelf plays a role in controlling the ice stream flow is a critical parameter, since it determines the extent to which the flow of grounded ice can be influenced by changes in the ice shelf.

Mass balance

Ice shelves are fed by the flow of ice from the grounded ice sheet and by the *accumulation* of snowfall on the upper surface. In some places accumulation of mass also occurs at the lower surface, through the *freezing* on of seawater. In most cases, the flow of ice from inland is the dominant input. Mass loss occurs by the *calving* of *icebergs* from the seaward edge, and by the *melting* of ice from the underside. More rarely, some mass loss occurs by surface melting or sublimation.

Calving from ice shelves tends to produce massive tabular icebergs, the largest of which can exceed 10,000 km^2 in area. The process is quasiperiodic, with long stages of steady ice front advance, lasting anywhere from a few years to many decades, interspersed with major calving events. A stable ice front will generally have its location determined by the arrangement of confining ice or land features. Periods of advance will take the ice front beyond the influence of the confining features, then calving will

eventually remove the less well constrained ice. If calving removes ice from parts of the ice shelf where the flow is controlled by lateral confinement, it has been suggested that the configuration is then unstable and further rapid retreat of the ice front is probable (Doake et al., 1998). However, our understanding of the processes by which fractures in ice initiate and propagate remains insufficient at present to formulate a physically based calving law, and the long timescales involved complicate the collection of the observational data required to validate such a model.

Their strong interaction with the seawater beneath them is a defining feature of ice shelves, and the processes that drive melting and freezing beneath ice shelves have been the subject of much research over the past 3 decades (see Jacobs et al., 1992 and Williams et al., 1998 for general discussions). One critical point is the pressure dependence of the freezing point of seawater. Seawater that is cooled through contact with the atmosphere cannot be made colder than about −1.9°C. At this temperature ice begins to form. However, the temperature at which the phase change occurs falls by about 0.75°C for every 1,000 m of water depth. Seawater that is cooled through contact with the base of an ice shelf can therefore attain a temperature lower than the surface freezing point. Water that has such a property is referred to as Ice shelf water (ISW).

When seawater that is warmer than its depth-dependent freezing point comes into contact with the base of an ice shelf, it gives up some of its heat to melt ice. Melting the ice shelf freshens the seawater, lowering its density. The less dense water rises toward the surface, constrained by the sloping ice shelf base. The reduction in pressure as the water ascends means that its freezing point rises, a process that would tend to reduce its potential to drive further melting, but the outflowing water gains heat continuously by turbulent mixing. If the heat supplied to the outflow is sufficient to maintain its temperature above the freezing point, melting will persist. The continued input of meltwater leads to a further increase in the buoyancy of the outflow, sustaining its motion along the ice shelf base. If the input of heat from turbulent mixing is insufficient to maintain the temperature above the freezing point, the water becomes *supercooled*, and melting will give way to freezing. Ice will be deposited in the form of *frazil ice* crystals on the ice shelf base and the loss of freshwater from the outflow will decrease its buoyancy, eventually halting its rise toward the sea surface.

Seawater temperatures observed near ice shelves range from the surface freezing point (−1.9°C) to about 3.5°C above the freezing point, while inferred mean melt rates range from a few tens of centimeters per year to several tens of meters per year.

Ice shelves in a changing climate

Being in contact with both the atmosphere above and the ocean below, ice shelves are seen as sensitive indicators of climate change. The retreat and disintegration of ice shelves along the Antarctic Peninsula appear to be linked to regional atmospheric warming and were among the earliest and most dramatic indicators of change in the Antarctic Ice Sheet (Vaughan and Doake, 1996). The most significant changes in surface elevation that have been revealed by radar altimetry since the early 1990s have occurred over the ice shelves of the Amundsen Sea, where thinning rates of several meters per year have been inferred (Shepherd et al., 2004). The magnitude of the thinning suggests that the cause is a change in the basal melt rate of the ice shelves, brought about by some change in the ocean.

There are several reasons why the Peninsula ice shelves have been the ones most dramatically affected by changes in surface air temperature. One is the fact that air temperatures along the Peninsula have been rising faster over the last 50 years than elsewhere in Antarctica, where little change has occurred (Turner et al., 2005). However, even a rapid change in surface temperature would have little impact on an ice shelf if the temperatures remained below freezing year-round. The warming has been critical because it has increased the area where summer temperatures rise above the freezing point, causing the surface of the ice shelves to melt. Wet snow and liquid water have a lower albedo than dry snow, so once melting starts the surface absorbs more shortwave radiation, which contributes toward further melting in a positive feedback cycle.

The lack of surface topography on ice shelves means that meltwater ponds locally. Runoff can only occur if drainage pathways open up through the ice shelf to the underlying ocean. This can happen when sufficient meltwater is generated to fill surface crevasses. The pressure within a water-filled crevasse exceeds that in the surrounding ice shelf, driving the crevasse open. Penetration of multiple fractures through the ice by this mechanism is thought to be the process behind the catastrophic breakup of the Peninsula ice shelves (Scambos et al., 2000). The vulnerability of ice shelves to surface melt imposes a strict climatic limit on their existence. If the summers become warm enough to generate significant surface melt, the ice shelf is no longer viable in the long term and its eventual demise appears to be inevitable.

In the Amundsen Sea, surface air temperatures remain below freezing even in summer, so despite suggestions that this region may also have warmed over the past 50 years (Steig et al., 2009), those changes have had little impact on the ice shelves. However, along the Amundsen Sea coast, subsurface water temperatures are more than 3°C above the pressure freezing point throughout the year (Hellmer et al., 1998). The warm water is a derivative of Circumpolar Deep Water (CDW), a water mass that circles Antarctica within the Circumpolar Current, but that only reaches the ice shelves in the Amundsen and Bellingshausen seas. Understanding the reasons for its presence close to the ice shelves and the possible causes of variability in its flow are critical steps in defining the cause of the observed ice shelf thinning. One possibility is that variability in the wind forcing of the Amundsen

Sea circulation is a source of variability in the flow of CDW toward the ice shelves (Thoma et al., 2008).

Links with the global climate system

Changes in the size of the ice shelves affect global sea level by two processes. Contrary to popular belief there is a small affect on sea level when floating ice is converted to meltwater (Jenkins and Holland, 2007). Since the meltwater is fresh it has a lower density than saltwater and hence occupies a volume that is about 2.5% greater than that of the seawater that was displaced by the ice. The density of seawater is an approximately linear function of its salinity, so the total volume of the ocean and fresh meltwater remains fixed as the two are mixed together. The net result of a reduction in the volume of the ice shelves is therefore a slight freshening and consequent expansion of the ocean. A further contribution to sea level that is generally more significant is related to the dynamical coupling between the ice shelves and the inland ice sheet discussed earlier. A reduction in the size of the ice shelves reduces the restraint they exert on the flow of the inland ice, allowing the outlet glaciers to accelerate and discharge more grounded ice into the ocean. Although the scale and rapidity of the inland changes that could result is still the subject of debate, the impacts have been observed. Following the disintegration of the northern peninsula ice shelves, the glaciers that fed them experienced marked accelerations, at least at their downstream ends (Rignot et al., 2004), while the ongoing changes in the flow of the main Amundsen Sea glaciers (Rignot, 2008) have generally been attributed to thinning of the floating ice shelves.

Around most of the Antarctic coastline outside of the Amundsen and Bellingshausen seas the winters are sufficiently cold that all the waters close to the ice shelves are cooled to the surface freezing point. Thus, further cooling beneath an ice shelf inevitably produces ISW, as described above. The production of ISW has implications for the global ocean circulation (Foldvik and Gammelsrød, 1988), since ISW is one ingredient in the densest form of Antarctic Bottom Water (AABW). AABW is found at the bottom of the ocean throughout most of the world, and its formation around Antarctica is one component of the global overturning circulation that regulates the Earth's climate.

Summary

Ice shelves are ubiquitous features of marine-terminating ice sheets. They form where the ice sheet margins are thin enough to float free of the seabed. Their flow is characterized by lateral spreading, and critically controlled by the degree of lateral confinement. They interact both with the atmosphere and, particularly strongly, with the ocean, which through melting the ice shelf base and transporting icebergs away exerts the primary controls on the thickness and extent of the ice shelves. Changes in the ice shelves have implications for global sea level, because of the control exerted by the ice shelves on the flow of the grounded ice sheet, and for the global ocean circulation, because of the role played by ISW in the formation of AABW.

Definition

Ice-cored moraines are ice-marginal landforms that comprise a discrete body of glacier ice buried underneath sediment. These landforms are transitional because any incorporated ice needs to melt out before the final resulting landform, e.g. a stable moraine, is formed.

Introduction

The term "ice-cored moraine" was introduced into the scientific literature by Østrem (1959, 1965) to describe the frequently observed occurrence of bodies of ice within sediment accumulations at or near ice fronts. Such landforms are widespread in modern glacier forelands and have been investigated in numerous settings over the past five decades.

Usually, ice-cored moraines evolve through a chain of processes involving: (a) the isolation of a body of glacier ice through the establishment of a sediment/debris cover near the margin which, if sufficiently thick, shields the ice from melting, resulting in (b) differential melting of protected sediment-covered ice and clean ice upglacier. At some point (c) the sediment-covered ice will be cut off from supply of active ice upglacier, leading to a transition to either stagnant or dead ice. From this point onwards (d) the body of sediment-covered ice, especially if ridge- or mound-like in appearance and occurring along the ice margin, can be regarded as an ice-cored moraine sensu stricto. Such landforms occur as individual mounds or ridges (Lukas et al., 2007; Figure 1) or constitute broad belts or zones up to several kilometers wide that are unconnected to a glacier (e.g., Kjær and Krüger, 2001). However, some authors prefer to use the term much more loosely to include moraine-like ridges in supraglacial sediment underlain by ice, irrespective of the fact that the ice is still flowing (active) and/or continuous underneath the sediment cover (e.g., Lønne and Lyså, 2005; Evans, 2009).

Ice-Cored Moraines, Figure 1 Photograph showing an ice-cored moraine at the margin of Gornergletscher, Switzerland, June 2007. The ice core was still in contact with the ice margin at the time this photograph was taken, illustrating the process of cutoff from a formerly coherent body of glacier ice.

Ice-core formation

There are three ways in which buried ice can be formed. Firstly, active glacier ice near the ice-margin can be covered by sediment and thus be cut off from supply of active ice upglacier during periods of negative mass balance. Secondly, continued delivery of material to the same spots (depocenters) can lead to thickening of the supraglacial debris cover and thus differential ablation. Thirdly, dead ice can remain in situ and be incorporated where a glacier advances over older dead-ice terrain.

The physical principle behind dead ice formation is that clean or debris-free glacier ice has a much higher albedo than dirty ice. While a thin cover of debris will lead to enhanced ablation (e.g., Adhikary et al., 2000), thicker layers will insulate underlying ice from melting; several decimeters to meters of debris may be required, depending on local factors. Uneven clean ice-debris distribution leads to differential ablation, and thicker layers of debris may lead to the cutoff of glacier ice near the margin and ultimately to the formation of ice-cored moraines.

This debris can be either derived from rockfall or reach the glacier surface through englacial debris septa in the ablation area. Supraglacial load tends to be concentrated near the margins by longitudinal compressive flow, leading to the establishment of thick supraglacial debris layers (Anderson, 2000). Englacial debris septa can either result from incremental adfreezing of meltwater and sediment (e.g., Alley et al., 1997) or folding, shearing, and thrusting near the margin (e.g., Glasser and Hambrey, 2003). They frequently occur as a result of flow compression at the transition between temperate and cold-based ice near the margins of polythermal glaciers. However, such debris septa have also been described from temperate glaciers in the Alps (Lukas et al., 2011).

If material from an englacial debris septum melts out at the glacier surface, it will mix with meltwater and slowly move down the glacier surface as a debris flow (Figure 2a). If the glacier surface lowers under negative glacier mass balance, the material along the top of the debris septum, as well as that relocated downslope, will protect the underlying ice and lead to the formation of an initial debris cone or ridge; this will subsequently be transformed into an isolated mound or ridge of debris overlying a conical or linear ice structure and may be classed as an ablation-dominant medial moraine (Figure 2b; Anderson, 2000).

If this process occurs in a setting where a number of debris septa are closely spaced (Figure 2c), a more uniform layer of supraglacial sediment may be created by lateral redistribution through debris flows, which may eventually lead to the isolation of wider tracts of glacier ice (Figure 2d) and the formation of controlled moraines where englacial structures of the parent ice are inherited (cf. Evans, 2009).

In permafrost environments, nivation and aeolian deposition are potentially significant extraglacial sources of supraglacial material (Lukas et al., 2005; Schomacker and Kjær, 2007). Additional sources are the meltout of material from englacial conduits or crevasse fills and collapse of preexisting material in the foreland onto the ice during glacier advance and bulldozing.

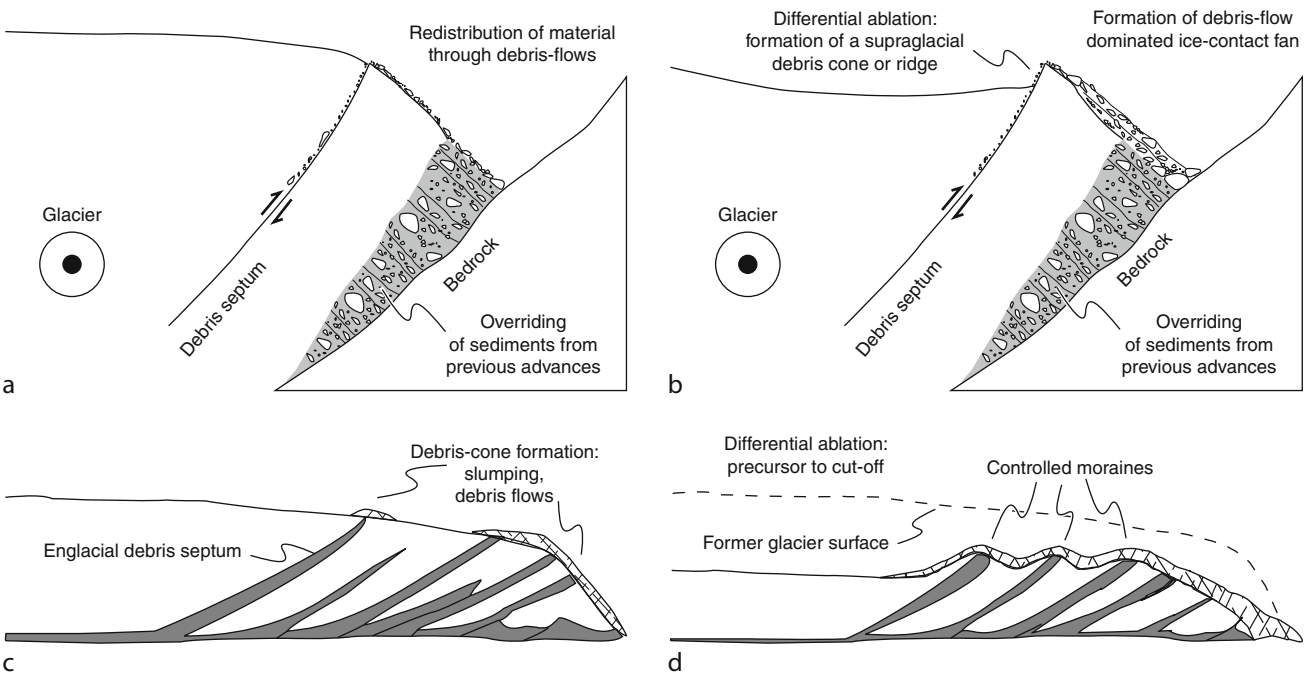
De-icing processes

Characteristic redistribution processes transform ice-cored moraines during de-icing. Two types of melting, classified according to the location of the melting front, have been described: downwasting and backwasting (cf. Kjær and Krüger, 2001).

Downwasting refers to a horizontally orientated melting front. Top-melt occurs where the debris cover is insufficiently thick to prevent conduction of thermal energy to the underlying ice. While the threshold thickness, above which melting ceases, varies in non-permafrost environments, it corresponds to the active layer thickness in permafrost environments. Bottom-melt is usually more limited than top-melt and may only equal or exceed the latter in areas with high geothermal gradients.

Backwasting is by far the dominant process in de-icing landscapes leaving a clear geomorphological imprint. It refers to all melting processes occurring on slopes and comprises the melting of free ice-cliffs and sediment-covered slopes.

De-icing processes include debris flows, gravity sorting, and melt pond formation. In humid, non-permafrost environments like Iceland, debris is redistributed in wider zones of dead-ice terrain, with debris being transferred from ice-cored moraines into depressions. Over time, topographic highs (ice-cored moraines) are lowered while



Ice-Cored Moraines, Figure 2 Schematic diagrams illustrating (**a**) the effect of emerging supraglacial debris along a debris septum and (**b**) the formation of a debris cone or ridge (cross-sectional view with ice flow away from the viewer). (**c**) Longitudinal view of the effect of a number of englacial debris septa emerging near a glacier margin and the effect of this (**d**) on the formation of a continuous debris cover and "controlled moraines."

former low-points (depressions) are infilled, resulting in relief inversion, but also an overall lowering of the relative heights within such dead-ice terrain.

In permafrost environments such as Svalbard debris flows have been reported to be by far the dominant process (Lukas et al., 2005; Schomacker and Kjær, 2008). This is probably because debris mostly exceeds the thickness of the active layer; therefore, any melt is limited to topographically unstable settings (slopes) where redistribution processes are active and expose buried ice.

Sedimentologically, the meltout of buried ice will leave an imprint that can help decipher the presence of paleo-dead ice in Quaternary sediments. Kjær and Krüger (2001) list a number of diagnostic criteria, such as de-stratification and openwork boulder accumulations within sediments. Benn (1992) and Lukas (2005) show how such structures can be used to reconstruct the presence of paleo-dead ice.

Implications

Ice-cored moraines (and other landforms containing buried ice) will be altered upon de-icing. However, the degree of alteration, and thus the preservation potential of an ice-cored moraine, will depend on the ice–debris ratio. If the latter is high, preservation potential will be low and vice versa. This is because (a) melting ice will release meltwater and cause redistribution of material (see above) and (b) dead ice occupies space that will be replaced with sediment during de-icing. Hence, any landscape containing buried ice cannot be taken as the final landscape. Consequently, any models that use such landscapes as modern analogues for interpreting paleo-glacier dynamics during the Pleistocene need to take this into account.

Some recent discussions on work in Svalbard have centered on precisely this problem: Some authors (e.g., Graham et al., 2007) have suggested that modern Svalbard glaciers, the forelands of which contain significant amounts of ice-cored moraines (termed "moraine-mound complexes" by those authors), can be used as one-to-one analogues of Younger Dryas glacial conditions in Upland Britain. However, the Svalbard landform assemblages used are largely transitional as outlined above, and thus this comparison ought to be viewed with caution (cf. Lukas, 2007; Evans, 2009). This debate illustrates the need to take into account the de-icing dynamics of ice-cored moraines.

Ice-cored moraines occur in a landscape which has, by definition, not completed deglaciation. Thus, while the glacier may have visibly retreated from a zone of apparently stable moraines, it needs to be considered that dead ice may still be present. De-icing can take decades to millennia (Everest and Bradwell, 2003); Dyke and Savelle (2000) even report an extreme case where ice-cored moraines have survived the entire Holocene under continuous permafrost conditions.

Therefore, the presence of dead-ice has profound implications on dating glacial landforms on Quaternary timescales. Any dead ice and its associated meltout will delay surface stabilization. This time lag means that any ages obtained, no matter by which dating method, represent minimum ages that are not a true reflection of the time of primary deglaciation. Therefore, any study using formerly ice-cored terrain in paleo-glacier and paleoclimate reconstruction needs to take great care to establish whether dead ice may have been present. This can best be achieved by using an integrated approach of geomorphology and sedimentology.

Conclusions

Ice-cored moraines are important features in glacial environments, because they occur in many ice-marginal settings under a wide range of glacier thermal regimes and alter significantly during de-icing. They are thus transitional landforms that cannot be used for glacier and palaeoclimate reconstruction or numerical dating in as straightforward a manner as de-iced, stable moraines. Likewise, any study using ice-cored moraines in conceptual models of ice-marginal dynamics and landform genesis needs to take into account de-icing processes in order to make robust predictions of future foreland evolution.

The term ice-cored moraine has been used rather widely in the literature to refer to quite different phenomena. It is suggested here that the term ice-cored moraine should be reserved for a landform (moraine) that (a) is disconnected from the active ice margin and (b) contains a discrete body of ice that is surrounded by sediment. This way, any overlaps with other parts of the ice-marginal/supraglacial debris-ice continuum, such as debris-covered ice margins, can be avoided.

ICE-DAMMED LAKES

Fiona Tweed
Department of Geography, Staffordshire University, Stoke-on-Trent, Staffordshire, UK

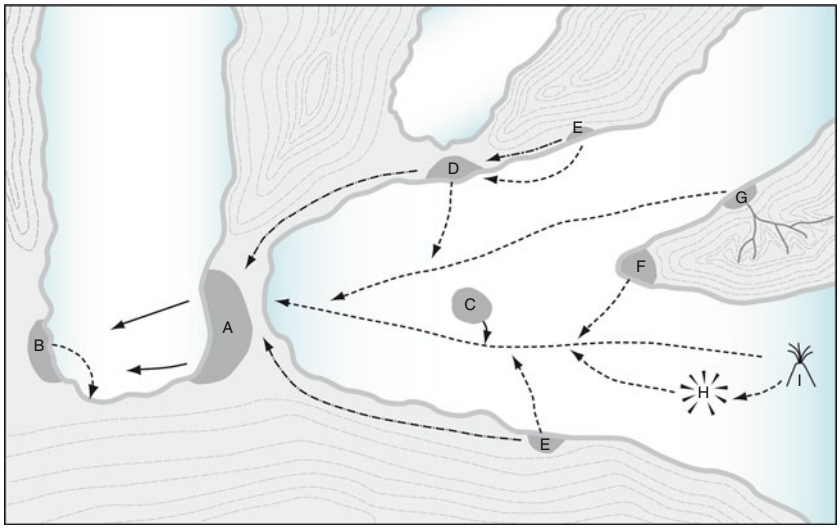
Definition

An ice-dammed lake is best defined as "a substantial body of standing water, located in, on, under or at the margin of a *glacier*, such that its existence is in some way dependent on damming by *glacier* ice" (Blachut and Ballantyne, 1976, p. 1).

The occasional or recurrent release of the water stored within ice-dammed lakes can effect significant geomorphic change in glaciated environments (Hydrology of Jökulhlaups). Ice-dammed lakes can form supraglacially, subglacially, or ice-marginally and can be classified by their position in relation to the damming *glacier* and the surrounding landscape (e.g., Hutchinson, 1957; Tweed and Russell, 1999). Figure 1 illustrates the range of topographic settings in which ice-dammed lakes form, identifying the type of lake and likely flood routing (after Tweed and Russell, 1999). In most settings, ice-dammed lake formation is a gradual process, linked to *glacier* mass balance and, ultimately, climate forcing (Evans and Clague, 1994). However, independently of climate, sudden glacial advance during surging can block drainage channels and create ice-dammed lakes (e.g., Clague, 1979; Clarke and Mathews, 1981; Mayo, 1989).

Ice-dammed lake drainage occurs when a lake exceeds a critical threshold, the triggering mechanism for any given lake depending on lake-basin topography and ice-dam characteristics (e.g., Tweed and Russell, 1999). Some ice-dammed lakes exhibit temporal changes in their drainage behavior in response to fluctuations in the nature of the ice dam (Evans and Clague, 1994). As glaciers recede, ice dams become thinner resulting in progressively decreasing depths of lake water being required to initiate floods. Under these circumstances, outbursts usually decrease in magnitude, but become more frequent. Conversely, under advancing conditions, a thickening glacial dam can impound lake water at increasingly higher levels and floods tend to increase in magnitude and decrease in frequency. Floods from ice-dammed lakes are part of a wider spectrum of floods generated by the failure of a range of natural dams, including the breaching of moraine dams (e.g., Vuichard and Zimmerman, 1987; Richardson and Reynolds, 2000), dams formed by landslide debris (e.g., Costa and Schuster, 1988; Korup, 2002), and snow dams (e.g., Gore, 1992).

The existence of ice-dammed lakes is documented for most presently glaciated areas. Alaskan and Canadian ice-dammed lakes are well reported (e.g., Stone, 1963; Mathews, 1965; Clarke, 1982; Sturm and Benson, 1985) and drainage of ice-dammed lakes in South America (e.g., Nichols and Miller, 1952; Bruce et al., 1987) and Asia (e.g., Gunn et al., 1930; Hewitt, 1982; Ives, 1986) is



Letter	Ice-dammed lake type
A	Tributary glacier water dammed in trunk valley
B	Water dammed proglacially
C	Supraglacial water
D	Water dammed between tributary and trunk glacier
E	Ice-marginally dammed water
F	Water dammed by converging glaciers
G	Stream valley blocked by trunk glacier
H	Subglacial caldera
I	Volcanic waters (usually no storage)

Ice-Dammed Lakes, Figure 1 The topographic settings of ice-dammed lakes and indicative floodwater routing (Adapted from Tweed and Russell, 1999). The key identifies the principal ice-dammed lake types illustrated.

also described. Ice-dammed lakes in Norway (e.g., Liestøl, 1956; Knudsen and Theakstone, 1988), Greenland (e.g., Dawson, 1983; Sugden et al., 1985; Russell et al., 1990), Iceland (e.g., Thorarinsson, 1939; Björnsson, 1976, 2002), and the European Alps (e.g., Haeberli, 1983) have been the subject of research; however, Arctic and Antarctic ice-dammed lakes are less frequently discussed (e.g., Blachut and McCann, 1981; Siegert et al., 1996). The sudden drainage of ice-dammed lakes during the last stages of the *Pleistocene Epoch* caused some of the largest floods on Earth (e.g., Bretz, 1928; Baker, 1973; Baker et al., 1993; Rudoy, 2002; Carling et al., 2002; O'Connor and Costa, 2004). Given the backdrop of climate change, the ability to monitor and predict the formation of ice-dammed lakes and the likely location, timing, magnitude, and impact of resultant outburst floods will be vital to the management of glaciated regions (Evans and Clague, 1994; Korup and Tweed, 2007).

ICE-MARGINAL DEPOSITION

Mahendra R. Bhutiyani
Hazard Assessment and Forecasting Division, Snow and Avalanche Study Establishment, Chandigarh, India

Definition

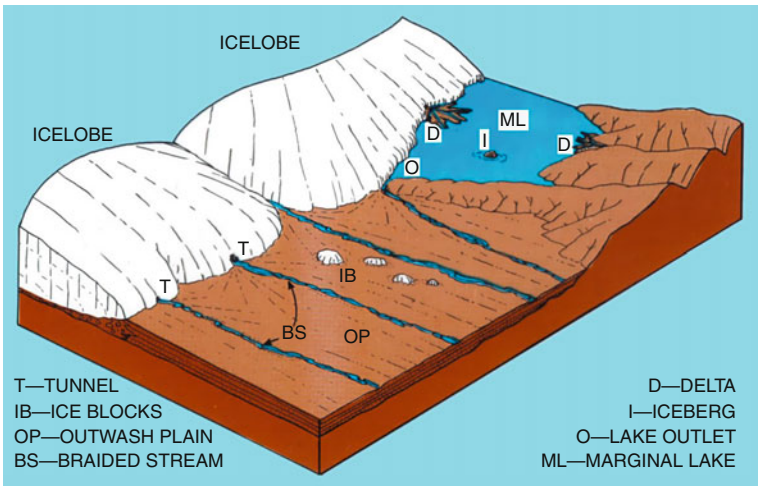
An undulating hilly belt consisting of an unsorted mixture of clay, silt, boulders, cobbles, and pebbles that was brought by the moving ice in traction on the surface and

accumulated beneath the ice margin (Figures 1 and 2). They are also termed as "glacier till" deposits or "moraines" and are exposed after the ice mass has disappeared. Melting of small ice blocks in this hilly belt, which is also described as "knob and kettle landscape," gives rise to the formation of kettles and may contain small lakes and ponds.

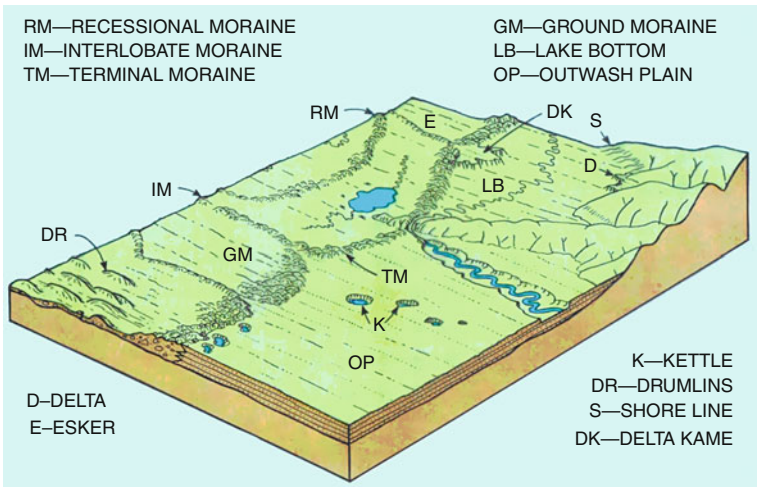
Origin

Outermost deposits at the periphery of a moving ice mass are "terminal moraines"; the moraine that is formed between two ice lobes is an "interlobate" moraine. Where the ice margin temporarily holds a fixed marginal position during its period of general retreat, a "recessional moraine" is formed. Behind the terminal moraine are commonly found "eskers" – the long, narrow ridges of gravels and cobblestones that were formed as deposits on the floors of ice tunnels. Eskers may be 30–70 m in height and may extend for tens of kilometers across the country. There may also be present numerous "drumlins" that are rounded hills of glacier till, shaped by moving ice as it dragged the till over the ground surface. At certain points the till was plastered in successive layers upon small knobs, eventually forming the drumlins, which resemble a shape of an inverted bowl of a teaspoon with the long dimension paralleling the ice motion. Drumlins are about 400 meters to about 1.5 km in length and 30–70 m in height.

Over the entire region previously covered by the ice, there may be found a layer of till, varying in thickness



Ice-Marginal Deposition, Figure 1 Marginal deposits of ice sheets before deglaciation.



Ice-Marginal Deposition, Figure 2 Marginal deposits of ice sheets after deglaciation.

from a few meters to about few tens of meters. This irregular blanket of till is known as "ground moraine." Because of uneven deposition, ground moraine has many areas of swamps and lakes.

The marginal lake shown in Figure 1 has now disappeared, but there remain various evidences of its existence. A small delta produced in front of the ice now stands as a flat-topped "delta kame." Along the hillsides are seen a "delta" and a "shoreline." On the lake bed are found alternating thin layers of clay and silt known as "varved" clays. On the outwash plain are "kettles," which are ice-block depressions with steep sides that give rise to lakes.

Significance

Ice-marginal deposits present excellent geomorphological evidences for the study of geographical coverage of past glaciation and paleoclimates in the region.

ICE-MARGINAL PROCESSES

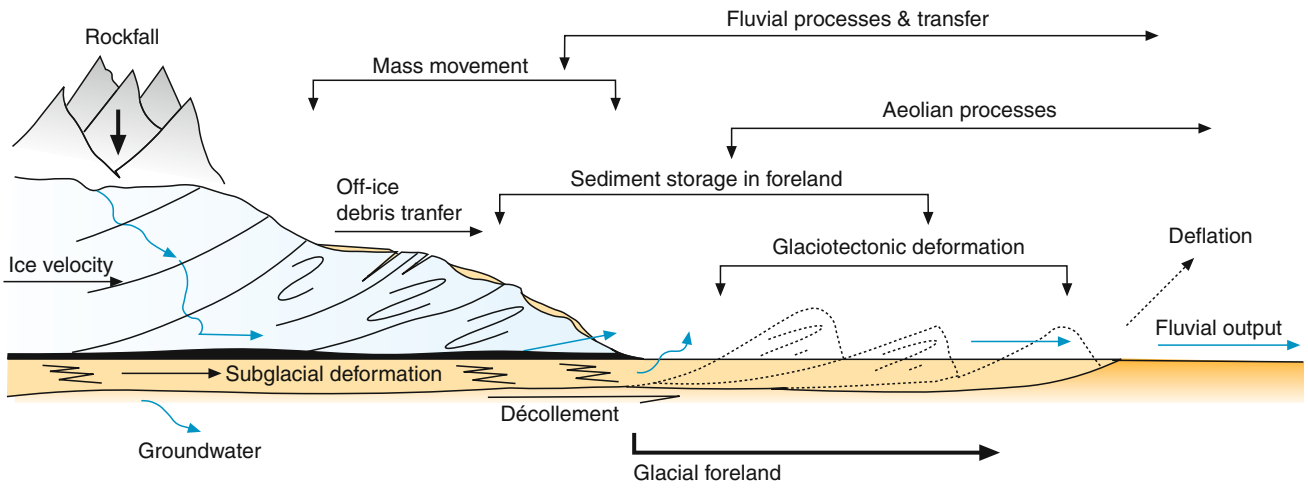
Matthew R. Bennett
School of Applied Sciences, Bournemouth University
Talbot Campos, Dorset, UK

Definition

Ice margin. The interface between ice and the glacier foreland or pro-glacial zone.
Pro-glacial. Area beyond the ice margin.
Glaciotectonic. Deformation of ice and/or sediment by glacier ice.
Décollement. Slip surface along which deformation is concentrated.

Introduction

Ice-marginal processes are extensive in scope and nature. At its simplest, the *ice margin* is the interface between ice and the glacial foreland, or *pro-glacial* zone. It is a zone of sediment transfer associated with the phase change of ice to water. As such, it can be seen as a transfer system with an input of glacial sediment, an output of sediment, an internal storage (landforms & sediments), and a range of transfer mechanisms that facilitate the movement of sediment within this system. Figure 1 provides a simple conceptual model of a terrestrial ice-marginal zone based on this idea. The input of sediment to the ice-marginal zone is determined by the debris content of the ice, the rate of delivery which is a function of ice velocity and ablation, the rate (if present) of subglacial sediment deformation and associated sediment advection, as well as the sediment discharged within glacial meltwater wherever it be located – supraglacial, englacial, subglacial, or as groundwater. The output of sediment from the glacial foreland is via meltwater discharge and in some cases by aeolian processes. Within the ice-marginal zone and immediate foreland, sediment is stored and/or transferred via a range of processes with a variety of residence times from a few hours to millennia depending on the geometry of the ice margin and the foreland basin in which it terminates along with the degree of "connectivity" between the glacial and non-glacial realms. We can recognize five major process families at work in transferring sediment within this ice-marginal system, they are: (1) mass movement; (2) fluvial; (3) glaciotectonic; (4) aeolian; and (5) groundwater.



Ice-Marginal Processes, Figure 1 Schematic model of a terrestrial ice margin based on the idea that it is a transfer system for water and ice at the interface between the glacial & pro-glacial zones.

Mass movement

Mass movement processes involve the transfer of sediment from the ice margin and may involve everything from rockfall and granular avalanches, to cohesive debris flows. Debris emerges on the ice surface both as a result of surface ablation revealing englacial debris in high-level transport and via direct rock fall onto the ice surface in the ablation zone. In addition, subglacial (low-level transport) debris may outcrop on the ice surface where it has been elevated to a supraglacial position via rising debris bands, stratification, thrusts, and folds associated with compressive flow in the terminal zone of a glacier. The ice-marginal debris supply of any given glacier is a function of the sediment load within the ice, the rate of surface ablation, and ice velocity which determines the rate of sediment delivery. As debris first melts out of the ice, it will darken the ice surface leading to enhanced melting, since dark surfaces absorb more solar radiation; however, as the debris thickens, it will begin to inhibit melting as it insulates the ice surface. The stability of this caprice of supraglacial debris in the ice-marginal zone depends on the ice surface gradient as well as the grain-size distribution of the debris and therefore its ability to hold moisture. Coarse debris on a steep ice surface will fall or move as a dry granular flow accumulating at the base of the slope as a talus- or scree-like deposit. In contrast, fine-grained sediment on a gentler ice slope may become water saturated and fail as a cohesive debris flow. Where the ice-marginal geometry is relatively smooth and steep, sediment will be transferred efficiently to the ice margin accumulating as a linear accumulation along the ice margin, either as a dump moraine, or as an ice-marginal debris fan. If the debris transfer is less efficient, or there is strong spatial variation in debris load within the ice, it will result in an ice-cored topography of ridges and mounds on the ice surface. In this scenario, debris may have a much longer residence time within the ice-marginal zone, being reworked repeatedly as the ice-cored topography changes over time. This re-working of sediment generates flow tills whose properties will reflect the debris sources (glacial transport pathway) from which the debris is blended as well as the fluidity of the debris flow via which the sediment was emplaced. Fluvial re-working may also be a feature of such a complex ice-marginal zone.

Fluvial

Fluvial processes are also important both in the ice-marginal and foreland zones. Supraglacial water flow helps transfer debris from the ice margin and is common where the ice is cold-based, meltwater production is high, and there are few crevasses. Sediment transfer will also take place where water flow occurs within or below the ice. Size sorting may occur in some cases, although, in most cases, the high discharge rates and rapid discharge fluctuations will tend to lead to massive and poorly sorted deposits. Surface flow may also be dominant in a complex ice-marginal zone with large amounts of buried ice leading to the deposition of glaciofluvial sediments in association with flow tills thereby creating "kame and kettle" topography as the ice melts.

As water emerges from meltwater portals in the ice margin, the velocity falls with the loss of confining water pressure and rapid deposition of coarse bed load may occur close to the portal entrance favoring the formation of outwash fans (Hochsander Fans). These may build up over the ice margin burying it and thereby blurring the location of the true ice margin. The degree of fluvial re-working at a given ice margin depends on the temporal stability of the meltwater portals at the ice margin as it fluctuates over time and with any advance or retreat of the ice margin. A stable routing of meltwater will limit re-working to a clearly defined fluvial corridor, whereas instability involving regular switching of meltwater portals along an ice margin will lead to more widespread re-working of sediment along the margin. Away from the ice margin in a distal direction, the meltwater route may become more stable and a braided river system will develop.

Storage of sediment within the pro-glacial zone depends on the degree of "connectivity" between the ice margin and the fluvial system. Connectivity in this context refers to the ease with which sediment is transferred from one process system to the next – in this case, glacial to fluvial. At glacier margins with a high meltwater discharge and good connectivity, sediment will be re-worked rapidly by the fluvial system and transferred efficiently away from the ice margin. The system is essentially supply limited and the pro-glacial zone will be dominated by fluvial rather than glacial landforms; the preservation potential, for example, of ice-marginal moraines will be limited. In comparison, where meltwater discharge is less or the degree of connectivity between the glacial and fluvial system is more limited, sediment storage will be the norm. In this case, the system and ice-marginal zone is transport limited and ice-marginal landforms of glacial original will be dominant. Connectivity is determined by a complex range of variables, including such things as the rate of sediment supply; the geometry of the ice margin; its temporal dynamics; the geometry of the foreland basin; meltwater discharge; and the spatial and temporal stability of the drainage routes along an ice margin. It is important to note that connectivity is also scale dependent and may change laterally along an ice margin as well as through time.

Glaciotectonics

Glaciotectonic processes may also be important within the ice-marginal zone both in terms of sediment supply via subglacial deformation and via the mass-transfer of sediment within the ice-marginal zone through the formation of glaciotectonic moraines. If an ice margin is advancing, whether in a sustained fashion or seasonally, and is well coupled to its foreland, it has the capacity to either compress part of the foreland and/or move it in a distal

direction. Ice-marginal to foreland coupling is aided by things such as a reverse bedrock slope at the ice margin, or an ice-marginal outwash fan against which the ice can push as it advances. Of equal importance at thin ice margins is the potential for the seasonal "freezing-on" of a subglacial sediment layer within the ice-marginal zone.

Glaciotectonic deformation, especially the distal movement of a thin slab of foreland, is facilitated by the presence of a basal décollement horizon, perhaps in the form of a more ductile sediment layer or one with elevated pore-water pressures, over which the foreland slab may slide. The nature of the deformation – folds versus thrust, for example – and the degree of distal movement will depend on the relative strength of the foreland slab with respect to the frictional properties of the décollement. A rigid slab resting on a weak décollement will favor distal movement of the slab, whereas a weak foreland resting on a stronger décollement will lead to in situ compression. The former may also be associated with a more brittle deformation regime (e.g., thrusts and faults) than the latter which will favor ductile deformation (e.g., folds). The interplay of the factors will determine the nature of the ice-marginal glaciotectonic landforms produced along the ice margin and also their size and internal tectonic architecture.

Groundwater

Groundwater and the hydrogeological properties within an ice-marginal zone may also be key processes especially in determining the nature of glaciotectonic deformation. They also provide a potential transfer route for dissolved or fine-grained sediment. For completeness, we should also include aeolian processes within this review of ice-marginal processes since in certain situations, they may assist with the export of fine-grained sediment from a pro-glacial zone.

Summary

In summary, therefore, it is possible to see the ice-marginal zone as the interface between the glacial and non-glacial process domains. It is a zone characterized by sediment transfer and storage and the degree of connectivity between the two process domains is critical in determining whether the ice-marginal zone is dominated by glacial or by fluvial processes. It is important to note that this discussion has focused on terrestrial ice-marginal environments, but the basic principles also apply in aquatic ice-marginal environments.

ICE-VOLCANO INTERACTIONS

Hugh Tuffen
Lancaster Environment Centre, Lancaster University, Lancaster, UK

Synonyms

Glaciovolcanism; Volcano-ice interactions

Definition

Ice–volcano interactions. The interplay between the activity of volcanoes and ice sheets or valley glaciers. This includes how individual eruptions interact with ice and meltwater, how basal melting in volcanic areas affects ice sheets, and how changes in ice thickness influence longer-term patterns of volcanism.

Glaciovolcanism. The interactions between magma and ice in all its forms (snow, firn, ice, and meltwater), on Earth and other planets.

Key localities

Iceland, West Antarctic Ice Sheet, Antarctic Peninsula, Andes, British Columbia, Alaska, Mars

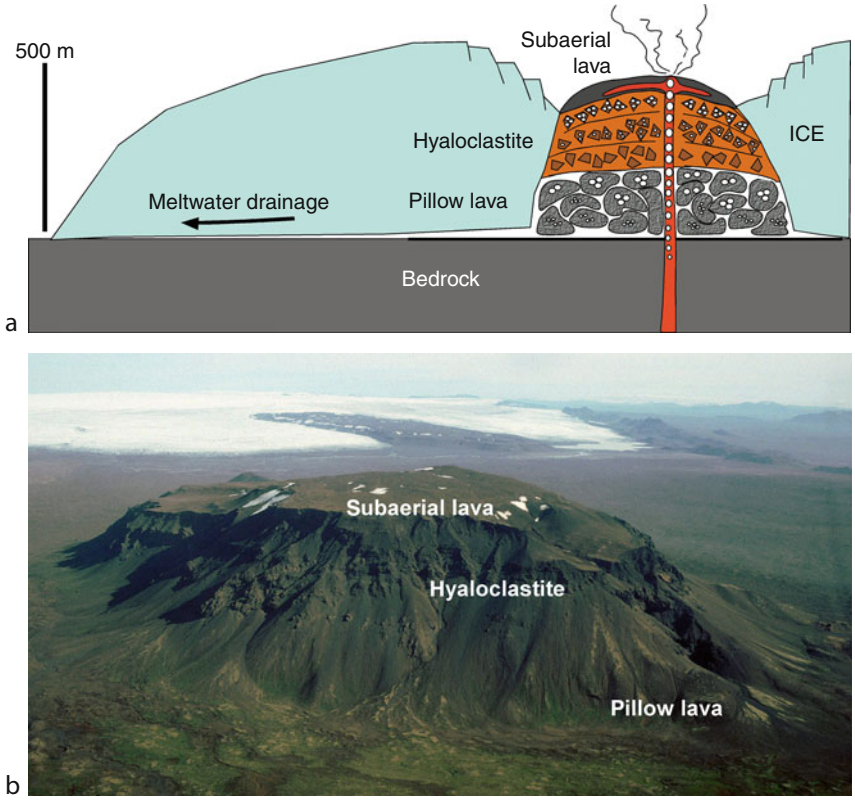
Interactions between magma, ice, snow, and meltwater during eruptions

The interactions between volcanic eruptions and ice and snow cover a broad spectrum from eruptions beneath ice sheets hundreds of meters thick to the melting of smaller bodies of ice or snow on volcanoes by pyroclastic deposits or lava flows (Major and Newhall, 1989; Smellie, 2000; Subglacial volcanism). A common feature of all interactions is the transfer of heat from magma to ice or snow, which leads to the production of meltwater.

Eruptions beneath ice sheets

During eruptions beneath ice sheets magma rises to the base of the ice either at a point source or a fissure (Wilson and Head, 2002; Tuffen, 2007), leading to the construction of a volcanic edifice and the generation of meltwater. In general, eruptions beneath thick ice begin with the gentle effusion of pillow lavas, which give way to increasingly explosive interactions between magma and meltwater as the edifice grows upward toward the ice surface within an ice-confined meltwater lake and the confining pressure decreases (Smellie, 2000). This phase of activity generates hyaloclastites. If the eruption is sufficiently sustained, it may pierce the ice surface and terminate with the effusion of subaerial lava flows (Figure 1); this is termed a tuya-building eruption. The products of such eruptions may thus approximately record past ice sheet thicknesses (Subglacial volcanism).

Observations of the 1996 Gjálp eruption, which occurred beneath 450–650 m of ice at the Vatnajökull ice sheet in Iceland, have greatly advanced our understanding of eruptions beneath ice sheets (Guðmundsson



Ice-Volcano Interactions, Figure 1 (**a**) Cartoon showing the products of a basaltic tuya-building eruption beneath an ice sheet, where the ice surface has been breached. The transition from hyaloclastites to subaerial lavas therefore provides a minimum estimate of the palaeo-ice thickness. (**b**) Aerial photograph of Hlodufell tuya (1,188 m) in western Iceland, which was formed in a basaltic tuya-building eruption during the last glacial period. Photograph by Prof. John Smellie.

et al., 1997; Smellie, 2000). Key observations include the astonishing rapidity of the melting (>450 m of ice was melted in only 36 h) and that local subglacial hydrology controls whether meltwater collects or escapes from the eruption site, and thus the pressure at the vent area and the style of eruption (Guðmundsson et al., 2005). Meltwater from Gjálp gathered in the nearby Grímsvötn caldera for several weeks before being discharged in a catastrophic jökulhlaup (jökulhlaup) with a peak discharge of 45,000 m^3s^{-1}.

Melting of snow and ice on stratovolcanoes

Many stratovolcanoes, particularly in the Andes, are mantled by permanent snow and ice both on their upper flanks and in their summit craters. This creates a major natural hazard as melting of ice or snow during eruptions may trigger meltwater floods (lahars) that inundate valleys on the volcano flanks, with devastating consequences (Major and Newhall, 1989; Natural hazards associated with glaciers and permafrost). The 1985 eruption of Nevados del Ruiz, a 5,300-m high stratovolcano in Columbia, triggered lahars that claimed the lives of 23,000 people (Lowe et al., 1986; Major and Newhall, 1989). The geological record of such volcano–ice interactions includes lahar deposits and ice-contact lava flows (Lescinsky and Fink, 2000; Subglacial volcanism).

Models of ice–volcano interactions

Several aspects of the complex processes that occur during ice–volcano interactions have recently been modeled mathematically, guided by observations of recent eruptions and the geological record of past eruptions. These include calculations of the volume and pressure changes during subglacial eruptions (Hoskuldsson and Sparks, 1997), the propagation of dykes and sills into ice sheets (Wilson and Head, 2002), the rate of heat transfer from magma to ice during eruptions (Guðmundsson, 2004), and the interplay between melting and deformation of ice (Tuffen, 2007). Nonetheless, many major uncertainties remain, including whether eruptions may fracture ice sheets or prise them from the bedrock, and which factors control the explosivity of eruptions under ice.

The geological record of past ice sheets and glaciers

The products of past eruptions that have interacted with ice and snow record a wealth of information about the extent, thickness, and nature of past ice sheets and glaciers

(Smellie et al., 2008). This is particularly valuable as many volcanic rocks can be readily dated, thus providing unique insight into the timing of palaeoenvironmental changes. When eruptions have pierced the ice surface, the transition from subglacial to subaerial formations roughly indicates the palaeo-ice thickness (Figure 1; Mathews, 1947; Smellie, 2000; Subglacial volcanism). The recognition of distinctive fracture patterns in lava flows that have contacted ice, snow, and meltwater allows precise reconstruction of ice and snow extents on stratovolcanoes (Lescinsky and Fink, 2000; Mee et al., 2006). The concentration of volcanic gasses dissolved in volcanic deposits may even record the pressure when they quenched beneath the ice and thus palaeo-ice thicknesses (Schopka et al., 2006), but there are currently uncertainties in this technique. Researchers are currently using these methods to record and unravel the history of ice sheet fluctuations in Antarctica, Iceland, and elsewhere.

Effects of changing ice thicknesses on volcanic activity

Fluctuations in the thickness of ice covering volcanic zones may strongly affect the amount of magma that is erupted. As an ice sheet, hundreds of meters thick, abruptly receded from the Northern Volcanic Zone in Iceland during the last deglaciation at about 11 ka, the rate of volcanism increased thirtyfold (Maclennan et al., 2002). This is because the removal of ice led to rapid decompression of the mantle and greatly enhanced melting and magma production. Crustal decompression can also open the fracture pathways that help magma to rise to the surface.

On a shorter timescale, thinning of the Vatnajökull icecap in Iceland by tens of meters during the twentieth century is thought to have increased magma production by over 1 km^3 (Pagli and Sigmundsson, 2008), although this increase is modest compared to the acceleration during the last deglaciation. On a still shorter timescale of hours to days, drainage of tens of meters of meltwater from the Grímsvötn caldera during jökulhlaups can trigger minor eruptions, showing that some volcanic systems are very sensitive to modest pressure changes at the base of the ice.

Changes in eruptive activity due to ice sheet fluctuations are not confined to Iceland, as deglaciation is also known to have accelerated rates of Quaternary volcanism in other volcanic areas, including the western USA, France, and Germany.

Effects of volcanic activity on ice sheets and glaciers

The mass balance of glaciers and ice sheets is strongly influenced by basal melting due to geothermal heat (Bell, 2008; Basal melting). As subglacial volcanoes are regions with exceptionally high geothermal heat fluxes they may therefore have a significant impact on the local mass balance. Enhanced basal melting in volcanic zones coincides with the presence of poorly consolidated volcanic rocks, thus encouraging basal sliding and, potentially, the formation of ice streams (Blankenship et al., 1993).

According to current knowledge, an individual eruption may affect an ice sheet or glacier in three principal ways. Firstly, volcanically produced meltwater may inundate the existing subglacial drainage system, encouraging glacier surging (Björnsson, 1998). Secondly, melting and fracturing at the eruption site may drastically change the ice surface topography (Guðmundsson et al., 1997). Thirdly, deposition of volcanic ash onto ice, which occurs if the eruption melts through the ice, may affect ablation rates (Wilson and Head, 2009).

Ice–volcano interactions and life on Mars

There is increasing evidence that widespread interactions between rising magma and the Martian cryosphere have occurred through much of the planet's history, creating a wide variety of landforms associated with meltwater movement and ice-contact volcanic deposits (e.g., Head and Wilson, 2007). This has generated considerable interest as areas of geothermal heating and meltwater production are the most probable environments where life may have developed on Mars. Current research includes documenting the landforms generated (Head and Wilson, 2007), modeling ice–volcano interactions in the Martian environment (Wilson and Head, 2002), and investigating whether the microbial ecosystems that develop at terrestrial ice-covered volcanoes may survive the harsh conditions on Mars (Cousins et al., 2009).

Outlook: current investigations, controversies, and gaps in current knowledge

As the study of ice–volcano interactions is still in its infancy, a number of fundamental questions remain unanswered. These include:

- Can enhanced volcanism during deglaciation play an important role in the destruction of ice sheets and glaciers?
- Will the current thinning of glaciers on Andean stratovolcanoes trigger more frequent eruptions and greater hazards?
- Is current thinning of Antarctic ice likely to trigger enhanced volcanism in the near future?

In order to address these issues, volcanologists and glaciologists need to look into the geological record to see how ice and volcanoes have interacted during previous episodes of climate change. Our understanding of the complex physical processes involved will improve with further field, experimental, and modeling studies of ice–volcano interactions.

ICEFALL

Mahendra R. Bhutiyani
Hazard Assessment and Forecasting Division, Snow and Avalanche Study Establishment, Chandigarh, India

Definition

Icefall is that portion of the glacier body where it gets vertically broken down into number of half-depth to full-depth crevasses across its flow, giving rise to a messy and rugged topography consisting of sharp ice columns and ridges called "seracs." An area where tributary glacier meets the main trunk glacier may also have an icefall if there is a sudden change in the gradient. A classic example is the Khumbu Icefall of the Khumbu Glacier (Figure 1) on the way to Mount Everest at an altitude of about 5,500 meters above sea level.

Origin

Glacier moves by basal sliding to some extent but largely by plastic deformation of ice under the influence of gravity, because of the gradient in its subglacial valley profile. Shear stress along the slope direction, caused by the gravitational pull, far exceeds the shear strength of the glacier ice. Consequent plastic deformation may fail to keep pace with such higher velocities, giving rise to multiple failures and formation of number of transverse crevasses. Once the gradient becomes normal, glacier-flow velocities slow down and crevasses close, making the glacier surface smoother.

Significance

Mountaineers, on their way to the summit, have to traverse highly crevassed treks of the glaciers in the icefall regions, with the help of ladders (Figure 2) or confining their movements to areas where the crevasses narrow down or on lateral moraines (Figure 3) or at times, on the steep valley escarpments. Although glacier-flow velocities in the icefall region are abnormally high on the yearly scale, they

are barely visible on hourly or daily basis and may cause sudden collapse of a serac without warning. Mountaineers are extremely vulnerable to such unpredictable behavior as moving ice columns may weaken/disturb the anchors/abutments of the ladders on both sides. A cautious approach employing a "roping-up" technique while crossing such areas, whereby the members of the team, are suitably roped up with adequate distance between two successive members, may mitigate the danger to a large extent.

ICELAND GLACIERS

Oddur Sigurðsson
Veðurstofu Íslands, Icelandic Meteorological Office, Reykjavík, Iceland

Introduction

Although, according to tradition, Iceland is named for sea ice, the glaciers of the country are very prominent. Glaciers covered 11,048 km^2 at the turn of the twenty-first century, i.e., 11% of the total area of the country (Figure 1) and add immensely to the scenery in most districts because they are generally on the highest mountains. Moreover, glaciers have had a considerable impact on the history of the nation from the very beginning, particularly as a result of the hazards associated with explosive, subglacial eruptions in ice-capped volcanoes and the glacierized part of the neovolcanic zone.

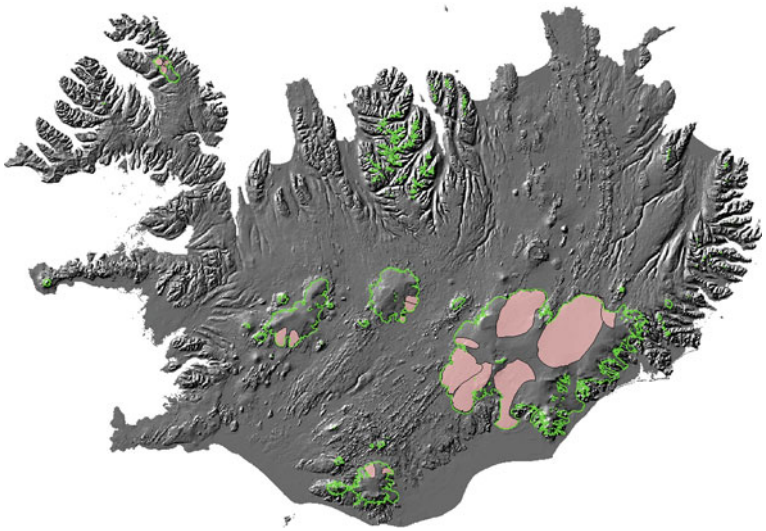
The largest ice caps are found where the precipitation is greatest in the southern and southeastern part of the country and the central highlands. One is situated on the northwest peninsula. Of ca. 280 glaciers in Iceland, about 190 are found in the northern highlands. All of those are quite small mountain glaciers, primarily facing north (Figure 2). About 40 similar mountain glaciers are distributed throughout the mountains of the eastern fjords. The highest mountains in the country are active volcanoes. All of them have ice caps. Of the glaciers and outlet glaciers in Iceland 269 have modern, documented place-names (Sigurðsson and Williams, 2008). Björnsson and Pálsson (2008) and Björnsson (2009a) summarized information about the glaciers of Iceland.

Oscillations of glaciers

During the last glaciation, Iceland was almost entirely covered by glacier ice. After the sudden end of the last glaciation glaciers more or less disappeared about 7000 years ago (Geirsdóttir et al., 2009), leaving only the very highest mountains with ice caps. The early manuscripts mention the presence of glaciers and the turbid water of the glacial rivers at the time of settlement 1,100 years ago. The word *jökull* (glacier) is commonplace in the oldest place-names which indicates the presence of glaciers during the time of settlement more or less in the same places as they are at the present time.

According to contemporary documents glaciers have advanced more or less continuously at least since the seventeenth century and probably since the thirteenth century. Grazing areas, forests, and inhabited districts were overrun by glaciers, which indicates that this was the greatest advance of glaciers since the last glaciation (Sigurðsson, 2005).

In Iceland the Little Ice Age ended about 1890. The retreat of glaciers, however slow, was obvious during the first decades of the twentieth century (Björnsson, 1998). In the 1920s considerable climate warming resulted in high rate of retreat of all glaciers in the country so that by 1960 all glaciers within the country had retreated from their 1930 position (Sigurðsson, 1998). This retreat continued at a moderate pace until about 1970. During the period 1970–1995 glaciers advanced almost continuously due to a cooler climate in an area extending from Labrador and across southern Greenland to Iceland (Hanna et al., 2004). During the first years of the twenty-first century glaciers have retreated faster than at any time since 1930, when meteorologist Jón Eyþórsson began monitoring



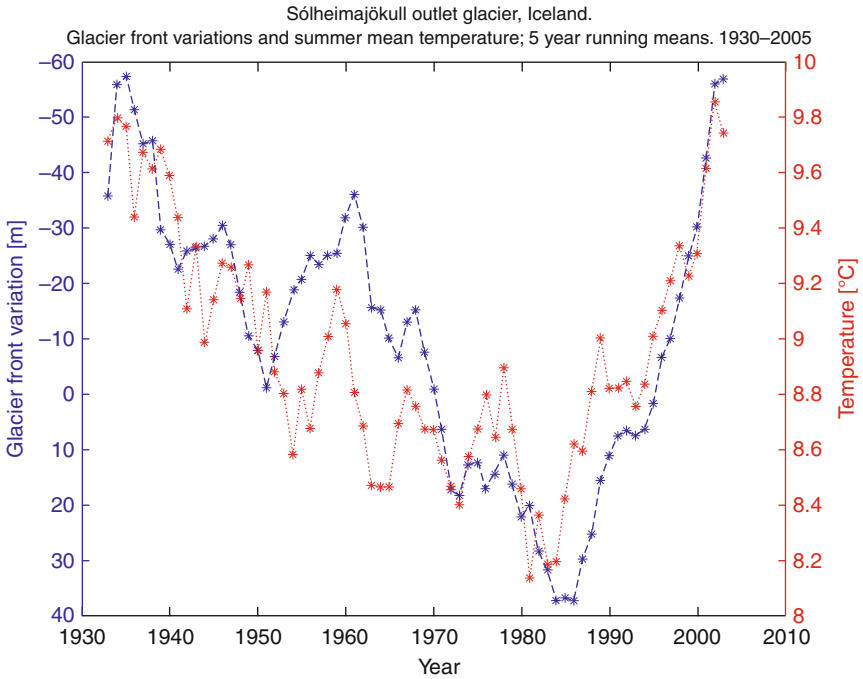
Iceland Glaciers, Figure 1 Location map of Iceland with glacier outlines. Identified surge-type glaciers are shaded.

Iceland Glaciers, Figure 2 Two surge-type cirque glaciers, Teigardalsjökull (quiescent) and Búrfellsjökull (surging) in Northern Iceland. (Photo by Oddur Sigurðsson).

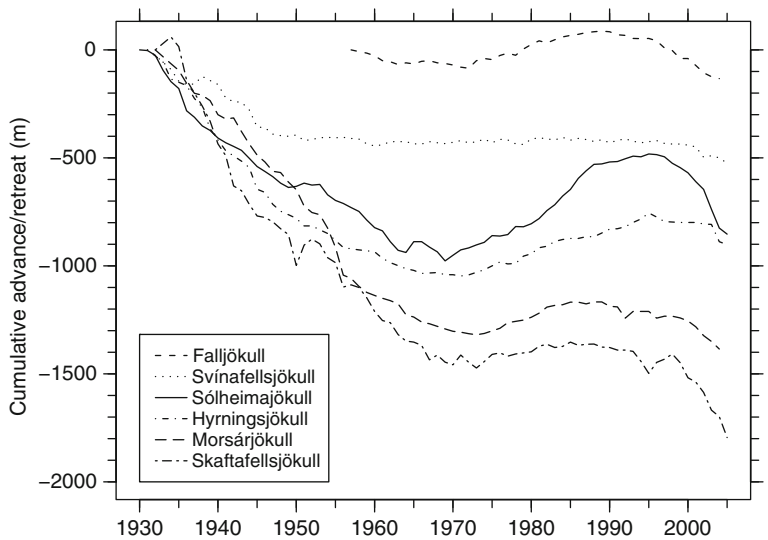
glacier front variations, a project that was continued by the Iceland Glaciological Society since it was founded in 1950 (Figures 3 and 4) (Eythorsson, 1963; Sigurðsson, 1998; Jóhannesson and Sigurðsson, 1998; Sigurðsson, 2006). During the first decade of the twenty-first century the glacier surface area has decreased on the average by about 20–30 km^2 (0.2–0.3%) per year, and by about 0.4% in thickness according to mass balance measurements (Sigurðsson, 2006). According to models of mass balance Icelandic glaciers will essentially disappear during the next two centuries if global warming continues as expected. The discharge of glacial rivers will increase accordingly (Jóhannesson et al., 2007).

Outlines of all Icelandic glaciers have been traced recently from conventional vertical aerial photographs, Landsat 7 and SPOT-5 images (http://gullhver.os.is/website/hpf/orkustofnun_english/viewer.htm) and the interpretation of the location of the outlines has been verified by oblique aerial stereo photographs.

The terminus of non-surge-type glaciers in Iceland usually reacts to change in mass within 1–3 years (Figure 3) (Sigurðsson, 2006). This is independent of the glacier size



Iceland Glaciers, Figure 3 Annual variations of the terminus of Sólheimajökull outlet glacier compared with mean summer temperature in Stykkishólmur, western Iceland (5-year running mean). (Updated from Sigurðsson, 2006).



Iceland Glaciers, Figure 4 Cumulative front variations of six non-surge-type outlet glaciers since 1930. (Courtesy of International Glaciological Society).

(Sigurðsson et al., 2007). Surge-type glaciers react in a different way as explained below.

During the twentieth century glaciers in Iceland retreated approximately as far as they advanced from 1600–1900 (Sigurðsson, 2005). Glaciers retreat in proportion to their length. The largest glaciers have retreated about 4–5 km during the twentieth century but the small mountain glaciers of northern Iceland have retreated only on the order of 100 m. Cirque glaciers that are covered by debris in the ablation area have decreased very little in length. A few of the smallest glaciers have disappeared entirely, leaving only remnants of ice-cored moraines.

Surge-type glaciers

Inherent differences among individual glaciers or outlet glaciers may affect the reaction of glacier termini to mass balance. In particular, it is important to distinguish between non-surge-type glaciers and surge-type glaciers. The common feature of surge-type glaciers is that they do not maintain balance velocity for steady state transport sufficient to stay in balance. This results in a gradually increasing surface gradient which inevitably results in a period of faster flow. This may evolve into a surge. Why some glaciers do not maintain balance velocity has not yet been adequately explained.

Quite a number of glaciers in Iceland have been identified as surge-type (Figure 1). They range in size from small cirque glaciers less than 1 km^2 in area (Figure 2) up to the largest outlet glaciers in Iceland, which measure about 1,500 km^2. Their average surface slope ranges from 1° to 13° (Björnsson et al., 2003).

The surges seem to have very little relation to climate changes and, therefore, surge-type glaciers cannot be used as an indicator of climatic conditions.

Climatic and non-climatic factors that affect mass balance

The two principal climatic factors governing the waxing and waning of glaciers are:

- Precipitation during the winter
- Temperature during the summer

In addition to surges several non-climatic factors can affect the mass balance of glaciers. In many locations onset of calving into lakes formed at a retreating ice margin ablates a substantial volume of ice in addition to the climate-related ablation. While calving, glaciers may not reach equilibrium with the climate or the equilibrium is offset.

Glacier surfaces in Iceland can become covered with debris by several means:

- Medial moraines
- Debris from the head wall of cirque glaciers that melt out in the ablation area (Figure 5)
- Landslides or rockslides from the side slopes
- Volcanic eruptions

Except when this layer is very thin (a couple of mm) the debris inhibits melting and thus affects the mass balance and the variations of the terminus.

Subglacial volcanic eruptions in Iceland occur on the average about 10 times per century (Larsen et al., 1998). The melting that results from such an event can be anything from negligible to huge in comparison with the volume of the glacier. Some of the historic eruptions of Katla volcano in Mýrdalsjökull ice cap are assumed to have melted several cubic kilometers of glacier ice in one eruption (Tómasson, 1996). This equates to several years of greatly negative mass balance, which has led to substantial retreat of the glacier terminus.

Iceland Glaciers, Figure 5 Kvarnárjökull northern Iceland is a cirque glacier covered by debris in the ablation area. (Photo by Oddur Sigurðsson).

Geothermal activity has considerable effect on the mass balance of several glaciers in Iceland. In some cases the geothermal activity creates a permanent cauldron in the glacier surface that funnels all precipitation in its vicinity through a sinkhole to the base of the glacier (Figure 6). From there the water discharges subglacially to the margin of the glacier. The area around the cauldron, confined by ice divides on all sides, can be considered as a glacier without terminus and exceeds 100 km^2 in the case of Grímsvötn (Björnsson, 1988).

Mass balance of glaciers

Continuous monitoring of mass balance of glaciers in Iceland started in 1988 (Björnsson et al., 2002; Sigurðsson, 2006). The measured glaciers have had negative mass balance every year since 1995. These measurements show that the variations of the summer balance are much greater than the variations of the winter balance. Therefore, the mean summer temperature, which is the main driver of summer balance, is mostly responsible for the annual variations of glaciers in the country.

During the measurement period glaciers in Iceland have on the average lost 0.5 m or more of their thickness per year. The highest net balance value for a single ice flow basin was positive ~1.7 m for Dyngjujökull outlet glacier in the year 1991–1992 and the lowest value was negative

Iceland Glaciers, Figure 6 Geothermal cauldrons in Vatnajökull ice cap by Pálsfjall nunatak. (Photo by Oddur Sigurðsson).

2.2 m for Eyjabakkajökull outlet glacier in 1996–1997 (Björnsson et al., 2002).

Airfall of volcanic ash on a glacier surface will in most cases increase ablation considerably due to decreased albedo but only during 1 year. This is because in the accumulation area snow will quickly bury the ash layer and in the ablation area the layer will be washed away.

Historical information contained in the glaciers of Iceland

Precipitation is heavy in Iceland, making the turnover of the glacier mass particularly high. The oldest ice in an Icelandic glacier is about 1,000 years old (Larsen et al., 1998); glaciers therefore contain material deposited continuously through the nation's entire history and they can shed light on how climate has varied during that time. The volcanic history is also well preserved in the stratigraphy of the ice. All glaciers in Iceland are temperate, which means that they are at the pressure-freezing point from bottom up. As a result, liquid water is to be found throughout. All soluble chemicals are, therefore, dispersed through the glacier body. However, dust layers, which form every summer on the glacier surface, and layers of volcanic airfall will keep their place in the stratigraphy.

The chemical fingerprint of volcanic tephra layers can be analyzed and traced to the volcano of origin (Figure 7). Through historical records, many of the volcanic eruptions can be dated to a specific year (Larsen et al., 1998). Thus, the age of the ice containing the tephra layers can be determined.

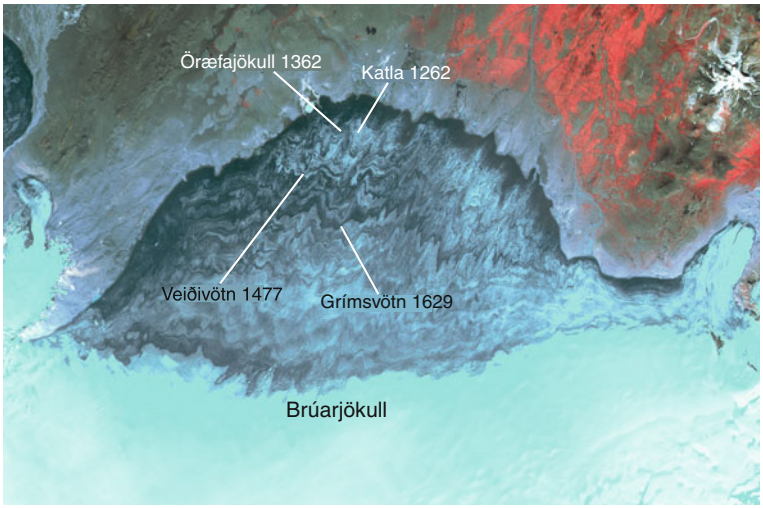
Jökulhlaup

Ice-dammed lakes, either subglacial or at the glacier margin, are common in Iceland. Periodically these ice dams fail, either suddenly or with a gradual exponential increase (Björnsson, 1988; Björnsson, 2009b). In either case, the result is a dramatic release of water from behind the dam, called *jökulhlaup* in Icelandic. As the phenomenon is more common in Iceland than any other place in the world, "jökulhlaup" has been adopted into the international terminology of glaciology. On the average about 5–10 jökulhlaups will occur each year in Iceland. On the order of 10 jökulhlaups per century will exceed 10,000 m^3s^{-1} in discharge and usually at least one per century will exceed 100,000 m^3s^{-1} (Sigurðsson and Einarsson, 2005).

The most catastrophic jökulhlaups are induced by subglacial volcanic eruptions. Substantial parts of the neovolcanic zone in Iceland are covered by thick glaciers so eruptions can occur at places with several hundreds of meters of ice overburden. The jökulhlaup associated with the 1996 Gjálp eruption within Vatnajökull is a prime example (Snorrason, et al., 2002). The energy required to melt the 3.2 km^3 of ice during the eruption was 10^{18} J or equivalent to 10,000 atomic bombs like the one that exploded in Hiroshima in 1945. The maximum discharge of the resulting jökulhlaup amounted to about 50,000 m^3/s, which is roughly the same as the discharge of the second largest river in the world, the Congo River. About 750 km^2 were inundated during the jökulhlaup. Katla volcano, which lies beneath the Mýrdalsjökull ice cap, usually produces the largest and most devastating jökulhlaups. In historical time it has averaged two eruptions per century. The maximum discharge of Katla jökulhlaups has exceeded that of the Amazon River, which is the largest river in the world. Katla last erupted in 1918; statistically the next eruption should be expected any time.

Summary

Glaciers constitute 11% of the area of Iceland. About 20% of the total precipitation falls on the glaciers. The outlines



Iceland Glaciers, Figure 7 Undulating lines of volcanic tephra (information from Larsen et al., 1998) can be identified even on satellite images. IRS satellite image of Brúarjökull outlet glacier in Vatnajökull ice cap 1998.

of about 280 glaciers have been identified and mapped in the country, most of them mountain glaciers in the northern districts but the main area and volume lies in the five major ice caps. Glaciers have posed great hazards to human populations historically by advancing over inhabited districts and causing jökulhlaups (glacier outburst floods) that have inundated hundreds of square kilometers in various districts of the country. In postglacial time glaciers had their minimum about 7000 BP when they were limited to the very highest mountains. Records of advancing glaciers go back to the fourteenth century and they advanced more or less continuously to about 1890. During the last century, glaciers have lost volume and retreated accordingly particularly during the second quarter of the twentieth century and again, even faster, at the turn and the beginning of the twenty-first century. The glacial discharge has increased as a result. Rivers have gathered in fewer courses as glaciers retreated. A few small mountain glaciers have vanished entirely during the last century. The vast majority of Icelandic glaciers are expected to disappear during the next two centuries if current warming trends continue.

The ICESat mission

The Ice, Cloud, and land Elevation Satellite (ICESat) mission, launched in January 2003, has been an exceptional new tool for laser exploration of the planet – measuring the Earth's surface and atmosphere in unprecedented three-dimensional detail. ICESat's measurements have proven the unique capability of spaceborne laser altimetry for a variety of advances in Cryospheric and Earth Sciences.

ICESat's instrumentation was designed to make accurate measurements of surface and near-surface elevations with a 1,064-nm laser channel. Return signals are digitized to provide unprecedented detail of the height distributions of the surface and near-surface (e.g., trees) and vertical distribution of backscatter from the atmosphere. ICESat is in a 600-km orbit with an inclination of 94°. The agile spacecraft control system directs the laser beam to reference ground tracks over the ice sheets to within 100 m, enabling close repeat tracks for elevation change detection, and to targets of special interest up to 5° off-nadir.

Although initially intended to run continuously for 3–5 years along a 91-day repeat orbit, unforeseen manufacturing defects caused significant reduction in the laser lifetime. A revised operation plan called for 33-day observation periods conducted three times per year. In 2007, this strategy was further revised to twice-yearly 33-day campaigns in March/April and October/November. To date, ICESat has completed 16 operations periods.

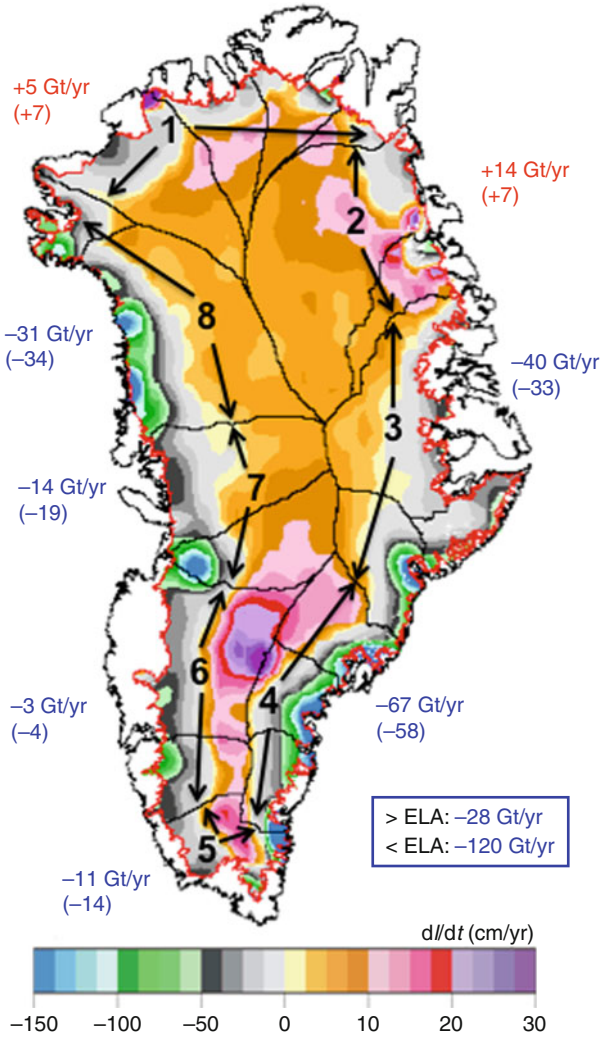
The 2-cm precision of ICESat's satellite-to-surface range is five times better than designed, making it very valuable for monitoring sea ice and for other applications. The accuracy of radial orbit determinations is about 2–3 cm. The achieved accuracy of ice surface elevations is 10 cm for individual point measurements over surfaces with low slopes, increasing to 20 cm over surfaces with 2° slopes.

Glaciological research highlights include mapping elevation changes of the Greenland and Antarctic ice sheets and mass-loss estimation; discovery of subglacial water drainage/transfer under West Antarctic ice streams; precision mapping of ice-shelf grounding lines; and seasonal and interannual changes in sea-ice thickness distribution. ICESat data is used to derive important information about the interactions between ice sheets and climate that is needed to develop models to assess ice sheet behavior as the climate changes as well as the associated sea-level contributions from this change. The ability to do this is greatly enhanced by measurements over a long duration.

Elevation change and mass balance of the Greenland ice sheet

Using knowledge of the precise location of ICESat and the laser footprint on the Earth's surface, the elevation of the surface can be determined. Elevation changes (dH/dt) presented here are derived from 12 sets of 33-day repeat tracks over 4 years (October 2003 to November 2007). The along-track analysis techniques to obtain reliable dH/dt results are described elsewhere (Zwally et al., Journal of Glaciology). Briefly, the elevation change along each ground track depends on the surface slope and the cross-track separation of the repeated passes (nominally 100 m), as well as the change in surface elevation with time ($H(t)$). This requires solution of the equation $H(X, \alpha, t) = X \tan \alpha + t\ (dH/dt)$ for dH/dt and the surface slope (α). Because of the limited number of passes, it is necessary to assume that dH/dt is constant with time and that there is no seasonal cycle. At each along-track point (separated by 172 m), at least four passes of the 12 repeats are needed to solve for both α and dH/dt. Error analysis (Zwally et al., Journal of Glaciology) demonstrates that the accuracy improves to about ~20 cm/year over surface slopes less than about 2° with data from 10 or more passes. Some data gaps are due to the higher frequency of clouds near the edges of the ice sheet, which prevent the transmission of the laser pulse. Continuing ICESat's 33-day repeat tracks in campaigns through winter of 2011 will provide five more opportunities for additional coverage and eliminating these gaps. Here, we highlight studies of mass loss from the Greenland ice sheet.

ICESat ice-thickness change (dI/dt) results for the Greenland ice sheet from 2003 to 2007 are shown in Figure 1 along with the derived estimates of mass change (dM/dt) from major drainage systems (Zwally et al., Journal of Glaciology). To obtain dI/dt, the measured dH/dt is adjusted for bedrock motion and the time–variable firn compaction (dC/dt). The firn compaction adjustment (Li et al., 2007) has become critically important because of increasing temperatures in Greenland that are increasing the rate of compaction. The dI/dt map shows detailed patterns of thickening and thinning, with thickening occurring most at the higher inland elevations. Although the



ICESat Data in Glaciological Studies, Figure 1 Mass loss estimates of the Greenland ice sheet are obtained from this ICESat-derived map of ice-thickness change (d*l*/d*t*) for 2003–2007. Mass gains and losses for each of the major drainage basins 1–8 (indicated by *black arrows*) are shown, along with the changes (in *parenthesis*) relative to values for the period 1992–2002 obtained from ERS radar altimetry and aircraft laser measurements. The ice sheet continues to thicken inland, as it did in the 1990s, but thinning at the margins has increased significantly due to increased summer melting and acceleration of outlet glaciers (Zwally et al., Journal of Glaciology).

lower elevations along the coast have a mixed pattern of thickening and thinning, areas of thinning are dominant. Compared to results for the 1990s from a combination of airborne laser surveys (Krabill et al., 2000) and satellite radar altimetry (Davis and Sun, 2004), the inland thickening at elevations above ~2,200 m has not changed. However, at lower elevations, the thinning has increased markedly, especially below the equilibrium line altitude (ELA). Zwally et al. (Journal of Glaciology) derive d*M*/d*t* by determining the average density associated with the elevation change; it is a combination of ice loss and change in firn compaction through time. The net mass loss has increased to 148 Gt/year from close to zero loss in the 1990s, with the loss below the ELA increasing from only 42 Gt/year to 120 Gt/year due to increased melting near the margins and accelerating outflow of some glaciers. Increasing losses are largest in the southeast and along the western margin, with small increases in the north perhaps indicative of increasing precipitation. The net contribution to global sea-level rise from the Greenland ice sheet is now about 0.4 mm/year.

Subglacial hydrology

To study "active" subglacial lakes, ICESat exploits surface deformation that occurs as the ice surface above the lake rises and falls in response to water moving at the glacier bed. ICESat data along repeated tracks were used to reveal an active subglacial system in the Whillans, Mercer, and MacAyeal ice streams, East Antarctica (Fricker et al., 2007). This study showed the subglacial system is composed of several "active" lakes connected by inferred channels, with water rapidly transferring between reservoirs.

Using 4.5 years (2003–2008) of ICESat laser altimeter data, Smith et al. (2009) made a comprehensive study of active subglacial lakes for the entire Antarctic ice sheet and detected 124 active lakes during this period. They determined that ICESat-detected lakes not only exist under the ice divides in the slow moving parts of the ice sheets, but are also present under most of the largest outlet drainage systems that transport ice from the continent to the ice shelves and, ultimately, deliver it to the ocean. Lakes sometimes appear to transfer water from one to another, but also often exchange water with distributed sources invisible to ICESat, suggesting that the lakes may provide water to or withdraw water from the reservoirs that lubricate glacier flow. This proves the significance of the subglacial water system throughout Antarctica, which affects ice flow rates and can alter Antarctica's mass balance and contribution to sea-level rise (Fricker, 2008).

Ice shelves

Recent studies have depended on ICESat's sampling characteristics to improve our understanding of ice shelf variability and the processes affecting ice motion and stability, especially at the critical juncture of grounded and floating ice near the grounding line (GL). Science teams have used ICESat elevation data in a multi-instrument study of long-term trends and shorter-term (interannual) variability in the surface height of the Amery Ice Shelf (King et al., 2009). The time series spanned 4 decades and used datasets acquired through optical leveling, GPS, ERS-1, and ERS-2 satellite radar altimetry, and ICESat. Fricker and Padman (2006) used ICESat altimetry at crossovers on ice shelves to measure time variability of ice shelf surface height, including high-frequency

contributions from the tide and dH/dt trends from processes such as surface accumulation and basal melt. ICESat altimetry acquired along repeat tracks across the grounding zone (GZ) at different phases in the tidal cycle identified both the landward and seaward limits of this tidal flexure zone.

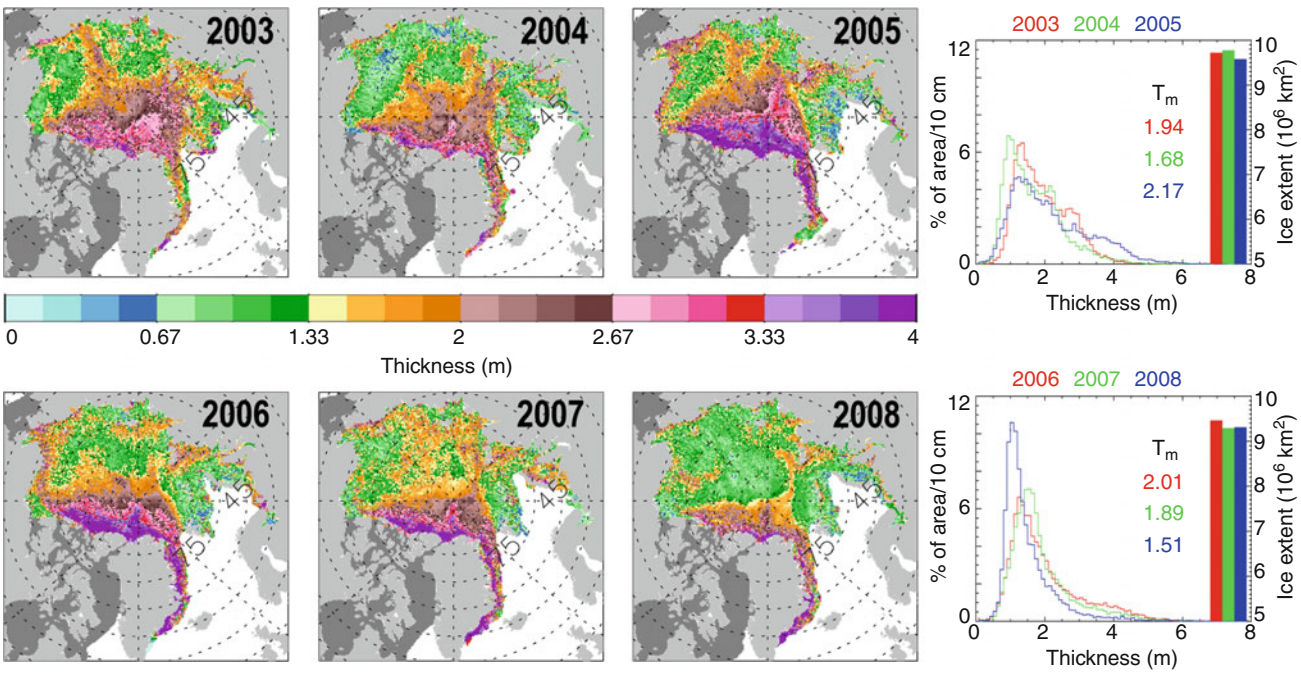
Knowledge of GZ extent and ice sheet thickness at the GL is required for ice sheet mass balance studies and to model ice-shelf/ocean interactions. ICESat is currently the only satellite capable of precisely locating the limits of flexure, by virtue of its high along-track resolution, and accurate ground track repetition. ICESat also provides accurate surface elevation data at the GL, from which ice thickness can be estimated. Comparisons between the landward flexure limit (the GL) and surface topography from MODIS imagery facilitates development of a detailed grounding-line data set beyond the intermittent coverage of the GL obtained from Interferometric Synthetic Aperture Radar (InSAR) (Fricker and Padman, 2006).

Smith and Joughin (2008) used an Antarctic DEM (Bamber et al., 2008) to calculate offshore ice mass flux and basal melt rate in the region of the GZ of northern Dronning Maud Land. Accurate knowledge of the surface elevation is critical in these areas, because the surface height of floating ice is used in calculating the ice thickness. This, combined with measurements of surface velocity, gives the rate of ice discharge into the ocean and the basal melt rate at the grounding line. Because of ICESat's small footprint, the data are uniquely able to resolve the sharp change in surface slope that is frequently found near the GL. The ICESat profiles revealed a systematic bias in the 5-km region around the GL in the DEM, which would have led to errors in the ice discharge rate of up to 15%, and severe overestimates of the basal melt rate near the GL.

ICESat data have been used to study processes related to ice shelf break-up. Elevation profiles across drifting icebergs were used to look at iceberg calving and ice shelf break-up processes by proxy (Scambos et al., 2008). A fortuitous acquisition along a ground track across Wilkins Ice Shelf on February 28, 2008, during the period of active break-up (Scambos et al., 2009), provided quantitative information about the disintegration mechanism.

Sea ice

Farrell et al. (2009) used data from ICESat to analyze sea ice freeboard in the Arctic Ocean. Using knowledge of the local sea surface height and sea ice elevation, they estimated sea ice freeboard and presented a time series of Arctic freeboard spanning 5 years between 2003 and 2008. ICESat data from fall (October–November) and winter (February–March) illustrate the seasonal and interannual



ICESat Data in Glaciological Studies, Figure 2 A significant decrease in the average wintertime thickness from about 2–1.5 m is derived from ICESat's measurements of sea ice freeboard heights for the February–March observation periods from 2003 to 2008. Much of the thicker multiyear (MY) ice located north of Canada and Greenland has disappeared. In October after the summer melt season, the average ice thickness decreased by about 25% while the areal extent decreased by a similar amount giving a volume loss of about 50% in only 5 years. Measurements of ice thickness changes are critical to understanding when the Arctic Ocean may become ice free in summer (based on Kwok et al., 2009).

variations in freeboard. Following the September 2007 record minimum sea ice extent, the fall 2007 and winter 2008 spatially averaged freeboards were below the seasonal means at −4.5 cm, and −6.8 cm, respectively. Over the observation period, mean freeboard has declined at a rate of approximately −1.8 cm/year during the fall period and approximately −1.6 cm/year during the winter period. Due to the short 5-year observation period, it is unclear whether these results represent a long-term, downward trend in Arctic freeboard or are part of a natural variability.

Kwok et al. (2009) present an estimate of the thickness and volume of the Arctic Ocean ice cover from ten ICESat campaigns that span a 5-year period between 2003 and 2008. Along with a more than 42% decrease in multiyear (MY) ice coverage since 2005, there was a remarkable thinning of ∼0.6 m in MY ice thickness over 4 years. In contrast, the average thickness of the seasonal ice in midwinter (∼2 m), which covered more than two thirds of the Arctic Ocean in 2007, exhibited a negligible trend. Average winter sea ice volume over the period, weighted by a loss of ∼3,000 km^3 between 2007 and 2008, was ∼14,000 km^3. The total MY ice volume in the winter has experienced a net loss of 6,300 km^3 (>40%) in the 4 years since 2005 while the FY ice cover gained volume due to increased overall area coverage (Figure 2). The overall decline in volume and thickness is explained almost entirely by changes in the MY ice cover. Combined with a large decline in MY ice coverage over this short record, there is a reversal in the volumetric and areal contributions of the two ice types to the total volume and area of the Arctic Ocean ice cover. In this period, seasonal ice became the dominant ice type. It seems that the near zero replenishment of the MY ice cover after the summers of 2005 and 2007 has played a significant role in the loss of Arctic sea ice volume over the ICESat record.

Summary

The Ice, Cloud, and land Elevation Satellite (ICESat) mission, launched in January 2003, has been an exceptional new tool for laser exploration of the planet – measuring the Earth's surface and atmosphere in unprecedented three-dimensional detail. ICESat's measurements have proven the unique capability of spaceborne laser altimetry for a variety of advances in Cryospheric and Earth Sciences. Glaciological research highlights include mapping elevation changes of the Greenland and Antarctic ice sheets and mass-loss estimation; discovery of subglacial water drainage/transfer under West Antarctic ice streams; precision mapping of ice-shelf grounding lines; and seasonal and interannual changes in sea-ice thickness distribution. ICESat data is used to derive important information about the interactions between ice sheets and climate that is needed to develop models to assess ice sheet behavior as the climate changes as well as the associated sea-level contributions from this change.

ICICLE

P. Pradeep Kumar
Department of Atmospheric and Space Sciences, Pune University, Pune, India

An icicle is a spike of ice formed when water dripping or falling from an object freezes. Typically, icicles will form when ice or snow is melted by either sunlight or some other heat source (such as heat leaking from the interior of a heated building), and the resulting melted water runs off into an area where the ambient temperature is below the freezing point of water (0°C), causing the water to refreeze. Icicles are mostly observed as hanging spike. They can form off building roof, from branches of trees, rocks near waterfalls, water seepage points, etc.

ICING

P. Pradeep Kumar
Department of Atmospheric and Space Sciences, Pune University, Pune, India

In general, the freezing of water on exposed surface can be called as icing. In the atmosphere, icing is usually associated with aviation. It occurs when the aircraft fly through clouds containing supercooled drops in clouds above freezing level. The rain striking the frame of the aircraft freezes on it and forms glace ice. Icing can also occur at seas when sea spray can freeze on the body of ships and boats.

IMPACTS OF SNOW AND GLACIERS ON RUNOFF

Sarah Boon
Department of Geography, University of Lethbridge, Lethbridge, AB, Canada

Synonyms

Nival and glacial runoff regimes

Definition

Effect of seasonal melt, water storage, and runoff from snow and glacier ice on discharge from snow-covered and/or glacierized basins.

Snow and ice extent

Seasonal snow cover has a maximum areal extent of 9% of the earth's surface, while glaciers cover ~10% (15×10^6 km^2) of the Earth's surface (NSIDC, 2008). In the Northern Hemisphere, peak snowpack extent occurs in January, north of 50° (Stewart, 2009). In the Southern Hemisphere, snowpack outside of Antarctica is confined to alpine regions of South America, Africa, and New Zealand. Glaciers and ice sheets are distributed at high latitudes and in lower latitude alpine regions of both hemispheres (Figure 1), and store >70% of global freshwater. Runoff production in mid- and high-latitude mountain ranges is influenced largely by seasonal snow cover, while glaciers are the dominant water source in low-latitude mountain ranges during the dry season (Hock et al., 2005). In arid and semiarid regions, snow- and icemelt can contribute more than 80% of annual streamflow (Viviroli et al., 2003). Approximately one-sixth of the global population lives in basins fed predominantly by snow- and icemelt (Barnett et al., 2005).

The water balance in snow- and glacier-covered regions can be written as:

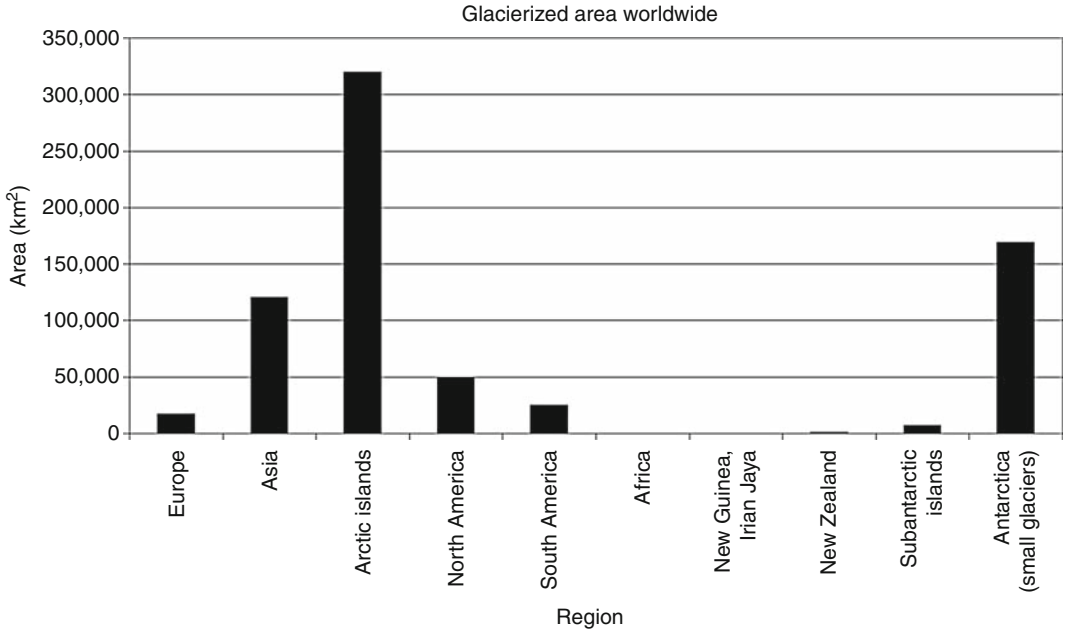
$$Q_{tot} = Q_s + Q_p + Q_i + Q_g + Q_l - Q_e \quad (1)$$

where Q_{tot} is the total potential runoff, Q_s is the snowmelt from ice-free areas, Q_p is the rainfall runoff, Q_i is the glacial contribution to discharge (including snowmelt from ice-covered areas), Q_g is groundwater discharge, Q_l is condensation of water vapor and Q_e is evaporation (Hagen et al., 2003). The latter three terms are often considered negligible.

The majority of research on snow and glacier runoff has been conducted in North America and Europe (Meier, 1969; Henoch, 1971; Krimmel and Tangborn, 1974; Fountain and Tangborn, 1985; Demuth et al., 2009), with far fewer studies in Central Asia (Hewitt and Young, 1993) and the Andes (Kaser et al., 2003; Casassa et al., 2009). Research in the Upper Colorado basin indicates that river flow is driven largely by seasonal SWE, with maximum discharge occurring in May or June (Fassnacht, 2006). Studies in the subarctic mountains of northwestern North America also note that snowmelt drives the majority of annual and peak runoff. In South America, tropical glaciers have been shown to provide the majority of dry season (May–September) runoff (Kaser et al., 2003). On Svalbard, north of mainland Europe, surface runoff from glacier snow and icemelt is slightly greater than that from snow accumulation alone, at 680 ± 140 mm/year (Hagen et al., 2003).

Snow- and icemelt

In contrast to pluvial systems, where runoff is a function of precipitation and evaporation, runoff production from snow- and ice-covered (nival and glacial, respectively) regions is a function of the net energy available for melt. This energy is derived mainly from incoming radiation. Radiative fluxes vary with latitude and altitude: for



Impacts of Snow and Glaciers on Runoff, Figure 1 Global glacier cover, by region. (Data from Dyurgerov and Meier, 2004.)

example, high latitude/low altitude (Arctic) basins receive continuous incoming radiation during the summer months, and thus have much different runoff response than low latitude/high altitude basins, which receive a diurnal cycle of incoming radiation (Hodson et al., 1998). The energy balance at the glacier surface is thus strongly affected by peak shortwave radiation inputs in midafternoon, resulting in subsequently high melt production. In tropical regions, however, low latitude/high altitude basins experience a fairly constant air temperature throughout the year, with changes only in precipitation (snow accumulation during the wet season, October–April) and sublimation (maximum during the dry season, May–September) (Kaser et al., 2003).

While shortwave radiation is the main driver of snow- and icemelt, melt energy is also derived from advection of heat from weather systems. For example, rain-on-snow events can accelerate snowmelt by transferring latent and sensible heat to the snowpack, reducing the snowpack cold content, and enhancing spring runoff peaks. Although this has largely been observed in maritime climates (e.g., Kattelmann, 1997), it can also occur in continental climates dominated by orographic precipitation generation (e.g., López-Moreno and García-Ruiz, 2004). The frequency and magnitude of regional pressure systems is thus highly significant for snow- and icemelt: high pressure systems with high air temperatures, clear skies, and high incoming radiation result in rapid melt and greater likelihood of rapid meltwater transfer to surface streams. Alternatively, low pressure systems with lower air temperatures and cloudy skies can reduce melt and delay runoff production. In some mountainous regions, föhn (chinook) events during the winter season, with their associated high wind speeds, high air temperatures, and steep vapor pressure gradients, can result in midwinter melt events and the possibility of melt contribution to winter streamflow (Hayashi et al., 2005).

Melt production is also strongly affected by the hypsometry (area-altitude distribution) of both the watershed and the glacier surface. In watersheds with relatively flat topography, melt is highly spatially synchronized given similar meteorological conditions across large spatial extents (Eaton and Moore, 2008). Melt is more desynchronized in watersheds with steep terrain, where air temperature and precipitation lapse rates are steeper and snowmelt at higher elevations is delayed. Melt production is greatest on relatively flat glaciers with high proportions of their mass in the ablation zone, as it is more likely that the annual snowline will retreat to the top of the glacier given this morphology. On steep glaciers, however, the corresponding steep temperature and precipitation lapse rates limit snowline retreat to the lower parts of the glacier except in years with above average energy inputs. Thus, these glaciers have a small proportion of their mass in the ablation zone and produce less melt.

Snow and ice runoff

Runoff generation from nival and glacial catchments is a function of basin hypsometry, total water available for melt, and the interaction between melt and intermediate storage locations prior to reaching the basin outlet (Young, 1982).

Flat watersheds with synchronized melt response can produce a large freshet peak of short duration. In steep terrain, the freshet peak may be of lower magnitude but

attenuated over a longer time period. As snowline retreats, runoff contributing area decreases and less permeable surfaces with lower albedos are exposed (Hodson et al., 1998), reducing hydrologic response.

Runoff volume from nival catchments is positively correlated with the water equivalent of snow (SWE) stored in the basin at the onset of melt, and the air temperature during the melt period. Snowpack is a natural storage reservoir for cold-season precipitation, releasing water to streamflow during the warmer months as a spring runoff peak, or freshet. As the melt season progresses and snowline retreats, the amplitude of the diurnal signal decreases and runoff becomes less responsive to temperature (Lafrenière and Sharp, 2003). SWE amounts drive the timing and magnitude of freshet: low SWE produces an earlier runoff peak than high SWE, and can result in faster melt and increased likelihood of flooding (Stewart, 2009). Research to measure spring snowpack for downstream flood management has been under way since 1909, when engineers in Nevada correlated water levels in Lake Tahoe with snow water content on nearby Mount Rose (Male and Gray, 1981). Further research by the US Army Corps of Engineers (1956) and Kuzmin (1961) forms the basis for current studies of snowmelt and runoff. In mountainous watersheds, up to 90% of snowmelt goes to runoff, indicating that upland snowpacks are critical to downstream systems. For example, in the western USA, spring/early summer snowmelt runoff accounts for 50–80% of the total annual runoff for snowmelt-dominated basins (Stewart et al., 2004).

While runoff from non-glacierized basins is correlated with precipitation (snow or rainfall) and evaporation (Collins, 2008), runoff from glacierized basins is highly correlated with summer air temperature and net radiation: as percent glacier cover in a watershed decreases, the correlation between runoff and annual precipitation increases (Meier, 1969; Krimmel and Tangborn, 1974; Meier and Tangborn, 1961; Meier, 1973; Chen and Ohmura, 1990). The glacial outflow hydrograph is similar to that of nival basins given the effect of significant snow cover. However, snow cover persists longer on glacier surfaces than on surrounding terrain, resulting in delayed snowmelt contributions to streamflow, followed by late-season glacier melt once the ice surface is exposed (Collier, 1958). Glacial runoff regimes are therefore characterized by a later maximum runoff peak than nival catchments (Figure 2) (Fountain and Tangborn, 1985) followed by augmentation of late summer streamflow (August/September), with higher winter baseflows (Fleming and Clarke, 2005). As the percentage of ice-covered area in a watershed increases, the proportion of runoff occurring during May–September increases (Figure 3). Interannual (2–3 years) variability in glacial runoff decreases with increasing fractional glacier cover (up to ~30–40% cover) given the mutual buffering of runoff variability between ice-free and glacierized portions of the catchment (Figure 4) (Henshaw, 1933; Collins and Taylor, 1990; Fleming and Clarke, 2005). Warm/dry years with low snow accumulation result in earlier snowline retreat and glacier ice exposure, leading to increased glacier melt that compensates for reduced snowmelt from ice-free areas. During cold/wet years, glacier melt decreases and snowmelt runoff from ice-free areas increases given greater precipitation amounts and reduced evaporation, maintaining total streamflow but reducing the proportion of glacial contributions.

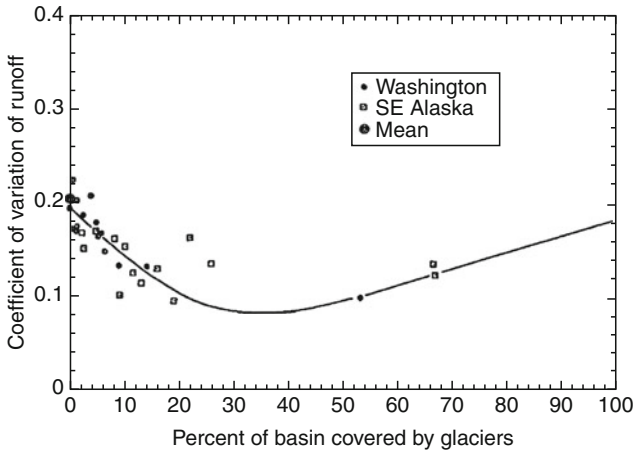
Impacts of Snow and Glaciers on Runoff, Figure 3 Time of peak specific runoff as a function of glacier cover for basins in the North Cascades, Washington. (From Fountain and Tangborn, 1985.)



Impacts of Snow and Glaciers on Runoff, Figure 4 Coefficient of variation of annual specific runoff values versus percent of basin glacierized. (From Fountain and Tangborn, 1985.)

Basin outflow hydrographs integrate the physiographic, climatic, and storage characteristics of basins fed by snow- and glacier melt. During the melt season, the rising limb of the hydrograph is driven by the melt rate while the recession limb is a function of basin storage characteristics. Recession analysis of discharge hydrographs over time can thus explain the storage characteristics of snow- and glacier melt-dominated basins.

In nival watersheds and the snow-covered portions of glacial watersheds, the lag between snowmelt onset and runoff production is initially a function of meltwater storage within the pore spaces of the snowpack. Once the snowpack cold content has been removed and its liquid water holding capacity maximized (US Army Corps of Engineers, 1956), meltwater is released to runoff. The time delay between meltwater production and release from the snowpack is a function of snow depth, and to a lesser extent the slope of the underlying terrain – steeper slopes allow for faster runoff than shallower slopes (Male and Gray, 1981). Meltwater runoff from the snowpack is then routed to soil moisture storage. If the soil is either frozen or saturated, the time lag for snowpack runoff to reach the stream is fairly short. However, the presence of unsaturated, unfrozen soils requires several days to reach saturation, thus increasing the time required for snowpack runoff to reach the stream. The final storage location is in-stream, as runoff from the snow-covered contributing area is transported to the watershed outlet (Male and Gray, 1981). This storage is a function of the standard in-stream water balance including bank flow, hyporheic exchange, and groundwater recharge.

In glacial watersheds, recession trends in the outflow hydrograph following exposure of glacier ice by the retreating snowline are caused by the presence of internal glacier structures delaying meltwater release. Glacial runoff is affected by storage processes at three temporal scales: daily, seasonal, and annual to decadal (Jansson et al., 2003). At the daily scale, short-term storage produces diurnal fluctuations in runoff. Short-term storage locations include the supraglacial snowpack and the glacier firn layer, which is a highly effective meltwater reservoir that affects the timing of runoff throughout the year, but has a minimal impact on total runoff (Fountain, 1996; de Woul et al., 2006).

At the seasonal scale, intermediate storage affects discharge patterns as melt is routed to runoff through the glacier drainage system. The effect of en- and subglacial storage is a function of the character of both glacier geometry and the glacier bed (Flowers, 2008). Adverse bed slopes, very thick or very thin ice, and short glaciers result in slow meltwater transport to runoff, as do the presence of many surface depressions and ice seams where meltwater can collect in glacier surface storage prior to flowing to runoff. Subglacially, a hard bed routes meltwater to runoff more quickly than a porous bed. These storage locations can reduce glacier contributions to streamflow during critical late summer low flow periods in high melt years (Hopkinson and Young, 1998). Meltwater stored over winter often contributes to the next summer's discharge (Tangborn et al., 1975), representing a lengthy delay between melt production and runoff generation.

At the annual to decadal scale, long-term storage changes control the net basin water balance. This is largely related to glacier mass balance fluctuations in response to large-scale atmospheric circulation, which are driven by precipitation and air temperature (Moore and Demuth, 2001). For example, the shift in the Pacific Decadal Oscillation (PDO) in 1976–1977 from a negative to a positive phase significantly affected streamflow in six southeastern Alaskan streams (Neal et al., 2002). The nival streams saw an increase in winter flows and a decrease in summer flows, as a greater proportion of winter precipitation fell as rain and thus contributed to streamflow during winter rather than being stored in the snowpack and contributing to spring streamflow. The glacial stream, however, showed an increase in all seasonal flows, likely due to an increase in glacier melt. Broadly similar responses have been found in relation to the effects of the Arctic Oscillation (AO) and the El Niño-Southern Oscillation (ENSO). In northwestern North America, positive AO years are associated with warmer spring–summer conditions, resulting in an earlier freshet in nival rivers with little change in the annual mean flow, but higher melt production in glacial rivers yielding overall yearly flow increases (Fleming et al., 2006). In the Western Cordillera, the 1997–1998 El Niño event caused increased flow in a glacier-fed river and decreased flow in a nearby nival river due to both low snow accumulation and enhanced glacier melt resulting from early snow disappearance (Lafrenière and Sharp, 2003).

Glacier runoff is also affected by episodic discharge events such as jökulhlaups, which occur when glacier runoff forms unstable lakes behind ice- or moraine dams (Clarke, 1982; Blown and Church, 1985). When these dams fail, the flood wave moves downstream, causing

significant destruction. Glacial outburst floods are an annual occurrence in catchments in northwestern British Columbia, southwestern Yukon and southeastern Alaska, and occur frequently in the Andes and Central Asia.

Climate change impacts

Climate change in snow- and icemelt-dominated regions is expected to result in increased air temperatures, particularly in the late winter and early spring, and increased precipitation, with a greater proportion at low- to mid-elevations falling as rain than snow (Mote et al., 2005). Global snow-covered area will also decline. These changes have already advanced the timing of spring freshet and reduced its magnitude in several regions of North America and Europe (e.g., Burn and Hag Elnur, 2002), thus reducing streamflow during the later part of the summer season. The opposite is seen in glacial flow regimes, where climate change increases glacier contributions to runoff during the summer season, due largely to glacier thinning. Climate change also reduces the extent of the glacier firn reservoir, reducing diurnal storage of meltwater. Once glacier thinning shifts to reductions in glacier extent, however, the glacier often becomes too small to contribute significantly to runoff – at which point runoff begins to decline. Glacierized basins in British Columbia and Alberta (North America), and basins with moderate to low glacierization in the European Alps have already passed this critical threshold extent, thus negating their ability to attenuate late-season streamflows (Stahl and Moore, 2006; Collins, 2008; Casassa et al., 2009). Others in the Yukon and Alaska (North America), Central Asia, the Andes, and highly glaciated basins in the Alps are still in the stage of increasing contributions to streamflow (Fleming and Clarke, 2005; Casassa et al., 2009), and will begin to reduce their contributions over the next few decades.

New directions

Groundwater/melt interactions

Recent research has shown that Q_g may be more important in the mountain water balance than previously thought, indicating the importance of quantifying the role of groundwater (subglacial, talus/moraine, subsurface) in snow and glacier melt-dominated systems. Results challenge the widely held assumption that runoff from mountain landscapes is initially snowmelt dominated, followed by glacial- and then groundwater-dominated flow (Liu et al., 2004; Brown et al., 2006b; Hood et al., 2006; Flowers, 2008; Roy and Hayashi, 2009). Flow separation has indicated that both quick flow and groundwater recharge are fed by snowmelt, resulting in runoff signatures from snowmelt in both rapid and slow response waters (Brown et al., 2006a). Groundwater may therefore play an important role in modulating streamflow response to snow- and icemelt, thus reducing variability in the melt signal and reducing effects on downstream systems.

Ecology and snow/glacier-melt dominated streamflow

New research is under way to assess the effects of snow- and glacier melt on river ecology. Results suggest that seasonal fluctuations in meltwater production and storage affect stream temperature and associated ecological processes, and are thus critical in maintaining between-site and regional biodiversity of macroinvertebrates in melt-dominated rivers (Brown et al., 2007).

Summary

Snow and glaciers have a significant impact on runoff. Melt produced from snow and glaciers is a function of the energy available for melt from radiative and advective fluxes and basin hypsometry. This melt is routed to runoff through a range of short-, intermediate-, and long-term storage locations within the snowpack, within the glacier, and within the watershed itself. Nival flow regimes are characterized by a spring runoff peak (freshet), with glacial flow augmenting runoff in the late summer (August–October). Nival and glacial basins have opposing responses to changing climate and atmospheric circulation, as glaciers constitute a larger storage than the snowpack on a seasonal timescale. Continuing climate changes are leading to shifts in the timing and magnitude of runoff from nival and glacial basins, with subsequent concerns regarding impacts on groundwater and ecohydrology in these regions.

INTERCEPTION OF SNOW

Manmohan Kumar Goel
Water Resources System, National Institute of Hydrology, Roorkee, Uttarakhand, India

Definition

When snow falls over a catchment, the whole of it does not fall directly on to the ground and contributes to runoff. A part of it may be caught by the vegetation. This part of snowfall is known as interception.

Precipitation falling on the vegetation may be retained on the leaves or blades of grass and evaporated back to the atmosphere (interception loss), may flow down the stem of trees to the ground (stem flow), or may fall off the leaves (through fall). Interception loss is solely due to evaporation and does not include transpiration, through fall, or stem flow.

The amount of interception in a basin during a storm is a function of the storm character, species, age and density of plants, and season of the year. Interception loss is large for small precipitation amounts and reaches to a constant minimum value for large storms. The total interception loss during a storm may be related to the storage capacity of the vegetation and the evaporation rate as:

$$L_i = S_v + R_i E t$$

where L_i is the total interception loss for the projected area of the canopy (mm), S_v is the storage capacity of vegetation for projected canopy area (mm), R_i is the ratio of the vegetal surface area to the projected area, E is the evaporation rate from the vegetal surface (mm/h), and t is the duration of precipitation (h). Interception process has significant impact on the water balance of a region. Usually, 10–20% of precipitation during the growing season is intercepted and returned to the hydrologic cycle through evaporation (Subramanya, 1991). Under very dense forest conditions, it may even be as high as 25% of the total precipitation.

Interception of snowfall by a vegetative canopy plays a major role in the snow hydrology processes. When snowflakes fall from the sky, small bridges form at narrow openings of the tree leaves and branches that increase the interception area of a tree. After the maximum holding capacity of a tree is reached, subsequent snow retention on a tree is roughly balanced by the loss of intercepted snow falling to the ground.

Snow interception by vegetation is affected by its mass, surface area, age, density, strength and flexure of branches, and configuration and orientation of leaves (Gray and Prowse, 1992). Since deciduous forests shed their leaves in winter, interception by coniferous forests is much greater than by deciduous forests. Meteorological factors also play an important role in the amount of snow interception. Subzero temperatures favor higher interception rates during storms. High winds reduce the amount of snow interception by disrupting the bridging process, vibrating the vegetation, eroding the intercepted snow, and by retaining snow particles in suspension.

The amount of intercepted snow continuously changes because of wind erosion, evaporation, sublimation, melting, and avulsion. It is difficult to quantify various components of the intercepted snow because of measurement problems and particular site-specific conditions (Gray and Prowse, 1992).

INTERFLOW

Manmohan Kumar Goel
Water Resources System, National Institute of Hydrology, Roorkee, Uttarakhand, India

Synonyms

Quick return flow; Storm seepage; Subsurface storm flow; Through flow

Definition

Interflow refers to that part of precipitation that infiltrates into the surface soil, moves laterally through the upper crusts of soil, and returns to the surface at some distance away from the point of entry into the ground.

When precipitation starts falling on a catchment area, some part of it is evaporated back to the atmosphere; some part is intercepted by the buildings, trees, shrubs, and other objects (known as interception); some part is infiltrated into the ground (known as infiltration); while some part finds its way to numerous depressions filling them to their overflow level (depression storage). Precipitation in excess of these storages starts building up on the ground before it can move laterally over the surface (detention storage). The runoff from precipitation commences after satisfying the evaporation, interception, infiltration, and depression and detention storage requirements of a catchment.

Interflow moves at shallow depths and reaches the surface channels in a relatively short time. Therefore, it is commonly considered as a part of the direct surface runoff. Depending upon the time delay between the infiltration and outflow, the interflow is also classified as prompt interflow and delayed interflow. Temporal distribution of interflow in a storm hydrograph is characterized by a slowly increasing rate up to the end of precipitation, followed by a gradual recession that terminates at the intersection of surface flow and base flow components.

The amount of interflow in a catchment depends on its geological conditions. If a pervious soil layer is underlain by a rock or hard surface in a catchment, then a large amount of interflow is expected. On the other hand, uniform permeable soil favors vertical passage of infiltrated water to the groundwater.

INTERNATIONAL POLAR YEAR 2007–2008

IPY 2007–2008

Definition and introduction

The international polar year (IPY) 2007–2008 was an intensive, internationally coordinated campaign of research and observations in both polar regions that took place mostly between March 1, 2007 and March 1, 2008. A large part of this research dealt with the ice and snow cover of the Arctic and Antarctica. IPY was cosponsored by the International Council for Science (ICSU) and the World Meteorological Organization (WMO). It included over 160 endorsed science projects assembled from the ideas of researchers in more than 60 countries and was supported by substantial new funding (estimated at more than US$400 million). This was coordinated with and supplemented the ongoing polar research and monitoring programs in many nations.

Previous International Polar Years

The IPY 2007–2008 built on more than a century of internationally coordinated study of the polar regions. The first IPY 1882–1883 was sponsored by the International Meteorological Organization (IMO), a predecessor of the WMO. The scientific goals of this program addressed geophysical phenomena that were beyond the capabilities of one nation alone. Twelve nations carried out 15 expeditions: 13 to the Arctic and 2 to Southern Ocean islands, resulting in important scientific advances and the exploration of new terrain. The first IPY set a precedent for international cooperation in natural science.

The second IPY was held in 1932–1933, also with the sponsorship of the IMO. It accomplished significant advances in meteorology, magnetism, atmospheric science, and the understanding of ionospheric phenomena. Forty nations participated in spite of the economic constraints of the 1930s Depression.

The International Geophysical Year (IGY), held between July 1, 1957 and December 31, 1958, was modeled on the earlier Polar Years, but covered the global domain. It was sponsored jointly by the ICSU and WMO, and brought together 67 nations. There was a considerable focus during IGY on Antarctic science and exploration, including establishment of a number of permanent Antarctic stations, the first estimates of the size of the Antarctic ice sheet, and the eventual negotiation of the Antarctic Treaty, a major geopolitical advance. Other accomplishments of IGY include the discovery of the Van Allen Radiation Belts encircling the Earth and confirmation of the theory of continental drift. The IGY took place at the height of the Cold War, but demonstrated that even in such tense times, scientists could collaborate internationally on projects of global significance.

Early development of IPY 2007–2008

An IPY 2007–2008, on the 50th anniversary of the IGY, was suggested independently by a number of scientists and organizations. In June 2003, the Executive Board of the ICSU established an IPY Planning Group charged with developing an IPY 2007–2008 science plan and

implementation strategy. This Planning Group consulted widely with the international research community in developing a framework for IPY (Rapley et al., 2004). The WMO, independently of the initial ICSU effort, also approved the concept of an IPY in 2003. In February 2004, it was agreed to merge interests and WMO became the cosponsor of IPY 2007–2008 (Figure 1).

The IPY Planning Group set four major goals for the program. These were:

- To make major advances in polar knowledge and understanding
- To leave a legacy of new or enhanced observational systems, facilities, and infrastructure
- To enthuse a new generation of polar scientists and engineers
- To elicit exceptional interest and participation from polar residents, schoolchildren, the general public, and decision-makers worldwide.

Scientific themes of IPY 2007–2008

The scientific issues that defined the themes of IPY 2007–2008 were determined by the broad polar science community in a process that was largely driven from the "bottom up." From this process, the IPY planning committee set six broad themes which were:

1. *Status*: To determine the present environmental status of the polar regions
2. *Change*: To quantify and understand, past and present natural environmental and social change in the polar regions; and to improve projections of future change
3. *Global linkages*: To advance understanding on all scales of the links and interactions between polar regions and the rest of the globe, and of the processes controlling these
4. *New frontiers*: To investigate the frontiers of science in the polar regions
5. *Vantage point*: To use the unique vantage point of the polar regions to develop and enhance observatories from the interior of the Earth to the Sun and beyond the cosmos
6. *Human dimension*: To investigate the cultural, historical, and social processes that shape the sustainability of circumpolar human societies, and to identify their unique contributions to global cultural diversity and citizenship.

International Polar Year 2007–2008, Figure 1 The logo of the International Polar Year (IPY) 2007–2008. The polar regions are clearly highlighted on the representation of the globe, a symbolic satellite orbit draws connection with the logo of the International Geophysical Year (IGY), and the human figure represents the inclusion of social and human science issues in IPY.

In November 2004, an ICSU/WMO Joint Committee for IPY was established with responsibility for overall scientific planning, coordination, guidance, and oversight of the program. This committee was supported by the IPY International Programme Office, based at Cambridge, UK. Over 900 expressions of intent were submitted as proposed IPY activities and, with guidance from the Joint Committee and the Programme Office, these were clustered into over 160 endorsed science projects and over 50 endorsed education and outreach activities. Effective data management leading to free and unrestricted data availability and education and outreach activities were two essential components of projects accepted as part of IPY. The scope of IPY defined by the endorsed science projects is described by Allison et al. (2007).

Endorsed IPY projects were required to obtain their own funding and logistic support and to be self-managed. While not all endorsed projects were eventually funded, there was considerable new support that resulted in a very substantial surge in polar science during the IPY.

IPY 2007–2008 activities and achievements

The full scientific legacy of IPY will evolve in the years and decades after the completion of the observational program. Already however, significant advances in scientific knowledge and understanding have begun to emerge.

New assessments of the state of the Greenland and Antarctic ice sheets were made which reinforced evidence that both the Greenland and the Antarctic ice sheets are losing mass and thus raising sea level, and that the rate of ice loss from at least Greenland is increasing. In both Greenland and Antarctica, a large part of the loss is due to increased ice outflow, and the potential for these ice sheets to undergo further rapid increase in ice discharge remains the largest unknown in projections of the rate of sea level rise. An internationally coordinated circum-Arctic survey also investigated the dynamics of the glaciers in that region that are decreasing in size in response to global warming.

International traverses across the interior of Antarctica resurveyed regions not visited for 50 years and collected ice cores for the study of climate change over periods from centuries to millennia. Collaborative airborne surveys, using sophisticated ice-penetrating radar and other geophysical systems, were used on a scale not seen since the 1970s to map characteristics of the ice and underlying bedrock over vast areas of Antarctica and Greenland. These new images of the ice sheet and the underlying terrain highlighted the presence of liquid water at the bed of the ice sheets and will be essential for producing accurate models to predict future changes to the ice sheets.

Intensive multi-ship surveys of both the Arctic and the Southern Oceans were made in support of IPY studies of oceanography, marine biodiversity, marine geophysics, and sea ice. During IPY, the summer minimum extent of Arctic perennial sea ice decreased by about a million square kilometers to its minimum extent since satellite records began. IPY expeditions recorded an unprecedented rate of ice drift across the Arctic basin, providing compelling evidence of changes in the Arctic ice–ocean–atmosphere system.

New evidence of the rate of global warming also came from the oceans. Data from robotic ocean profiling floats, instrumented marine mammals, and IPY research vessels confirmed that the Southern Ocean, and particularly the southern flank of the Antarctic Circumpolar Current, had warmed more rapidly than the global ocean average. In addition, the dense bottom water formed near Antarctica had freshened in some locations and warmed in others. The freshening is consistent with increased melt from the Antarctic ice shelves and ice sheet.

Pools of carbon stored in permafrost, which are larger than previously estimated, were identified during broad-scale IPY observations. These are perhaps more likely to reach the atmosphere as additional greenhouse gases as warming continues, although the patterns of permafrost change vary widely across the Arctic. Modeling studies completed during the IPY suggest that terrestrial permafrost degrades much faster than expected, and that gas hydrates in the seafloor can escape more easily to the atmosphere with decreasing sea ice extent. IPY research cruises along the Siberian coast observed substantial outgassing of methane from ocean sediments.

Summary

IPY 2007–2008 took place during a period of significant planetary change, change particularly evident in polar regions. It eventuated as the largest internationally coordinated planetary research effort in the past 50 years, engaging the intellectual resources of thousands of scientists, often from "nonpolar" countries. The IPY was a truly international and interdisciplinary endeavor that laid the foundation for major scientific advances in knowledge and understanding of the polar regions and their role in the functioning of our planet. New observational and analysis technologies (including both in situ and remote sensing) and novel system-level approaches were fundamental features of IPY science.

The rapid pace of scientific advance and our increasing awareness of mankind's impact on the Earth system as a whole suggest that research and data from this IPY will leave a lasting legacy in many fields of science, particularly in providing a clearer picture of what future changes may occur and what effects they may have.

INTERSTITIAL ICE

P. Pradeep Kumar
Department of Atmospheric and Space Sciences, Pune University, Pune, India

When ice is formed in narrow spaces between rocks or sediments in soil, it is called as interstitial ice. Interstitial ice zones are important in the permafrost in the cold regions. Interstitial means that it lies in between any two things or spaces.

INTRUSIVE ICE

Chelamallu Hariprasad
Centre for Studies in Resource Engineering, IITB, Powai, Mumbai, Maharashtra, India

Intrusive ice is defined as the ice formed from water injected into soils or rocks. Intrusive ice may form layers up to several meters in thickness as a result of pressurized water flow toward the freezing zone. The pressurized water

may be derived from groundwater flow beneath permafrost (open system), or arise from pore water expulsion ahead of a penetrating freezing front in saturated coarse sands and gravels. Expulsion of water results from the expansion that occurs as pore water changes phase from water to ice.

INVENTORY OF GLACIERS

Frank Paul
Department of Geography, University of Zurich, Zurich, Switzerland

Synonyms

Glacier inventory; Inventory of perennial snow and ice

Definition

An inventory of glaciers is a detailed compilation of topographic and morphometric data (e.g., size, length, elevation, aspect) about the individual glaciers in a larger region.

Historic background

An inventory of glaciers should provide quantitative information about the overall area covered by glaciers in a certain region (e.g., an entire country) as well as topographic details on individual glaciers. The latter implies that a glacier is defined in a physical sense, that its extent has been mapped in a cartographic sense, and that the perimeter of individual entities can be determined in a topological sense (ice divides, tributaries). These constraints imply that the compilation of glacier inventories is closely related to the state of cartographic and topographic surveying in a country as well as to the available knowledge on the physical nature of glaciers. For these reasons, initial assessments of overall glacier coverage had been made in the Alps. For the eastern part of the Alps, such a first inventory of overall glacier coverage was compiled by Richter (1888) and for Switzerland by Jegerlehner (1903). For some smaller regions, special glaciological maps exist from earlier times, but their limited cartographic quality limits possibilities to interpret them in a quantitative way (e.g., Kinzl, 1955; Kretschmer, 2002). However, for some individual glaciers or parts of them high-quality maps exist from the mid-nineteenth century (Brunner, 1988).

The main impetus for a worlwide inventory of glaciers came from hydrology. Large differences in the estimated total area of glaciers outside the two continental ice sheets Greenland and Antarctica were recognized in the 1960s. At a symposium on glacier mapping in 1965 this deficit was addressed and "the necessity of a new world inventory of glaciers based on recently surveyed maps" (Hoinkes, 1968) was discussed. The Commission on Snow and Ice decided one year later to establish a working group led by Fritz Müller to prepare guidelines for a "world inventory of perennial ice and snow masses on and beneath land surfaces" (Hoinkes, 1968) and a global effort to create a new glacier inventory was launched as part of the International Hydrological Decade (1965–1974). This initiative resulted in a set of guidelines (UNESCO, 1970; Müller et al., 1977) and a status report on the World Glacier Inventory (WGI) was published in 1989 (WGMS, 1989). The main purpose of the WGI was to obtain information on the distribution of surface area and ice volume of all glaciers outside the two ice sheets and to repeat a similar effort after a few decades to detect changes. However, it was realized that the original inventory method using aerial photography, topographic maps, and planimetry was too time consuming to keep up with the rapid changes that glaciers are experiencing.

The use of satellite imagery for glacier inventory creation was proposed by Howarth and Ommanney (1986). With the availability of 30 m resolution data from the Thematic Mapper (TM) sensor (launched in 1982), automated mapping of glaciers from multispectral bands became possible and related methods were developed (Automated Glacier Mapping). In combination with geographic information systems (GIS) and digital elevation models (DEMs), automated procedures allow the extraction of glacier inventory data (Paul et al., 2002). Within the framework of the Global Land Ice Measurements from Space (GLIMS) initiative a global network of regional centers was established, which map the glaciers in specified regions and provide the digital vector outlines and related further inventory information to the GLIMS glacier database (Raup et al., 2007). This database is steadily growing, all data are freely available, and change assessment from multitemporal datasets become possible. Several guideline documents have been created that help the analysts with the interpretation and delineation of glaciers (e.g., Rau et al., 2005; Raup and Singh Khalsa, 2007).

The World Glacier Inventory

The objectives of the WGI were threefold (cf. Müller and Scherler, 1980):

1. To increase the knowledge about the local, regional and global water cycle and balance
2. To serve as a database for practical purposes (e.g., fresh water resources, hydropower, irrigation, disaster prevention, and recreational facilities)
3. To provide data for the study of climatic processes and for monitoring climatic change

To fulfil the above objectives, it is required to compile a standardized dataset for each glacier that can be analyzed. Because the WGI was compiled during the 1970s and 1980s, data storage and processing was based on the possibilities of that time, i.e., Fortran and punch cards. As a consequence, the entries in the WGI have been organized in a fixed syntax of machine readable codes (Müller et al., 1977) and look-up tables provide the code for each attribute to be translated. The entries listed for each glacier include (cf. Hoelzle and Trindler, 1998): A unique code,

name, location (lon./lat., country), year of map/photo, size, length, aspect, various elevations (minimum/maximum/median), a classification scheme (type, front, profile, nourishment, activity, moraine) and, where available, additional data on the snow line (elevation, accuracy, date) or glacier thickness. From these entries a large number of additional glacier characteristics can be calculated using simplified schemes (Haeberli and Hoelzle, 1995) and assessments on a global scale were possible (e.g., Raper and Braithwaite, 2006).

However, the detailed information in the WGI is spatially incomplete and some highly glacierized regions have information about total area only (WGMS, 1989). An overview of the regions covered in the WGI with detailed information is shown in Figure 1. In some regions like Arctic Canada, the data were compiled but not entirely forwarded to the world data centers (Ommanney, 2009). In an attempt to fill some of these data gaps in the WGI and to extend, standardize and better describe the attributes, Cogley (2009) has prepared an extended version of the WGI called WGI-XF. This data set is closely related to the original WGI as the reference period (1970s to 1980s) and the way of geographic notation (coordinates of label points) is the same. As it is difficult or even impossible to use the point information for change assessment, the GLIMS glacier database also stores glacier outlines.

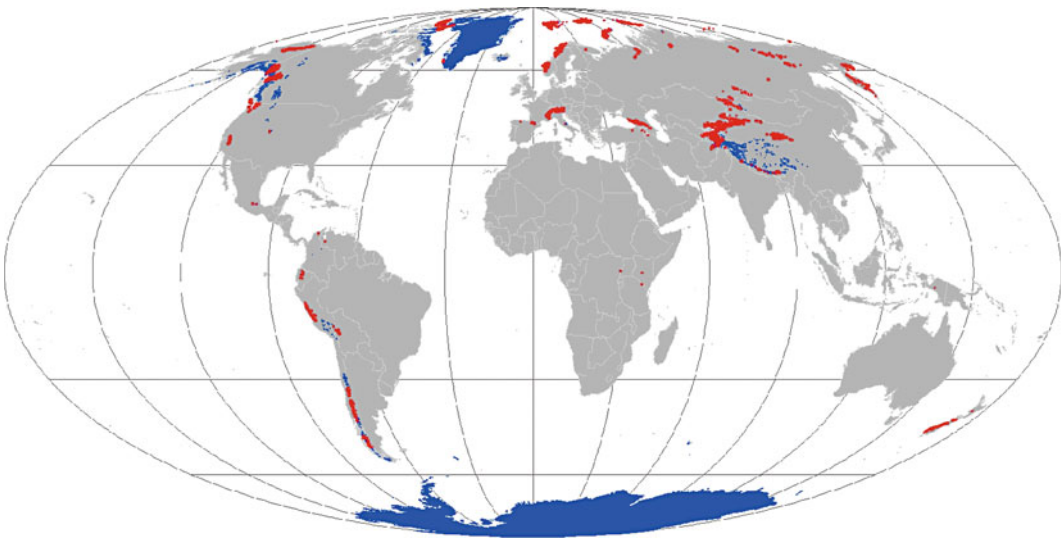
The GLIMS glacier database

The GLIMS glacier database can be seen as an update of the WGI regarding the temporal frame, but it is more an update of available technology as it is open to store also the information of the WGI when the data are made available in the required digital format, i.e., GIS compatible vector outlines (Raup et al., 2007). In principal, the source of the glacier outlines does not matter, but the use of satellite derived products is strongly encouraged (e.g., Haeberli, 2006) and the Advanced Spaceborne Thermal Emission and reflection Radiometer (ASTER) on-board the Terra satellite was specially programmed for glacier mapping (Raup et al., 2000).

The entries in the GLIMS database are comparable to those from the WGI, but the organization is somewhat more complex and special emphasis is given to consider the remote sensing nature of most data sets (see the webpage glims.org for details). When glacier inventory data are calculated automatically from digital sources (e.g., intersection of outlines with a DEM), they have a slightly different interpretation than in the WGI (Paul et al., 2009). For example, mean aspect refers in the WGI to the direction of the central flowline rather than to the mean of all cells a glacier is composed of. Moreover, the GIS-based calculations are reproducible and they can be standardized to a high degree. Apart from this, two further advantages of the digitally available datasets in the GLIMS glacier database are: a sound change assessment is possible as the calculation can be related to exactly the same glacier entities and corrections can more easily be applied to parts of the data when errors are detected.

Challenges

The main challenge for creating a glacier inventory is related to the correct interpretation of the available imagery (either from space-borne or aerial sources). This issue has a methodological component (e.g., which parts belong to a certain glacier?) and a practical part, which is related to the interpretation of regions with clouds, seasonal snow, debris cover, and low contrast (cf. Automated



Inventory of Glaciers, Figure 1 Data holdings in the WGI (*red*) compared to the ice cover (*blue*) in the digital chart of the world (DCW). The map was provided by M. Zemp from WGMS.

Glacier Mapping). These are the major sources of uncertainty and require careful consideration and expert knowledge during processing (e.g., Paul and Andreassen, 2009). When a direct comparison with a previous inventory is attempted, two issues have to be considered: At first, the used ice divides must be identical and secondly, the classified objects (glaciers versus perennial snow) should be the same.

The guidelines for the WGI state that all perennial snow and ice should be included in the inventory as the main purpose at that time was a hydrologic one (Müller et al., 1977). Today, an important purpose is a climatic one (i.e., glacier changes as indicators of climate change) and there is thus a focus on change assessment. As the location and extent of perennial snow is often controlled by local topography (e.g., avalanche deposits) rather than climate, they tend to be unchanged for decades (e.g., DeBeer and Sharp, 2009). This requires that they are treated separately in the inventory and have to be identified properly. Due to the difficulties in distinguishing seasonal from perennial snow, this is hardly feasible and it is recommended to map glaciers only, that is, with visible bare ice. Of course, this also decreases the comparability with previous data sets. Baseline imagery without seasonal snow would be optimal, but they are only rarely acquired in most parts of the world.

Outlook

The current entries in the GLIMS database already complement the WGI in previously uncovered regions (see glims.org for the recent coverage). It is expected that it might take some further years to have a globally complete and detailed glacier inventory. Existing and upcoming opportunities of globally available DEM data will help to make this dataset particular valuable. For instance, hypsographic information (area-elevation distribution of the ice cover) can be appended to each glacier which will greatly improve the calculation of the glacier contribution to global sea-level rise (e.g., Raper and Braithwaite, 2006; Hock et al., 2009).

INVERSE METHODS IN GLACIOLOGY

G. Hilmar Gudmundsson
British Antarctic Survey, Cambridge, UK

Definition

Inverse methods deal with the indirect estimation of parameters. When set of measurements (y) can be linked to the parameters to be estimated (x) through a function f, i.e., $y = f(x)$, then the inverse problem is that of estimating x given the measurements y and the function f. In the terminology of inverse methods, the function f is commonly referred to as the forward model, x as the system state, and y as the measurement vector.

Introduction

Inverse methods are routinely used in glaciology to estimate model parameters. Examples of such inverse problems include the estimation of basal conditions from surface measurements on glaciers (e.g., MacAyeal, 1992, 1993; Vieli and Pane, 2003; Thorsteinsson et al., 2002; Joughin et al., 2004; Gudmundsson, 2004; Truffer, 2004; Maxwell et al., 2008; Gudmundsson and Raymond, 2008; Raymond and Gudmundsson, 2009; Joughin et al., 2009), the determination of geothermal heat flux from englacial temperature measurements (e.g., Dahl-Jensen et al., 2003; Buchardt and Dahl-Jensen, 2007), dating of ice cores (Parrenin et al., 2001), and the inference of spatial pattern of surface snow accumulation from the distortion of layers within a glacier (Martín et al., 2006; Waddington et al., 2007; Eisen, 2008).

Inverse problems typically share a number of features that complicate their solution. There is, in general, no guarantee that such a problem has a unique solution for a given set of measurements. Solutions to inverse problems are also often sensitive to small changes in the measurement data. One of the consequences is that even when two sets of measurements are in some sense "similar," the solutions of the two corresponding inverse problems may not be "similar." Measurements are never completely free of errors and we can therefore, in general, expect that a given inverse problem has not one but an infinite number of possible solutions, and that some of these solutions differ greatly. If the number of unknown parameters is limited, some trial-and-error techniques can often be used for parameter estimation. However, in many inverse problems, the number of parameters is large and some systematic approach is needed.

There are, broadly speaking, two different approaches commonly used to deal with such illposed problems involving large number of unknowns: regularization and statistical inference. The idea behind regularization is to introduce some additional constraints on possible solutions. For example, one might select a solution that is in some sense "smooth" while at the same time giving a reasonably good fit to measurements. The most commonly used statistical inference approach is Bayesian inference where one calculates the conditional probability $P(x|y)$ of the system state x for given set of measurements y.

Most nonlinear inverse methods involve a repeated minimization or maximization of some objective function. In a regularization method, the objective function to be minimized might be written as $|x|_a + |y - f(x)|_b$ for some function norms $|.|_a$ and $|.|_b$, while in Bayesian inference the quantity to be maximized is the conditional probability $P(x|y)$ as a function of x. Due to the large number of unknown variables typically involved in inverse problems, solving such problems is often only feasible if either the forward model is computationally inexpensive or if an effective way of maximizing/minimizing the objective function can be found. Most efficient minimization algorithms require estimates of the gradient of the cost function with respect to the model parameters. The gradients are in turn often difficult to estimate. Adjoint methods, first introduced in glaciology by MacAyeal (1993), are commonly used to speed up the calculation of the gradient of the objective function.

Inverse modeling is often performed as a part of a model validation exercise. The inverse modeling step delivers the best possible values for model parameters, i.e., the parameter values that minimize/maximize the objective function, given some statistical estimates about data errors and the propagation of errors from system state to measurement state through the forward model. Model validation involves determining if both the size and distribution of the model residuals are in accord with those statistical error estimates. If not, either the forward model, or the error description used, is lacking in some sense. If successful, model

validation provides some confidence that the forward model is capable of simulating the physical situation under study.

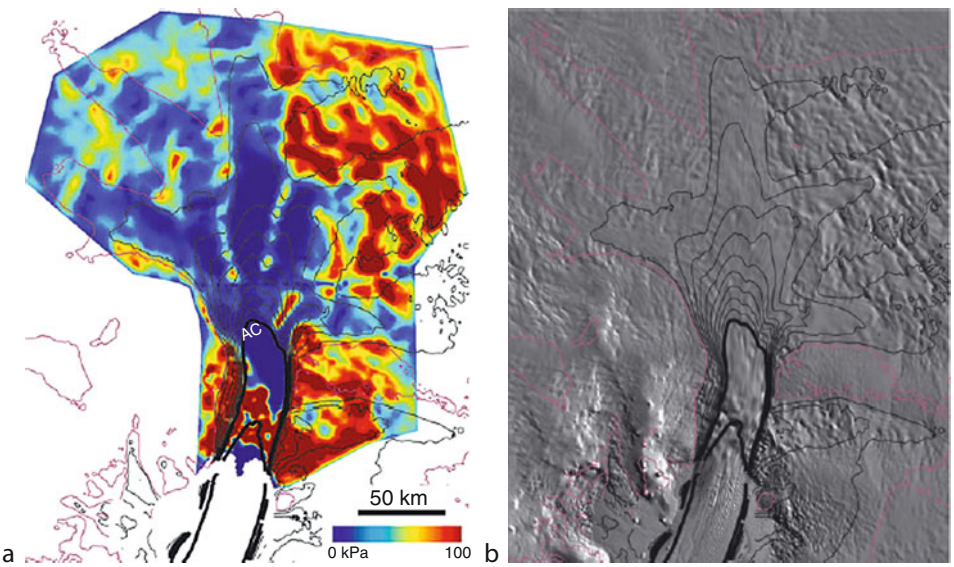
Main uses of inverse modeling in glaciology to date

The inverse problem that has received the greatest attention in glaciology to date is that of determining basal conditions of glaciers using surface measurements of velocities and topography. There are a number of reasons why glaciologists are interested in mechanical conditions at the base of ice streams and ice sheets. On fast-flowing ice streams, most of the forward movement is due to basal motion as opposed to internal deformation of ice. Without a good understanding of what controls the basal motion, our understanding of ice streams dynamics is severely lacking and the possibility of predicting future behavior limited. In most flow modeling work of glaciers, the modeler is also often faced with the practical problem of initializing the model parameters to ensure good fit with surface measurements. Such an initialization is often needed before any transient runs and perturbations experiments can be conducted. For glaciers where large part of the forward movement is due to basal motion, the most important model parameters tend to be those defining the mechanical properties of the lower boundary. Basal motion is often parameterized using a sliding law that relates the basal sliding velocity to the forces acting on the glacier. Inverse methods can be used to systematically determine the spatial variation of the parameters in the sliding law.

The first systematic approach to determine basal conditions using surface data was given by MacAyeal (1992, 1993). He showed how adjoint methods could be used to efficiently calculate the gradient of an objective function describing the misfit between surface data and the output from a forward model. One of the earlier uses of this method was to calculate spatial distribution of basal friction on Ice Stream E (MacAyeal, 1992) (Ice Stream E was later renamed to MacAyeal Ice Stream). This method can currently be considered the standard method for inverting surface data on ice streams. A recent application of this method is that of Joughin et al. (2009) who determined the basal stress distribution of Pine Island and Twhaites Glaciers, West Antarctica, using extensive data sets of surface velocities and surface topography (Figure 1).

Recently several new methods of determining basal conditions on glaciers have been proposed. Maxwell et al. (2008) suggest using an iterative method where two different well-posed forward problems are solved in sequence. One forward problem uses an estimate of basal stresses and measured surface data as boundary conditions (N step). Another forward problem, the D step, uses as boundary conditions the previously calculated basal velocities from the N step, together with the free surface condition. A series of alternating N and D steps is calculated until a stopping criterion based on the misfit between measured and modeled surface velocities from the D step is met. Maxwell et al. (2008) used their method to estimate basal velocities of Athabasca and Perito Moreno glaciers using a full Stokes forward model.

Arthern and Gudmundsson (2010) proposed a further new method of calculating the basal drag coefficient and the effective ice viscosity from surface data. Similar to the approach of Maxwell et al. (2008) the only



Inverse Methods in Glaciology, Figure 1 Example of an estimate of basal shear stress distribution of a glacier obtained from inverse modeling of surface data (Joughin et al., 2009). The area shown is Pine Island Glacier, West Antarctica. *Contour lines* show surface flow velocities. (**a**) Basal shear stress distribution. (**b**) Satellite image (MOA) from the same area.

requirement that the method places upon the forward solver is that the Newman, Dirichlet, and Robin type boundary conditions can all be implemented. One of the advantages of the methods of Arthern and Gudmundsson (2010) and Maxwell et al. (2008) is the ease by which they can be implemented given a forward model. Arthern and Gudmundsson (2010) give an example of a three-dimensional flow problem where the basal drag coefficient is extracted from surface data using a commercial Stokes solver.

One of the difficulties associated with estimating basal stresses and basal velocities for glaciers is the fact that the geometry of the glacier bed is only known approximately. Gudmundsson (2004) suggested solving simultaneously for both bedrock geometry and basal slipperiness using Bayesian inverse methods. An application of the method to a flow line down Rutford Ice Stream, West Antarctica (Raymond-Pralong and Gudmundsson, 2010), showed all short scale (<10 ice thicknesses) spatial variability in surface ice speed to be caused by variations in bedrock geometry rather than to variations in basal slipperiness.

A further use of inverse methods in glaciology is the determination of spatial variations in effective viscosity of ice in flow models. The rheology of ice is nonlinear and the effective viscosity of ice a function of stress. In addition, temperature strongly affects the effective viscosity. Calculating englacial temperatures in ice sheets is, in principle, a fairly straightforward task given accurate boundary data such as geothermal heat fluxes. However, such data is often lacking and the reliability of calculated temperature distributions therefore sometimes limited. A way of circumventing this problem is to calculate ice flow using spatially variable viscosity distribution that has been indirectly determined from surface data using inverse methods. As ice rheology is not expected to change markedly in a short span of time, having reliable estimates of the effective viscosity distribution greatly enhances the potential to make short-term (decadal time scale) predictions about future ice sheet behavior. Examples of this approach include the determination of the effective viscosity distribution of ice Ronne and the Larsen B Ice Shelves, West Antarctica (Larour et al., 2005; Vieli et al., 2006; Khazendar et al., 2007).

Determining the effective viscosity from surface data prior to conducting perturbation experiments with the forward model is an example of a model initialization. To date, the number of such forward model initializations studies in glaciology using formal inverse models is rather limited, but this shortcoming can be expected to change in the future. One of the attractive aspects of this methodology is that after initialization, and once the level of confidence in the forward model has been established through forward model validation, predictions about future development of the ice sheet can be made together with an estimate of the forecast error. Arthern and Hindmarsh (2006) discuss how the future contribution of Antarctica to sea-level change can be estimated in this fashion.

Layers within glaciers and ice sheets reflect spatial and temporal variations in surface snow accumulation and the effects of ice flow. Extracting information about patterns of surface accumulation from internal layers using a flow model that calculates internal layering for given spatial and temporal variations in surface mass balance, is an example of an inverse problem. Various approaches to this inverse problem have been proposed (Martín et al., 2006) applied control method to optimally match modeled and measured internal layers using parameters describing spatial variability in surface accumulation as control variables while Eisen (2008) used inverse methods to determine the velocity field from the spatial structure of dated firn layers. Recently, Waddington et al. (2007) showed how spatial patterns in surface snow accumulation can be inferred from deep layers in glaciers using a formal geophysical inverse modeling approach.

Because of steady increase in computer power and ongoing development in the design of inverse algorithms, it can be expected that in the future even greater use will be made of inverse modeling techniques in glaciology. Increasingly, modelers of large ice masses have at their disposal large and high-quality data sets obtained from both in situ geophysical measurements and remote sensing. Inverse modeling methods provide a systematic way of exploiting the potential of models and of extracting information from such data sets.

Summary

Inverse methods are ideally suited for the indirect estimation of a large number of model parameters. Such problems arise naturally in many types of glaciological modeling work, the prime example being the indirect estimation of basal boundary parameters on ice streams using surface data. In the future, inverse methods can be expected to play an increasing role in glaciological modeling work. In particular, the use of inverse methods for model initialization when forecasting the near-future (several decades) behavior of ice sheets is an interesting prospect.

INVERSION LAYERS

Mahendra R. Bhutiyani
Hazard Assessment and Forecasting Division, Snow and Avalanche Study Establishment, Chandigarh, India

Definition

Under normal atmospheric conditions in the troposphere, temperature generally decreases with altitude at the rate of about 6.5° km^{-1}. This gradient is called as the temperature lapse rate in meteorology. However, under certain conditions, a deviation occurs and temperature is seen to increase with altitude, giving rise to an inversion layer where the air is colder near the ground surface than higher elevations.

Origin

Inversion layer generally occurs at night when the ground cools more rapidly than the air above it, because of radiative, or direct, cooling from the earth's surface. The effects of an inversion are thus greatest during early morning hours, usually the coolest part of the day. Inversions also occur as a result of subsidence (sinking) of air in an anticyclone, or high pressure system, where the descending air warms adiabatically, that is, within itself, while the ground remains cool. In the Polar and high altitude mountainous regions such as the Alps, Rockies, and the Himalayas, inversions are quite common in winters during clear, cloud-free nights and early morning hours. As the sun rises, the valley sides warm up gradually; creating local eddies along the valley walls and the convection currents within the inversion layer destroy the inversion layer in a few hours.

Significance

In urban and plain areas, inversion layers block the upward movement of air, trapping moisture and natural and man-made pollutants near the ground, resulting in fog and smog.

INVERTED CUP DEPTH HOAR CRYSTALS

Mahendra R. Bhutiyani
Hazard Assessment and Forecasting Division, Snow and Avalanche Study Establishment, Chandigarh, India

Definition

These are large-grained, faceted, cup-shaped crystals (up to 10 mm in diameter) that resemble the sugar granules. They are also called as temperature-gradient or TG crystals. Layers of such crystals are generally found in early winter when clear sky conditions along with cold air temperatures prevail for a very long duration and the snowpack is thin. They are also found in areas where

snowpack remains in the shady condition for long, particularly on slopes with the northern aspect in the North Hemisphere.

Origin

They are formed because of strong temperature gradient ($>0.25°C\ cm^{-1}$) in the layers of the snowpack when the ground is warmer and the snow-surface temperatures are lower (−2 to −15°C). As a result of vapor transfer (sublimation), snow crystals occurring at the base of a snowpack grow bigger at the cost of smaller grains as uprising water vapor freezes at their base and they ultimately acquire an inverted cup shape.

Significance

Because of the absence of intergranular bonds, the layers with TG or inverted cup depth hoar crystals have very weak shear strength. They are likely to fail easily and lead to catastrophic collapse of the layer. Fractures commonly propagate long distances and around corners. Almost all catastrophic, hard wind slab climax avalanches (involving the entire season's snow cover) are triggered due to the failure of snow layer with inverted cup depth hoar crystals.

IRREDUCIBLE WATER

Mahendra R. Bhutiyani
Hazard Assessment and Forecasting Division, Snow and Avalanche Study Establishment, Chandigarh, India

Definition

Like in a soil, liquid water occurs in a snowpack in three different forms: the hygroscopic water, the capillary water, and gravitational water. Irreducible water or "hygroscopic water" occurs as a thin film of water molecules around the snow grains.

Origin

Meltwater on the snow surface, which is produced as a result of complex heat transfer process at the snow-atmosphere interface, percolates down in the snowpack. Water holding capacity of snow depends primarily upon the temperature regime of the snowpack and its physical properties such as porosity, permeability, and particle size and saturation level. Hygroscopic or irreducible water is held by a strong adhesive force between the water molecules and the ice molecules in the snow grains, against the force of gravity. Moist snowpack that is isothermal at 0°C and at a very low saturation level is likely to have irreducible or hygroscopic water. It is generally less than 3% (by pore volume) of the snow. It is not available for generation of melt-runoff unless the whole crystal melts.

ISOTOPE ANALYSIS

Tandong Yao, Wusheng Yu, Huabiao Zhao, Yongqin Liu
Laboratory of Tibetan Environment Changes and Land Surface Processes (TEL), Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Haidian District, Beijing, China

Introduction

Naturally occurring oxygen includes three stable isotopes, ^{16}O, ^{17}O, and ^{18}O, with the relative abundances of 99.763%, 0.0375%, and 0.1995%, respectively. Isotopic analysis does not consider the absolute abundances of the isotope, but rather, the ratios of ^{18}O to ^{16}O relative to one of the two standards: Vienna Standard Mean Ocean Water (VSMOW) or Vienna Pee Dee Belemnite (VPDB). Isotope mass spectrometry measures oxygen and hydrogen stable isotopic ratios (Craig, 1961). Carbon dioxide that has equilibrated with water at a constant temperature provides the oxygen for analysis (Epstein and Mayeda, 1953).

Numerous papers and books have discussed environmental isotopes in hydrology and stable isotope paleoclimatology over the past 50 years. Some of the more common in the key theme areas of stable isotope in water include: the Handbook of Environmental Isotope Geochemistry series, edited by Fritz and Fontes in the 1980s, as well as reviews by Fontes and Edmunds (1989), Coplen (1993), and Gat (1996); textbooks by Mazor (1997), Clark and Fritz (1997), and Cook and Herczeg (2000); and some excellent research papers delivered by Dansgaard (1964), Epstein et al. (1965), Gat (1996), Johnsen et al. (1972), Jouzel et al. (1987), Rozanski et al. (1992), and Thompson et al. (2000).

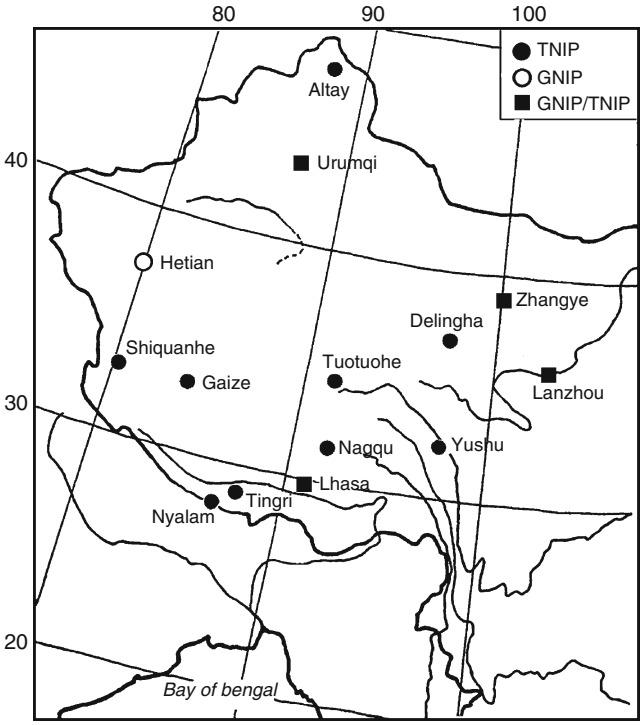
Stable isotopes are widely used to reconstruct paleoclimate variations preserved in ice core records (Lorius et al., 1985; Jouzel et al., 1987; Dansgaard et al., 1993; Cuffey et al., 1994; Johnsen et al., 1972, 1995; Thompson et al., 1997, 2000). However, the interpretation of stable isotope records in ice cores must be based on the knowledge of temporal and spatial variations of stable isotopes in precipitation and their relationships with meteorological conditions. The precipitation isotopic compositions ($\delta^{18}O$) represent an integrated climatic parameter, reflecting the evaporation and condensation history of an air mass (Dansgaard, 1964; Merlivat and Jouzel, 1979; Rozanski et al., 1982, 1992; Jouzel and Merlivat, 1984; Schoch-Fischer et al., 1984; White et al., 1997).

Since 1961, the International Atomic Energy Agency (IAEA), in cooperation with the World Meteorological

Organization (WMO), has set up 550 meteorological stations for measuring the isotopic composition of monthly precipitation (the Global Network of Isotopes in Precipitation, GNIP). However, few of these stations lie on the Tibetan Plateau, limiting studies on stable isotope ratios in precipitation in this region. The difficulty in accessing such high-altitude sites strongly limits the ability to maintain continuous precipitation sampling, especially during the monsoon season. However, high-altitude Tibetan glaciers offer unique archives of past tropical precipitation and several ice cores have been successfully retrieved (e.g., Thompson et al., 1995). One must have some knowledge of the seasonal and spatial distributions of isotopic compositions in modern Tibetan Plateau precipitation in order to interpret past changes in the isotopic compositions. The isotopic composition of precipitation also offers an opportunity to distinguish between different water sources and therefore better define the northward limits of the monsoon influence. Beginning in 1991, the Chinese Academy of Sciences (CAS) launched a project to establish a new observation network (Third Pole Regions Environment Observation & Research Platform, TORP) to continually survey stable isotope variations in individual precipitation events on the Tibetan Plateau and adjacent regions. In 2007, launched an even larger network, titled as China Network of Isotopes in River and Precipitation (CNIRP), to observe stable isotope variations in river water and precipitation in China. Many scientists have investigated various climatic factors, especially regarding how the Asian monsoons influence the $\delta^{18}O$ composition in precipitation (Aizen et al., 1996; Hoffmann and Heimann, 1997; Posmentier et al., 2004; Johnson and Ingram, 2004; Vuille et al., 2005). In China, Yao et al. (1995, 1996, 1999) and Zhang et al. (1995) analyzed the correlation between $\delta^{18}O$ in precipitation and air temperatures at Urumqi, Delingha, and Tuotuohe, and found that a good linear relationship exists between $\delta^{18}O$ in precipitation and air temperature, indicating that temperature effects control $\delta^{18}O$ in precipitation. As scientists began to take interest in the variations of stable isotopes in precipitation at Lhasa on the southern Tibetan Plateau, their studies showed that stable isotopes in precipitation reflected an apparent precipitation "amount effect" (Araguás-Araguás et al., 1998; Tian et al., 2001a, b, 2003).

Understanding stable isotope variations in precipitation over this large region and a longer time scale can provide insight and a theoretical basis for interpreting observations of stable isotopes in ice cores. Based on the above-mentioned references, precipitation samples were collected continuously at Nyalam, Lhasa, Nagqu, Tuotuohe, and Delingha (from south to north on the Tibetan Plateau) from the 1990s to 2008 (Figure 1). More recently, observations initiated on stable isotope variations on the eastern and western Tibetan Plateau have also contributed to an understanding of these effects (Yu et al., 2006, 2007; Tian et al., 2007).

Our study sampled each precipitation event. The precipitation sampling program recorded the duration of each



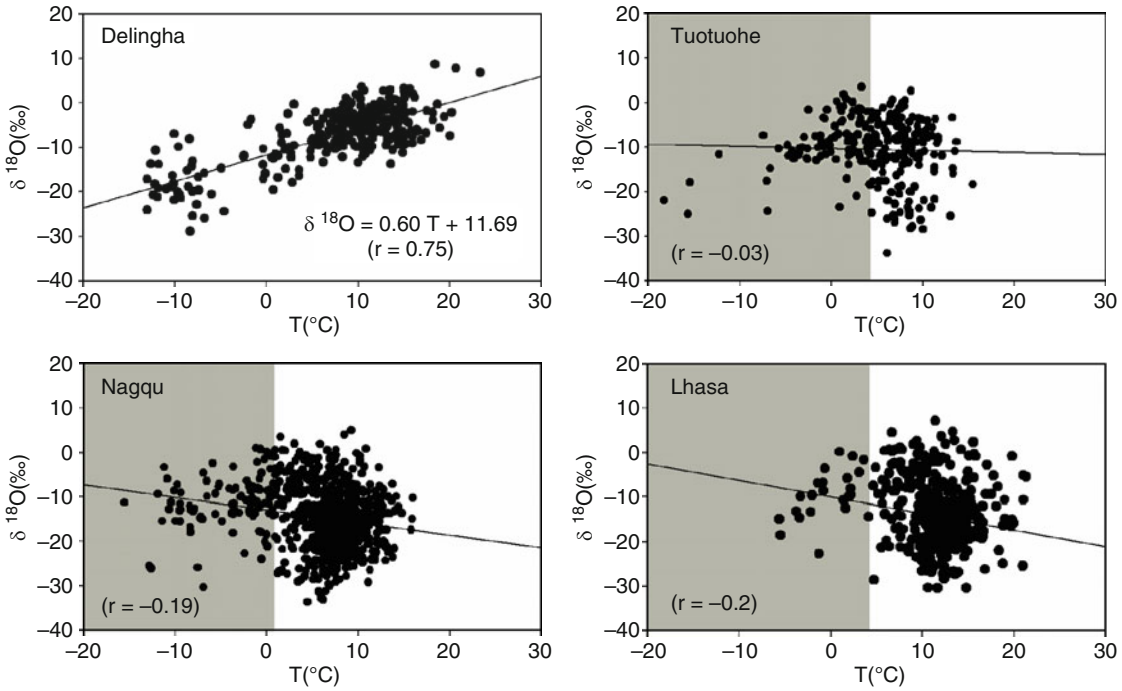
Isotope Analysis, Figure 1 Map of the precipitation sampling sites.

precipitation event, rainfall amount, and surface air temperatures before and after each precipitation event. Rainfall samples were collected and immediately sealed in plastic bottles. Snow and other solid precipitation were collected on clean porcelain plates, put into clean plastic bags, and sealed. After the samples melted at room temperature, they were processed the same as rainfall. All the samples were stored below freezing in a cold laboratory until analyzed. The State Key Laboratory of Cryospheric Science, Chinese Academy of Sciences, Lanzhou, China, measured oxygen isotope compositions of all the precipitation samples using a MAT-252 mass spectrometer with a precision of ±0.2‰. The measured $\delta^{18}O$ in precipitation samples is expressed as parts per mil (‰) of their deviation relative to the Vienna Standard Mean Ocean Water (VSMOW). The Laboratory of Ecological Research Center of Kyoto University, Japan, also measured oxygen isotope ratios in some of the samples using a MAT-252 mass spectrometer, for quality assurance.

$\delta^{18}O$ in precipitation from north to south on the Tibetan Plateau

Temperature dependence of $\delta^{18}O$ in precipitation

Figure 2 shows the relationships between $\delta^{18}O$ values of individual precipitation events and air temperatures at the four stations across the Tibetan Plateau: Delingha, Tuotuohe, Nagqu, and Lhasa. A significant positive



Isotope Analysis, Figure 2 Relationships between $\delta^{18}O$ and air temperature in recent precipitation events at four meteorological stations on the Tibetan Plateau.

relationship between $\delta^{18}O$ in precipitation and air temperature exists at the Delingha station, on the northern Plateau. The correlation coefficient is 0.75, within a 0.01 confidence limit. This demonstrates a significant temperature effect on $\delta^{18}O$ in precipitation during the sampling period from the seasonal variations at Delingha. However, from the middle to the south of the transect, the oxygen isotopic compositions of precipitation at the Tuotuohe, Nagqu, and Lhasa stations show a weak *inverse correlation* between $\delta^{18}O$ values and air temperatures in individual precipitation events. Moreover, the *inverse correlation* weakens with increasing latitude from Lhasa to Tuotuohe (Yu et al., 2008).

Compared with the relationship for individual precipitation events, the correlations improve between monthly amount-averaged $\delta^{18}O$ values and monthly-averaged air temperatures (during precipitation events) at the Delingha and Tuotuohe stations (Equations 1 and 2). Moreover, the monthly-averaged $\delta^{18}O$ – T correlation at Delingha, in the northern Tibetan Plateau, is more significant than that at Tuotuohe, in the north-central Tibetan Plateau.

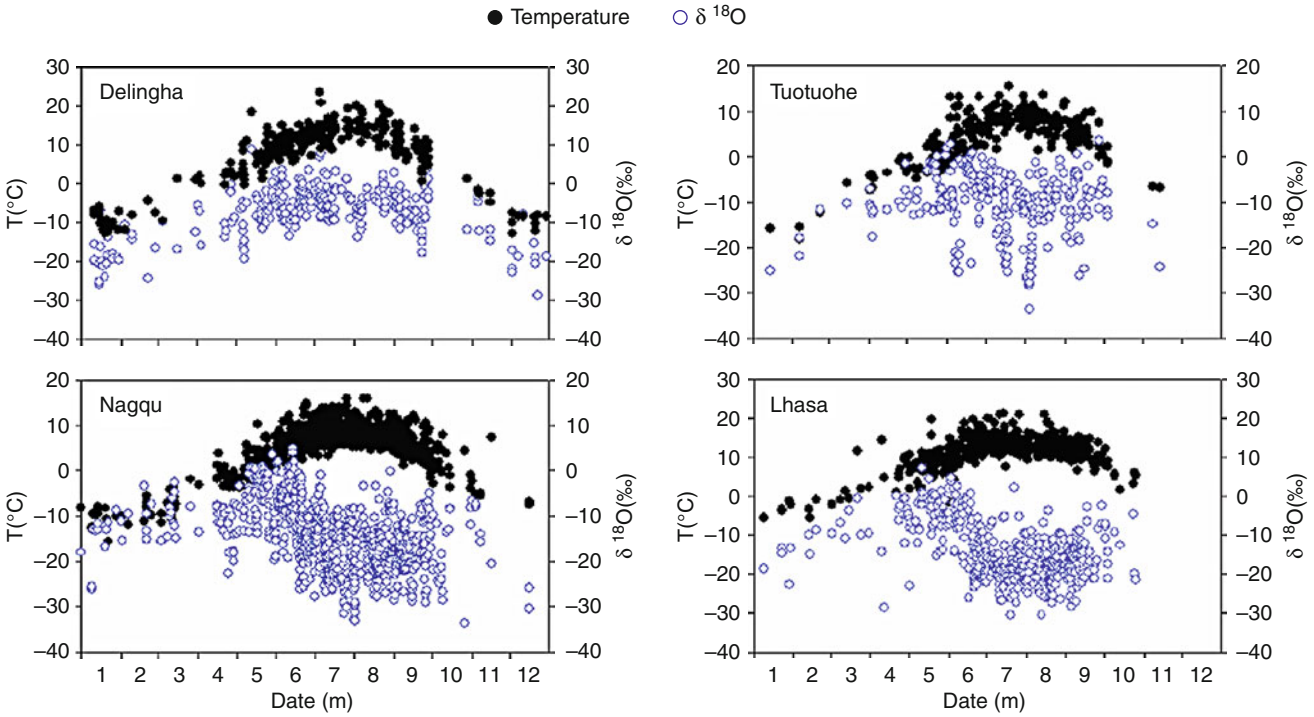
$$\text{Delingha}: \delta^{18}O = 0.56\overline{T} - 11.16\,(r = 0.84,\ n = 36,\ p < 0.01) \quad (1)$$

$$\text{Tuotuohe}: \delta^{18}O = 0.33\overline{T} - 11.71\,(r = 0.51,\ n = 24,\ p < 0.05) \quad (2)$$

Temperature effects still appear to largely control the $\delta^{18}O$ values in precipitation at the Tuotuohe station, although the influence of air temperature upon individual precipitation events at the synoptic scale is very weak. Siegenthaler and Oeschger (1980) have demonstrated that the temperature effects are best analyzed on an averaged basis rather than from individual events.

Temporal and spatial variations of $\delta^{18}O$ in precipitation

From north to south, the seasonal distribution of $\delta^{18}O$ in individual precipitation events at the four stations across the Tibetan Plateau shows a continuous change (Figure 3). At Delingha, on the northern Tibetan Plateau, $\delta^{18}O$ values and air temperature trends correlate strongly with high values in summer and low values in winter. The occurrences of high $\delta^{18}O$ values in summer precipitation and low $\delta^{18}O$ values in winter precipitation at the Delingha station match the temporal distributions of oxygen isotopes in precipitation in other inland areas of central Asia (Araguás-Araguás et al., 1998). On the other hand, the $\delta^{18}O$ values in precipitation remain low in summer precipitation at both Lhasa on the southern Plateau and Nagqu on the south-central Plateau. Compared with the low $\delta^{18}O$ values in summer precipitation at Nagqu and Lhasa, most of the $\delta^{18}O$ values in summer precipitation at Tuotuohe, north-central Tibetan Plateau, are less negative.



Isotope Analysis, Figure 3 Seasonal distribution of air temperatures and $\delta^{18}O$ in precipitation events at four meteorological stations on the Tibetan Plateau: Delingha, Tuotuohe, Nagqu, and Lhasa.

Figure 3 also shows that from January to May, before the onset of the southwest monsoon, the $\delta^{18}O$ values increased gradually at all four stations, in sync with their air temperature trends. We therefore calculated the correlations between $\delta^{18}O$ values and air temperature before the monsoon onset at the four stations (Table 1), and found that these correlations are more significant than those for individual precipitation events over the entire year. Furthermore, the correlations weaken gradually from north to south across the Tibetan Plateau (Table 1). This shows that temperature effects on $\delta^{18}O$ in precipitation during the pre-monsoon period along this transect exceed those in the entire year. It was also found that from January to May, the slopes ($d\delta^{18}O/dT$) and correlation coefficients (r) of the regression result between $\delta^{18}O$ and air temperature at Tuotuohe resemble those at Delingha. On the other hand, the slope and correlation coefficient at Nagqu appear similar to those at Lhasa (Table 1).

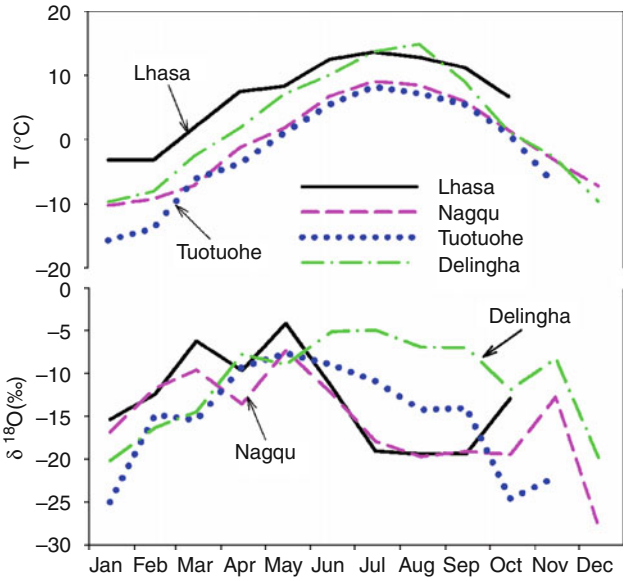
Figure 4 displays the temporal variations of monthly weighted mean $\delta^{18}O$ values in precipitation and air temperature at each of the four stations on the transect. The air temperature trends for the four stations vary similarly, with temperatures high in summer and low in winter. However, the trends of the corresponding $\delta^{18}O$ values in precipitation exhibit obvious differences. From January to May, all the $\delta^{18}O$ trends increase gradually, paralleling those of air temperature. The $\delta^{18}O$ values in precipitation at the Lhasa, Nagqu, and Tuotuohe stations rise to their maxima in May. Beginning in June, the $\delta^{18}O$ values of precipitation at both Lhasa and Nagqu fall rapidly to relatively low values in July. During this period, the $\delta^{18}O$ values in precipitation at the Tuotuohe station decrease more moderately, reaching a minimum in August. In contrast, after the $\delta^{18}O$ values at the Delingha station continue to increase from January to May, rising to a maximum in July, they then begin a slow decrease. The tendency for low $\delta^{18}O$ values during the mid-summer precipitation progressively strengthens from north to south (Figure 4).

Several factors may affect the relationship between $\delta^{18}O$ in precipitation and air temperature. Spatial variations of $\delta^{18}O$ may be a factor at stations exposed to homogenous moisture origin (Tian et al., 2003). Figure 5 shows the spatial variations of mean air temperature and the weighted mean of $\delta^{18}O$ for the separate periods, January–May (solid lines), June–September (dotted lines), and the entire year (dash-dotted lines) at the four Plateau stations. The bar graphs at the bottom of Figure 5 show elevation (filled bars) and annual precipitation (open bars).

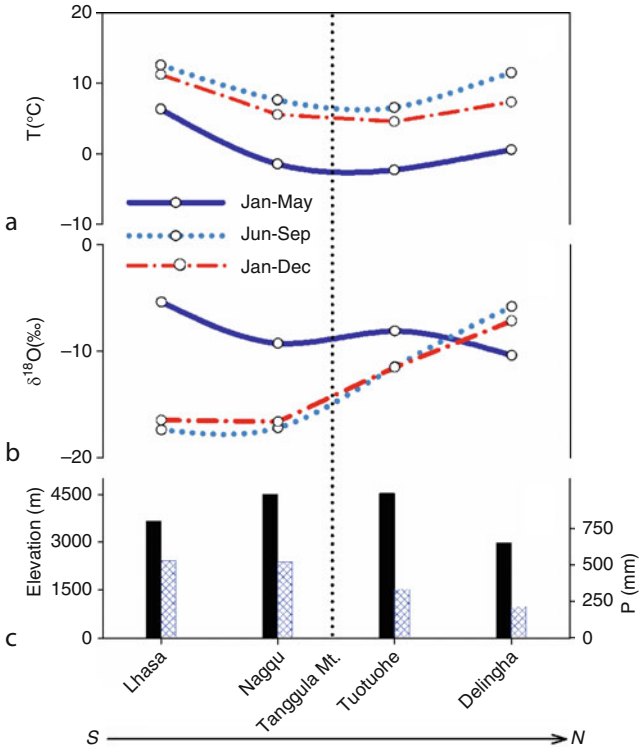
Between January and May, the spatial variations of $\delta^{18}O$ values in precipitation positively correlate with air temperature at the two southern stations (Lhasa, Nagqu). That is, the mean $\delta^{18}O$ values and mean air temperatures both decrease with increasing latitude and altitude. However, between the two northern stations (Tuotuohe and Delingha), although the elevation is lowering and the corresponding mean air temperature increases, the mean $\delta^{18}O$ value decreases (Figure 5a and b). The observed variation of $\delta^{18}O$ values results from the rainout effect due to

Isotope Analysis, Table 1 Comparison of the regression results between $\delta^{18}O$ and temperature at the four stations on the Tibetan Plateau prior to the monsoon

Station	Period	$d\delta^{18}O/dT$	r	n
Delingha	January–May	0.68	0.78	77
Tuotuohe	January–May	0.78	0.73	44
Nagqu	January–May	0.57	0.51	128
Lhasa	January–May	0.50	0.38	74



Isotope Analysis, Figure 4 Temporal variations of monthly weighted mean $\delta^{18}O$ in precipitation and air temperature for the four stations on the Tibetan Plateau.



Isotope Analysis, Figure 5 South to north spatial variations during three periods of air temperature (**a**), and weighted mean $\delta^{18}O$ values (**b**). *Solid lines* indicate weighted monthly means for January–May; and *dotted lines* indicate weighted monthly means for June–September; and the *dash-dotted lines* stand for weighted annual means for the entire year. For reference, (**c**) shows the elevations (*filled bars*) and annual precipitation (*open bars*) at the four stations.

increasing continentality. In winter, the westerlies mostly control the moisture on the Tibetan Plateau and adjacent regions. Because of the greater distance to Delingha from west or south, the rainout effect at Delingha is more intensive than that at the other three stations, resulting in low $\delta^{18}O$ values.

Between June and September, the mean $\delta^{18}O$ values increase gradually from Lhasa to Tuotuohe, but the corresponding mean air temperatures decrease gradually. As seen at Delingha on the other hand, to the north of Tuotuohe, the mean $\delta^{18}O$ values increase further, but the corresponding air temperature increases (Figure 5a and b).

The trends of averaged air temperature and weighed-averaged $\delta^{18}O$ values for the entire year appear similar to those for June–September (Figure 5a and b). This results from the summer season from June to September capturing about 80% of the annual precipitation at the four stations. Accordingly, the variations of $\delta^{18}O$ in summer precipitation at the four stations generate the main trends of $\delta^{18}O$ for the entire year. As discussed above, the southwest monsoon impacts $\delta^{18}O$ in summer precipitation in the middle and the southern portions of the Tibetan Plateau. That probably causes the poor correlation between air temperature and $\delta^{18}O$ in precipitation for the entire year at the Lhasa, Nagqu, and Tuotuohe stations.

The temporal and spatial variations of $\delta^{18}O$ in precipitation on the Tibetan Plateau indicate the period around late May or early June to be an important time, and the Tanggula Mountains an important boundary. A major limitation exists for discussing the correlations between $\delta^{18}O$ in precipitation and air temperature in this study, namely that the air temperatures come from ground measurements, and not temperatures at the condensation levels in the cloud. This limitation significantly impacts this study. Findings indicate that temperature differences between the ground and the condensation levels (in the cloud) during convective storms in the winter and spring are likely much smaller than during summer monsoon events. Moreover, the convection within winter storms is far less intense than that in summer over the Plateau. Furthermore, during periods of low ground-level air temperature, the temperature difference between ground and the condensation level remains small. Accordingly, before late May or early June,

the correlations between $\delta^{18}O$ in precipitation and air temperature are very significant.

Other recent studies also conclude that the region of the Tanggula Mountain range, extending from west to east between the Nagqu and Tuotuohe stations, forms an important climatic divide (Yao et al., 1991; Tian et al., 2001b, 2003; Yu et al., 2006). These massive mountains block the flow of the southwest monsoon from the south. As a result, the southwest monsoon prevails at the Lhasa station during summer, south of the Tanggula Mountains, but without the monsoon influence in winter, the westerlies provide most of the moisture to Lhasa. At the Delingha station, north of the Tanggula Mountains the westerlies and continental air masses provide the dominant influence all year round. Hence, temperature effects control $\delta^{18}O$ in precipitation in the north (such as at Delingha), whereas the "amount effect" plays an important role for the $\delta^{18}O$ values related to the monsoon precipitation in the south (such as at Lhasa).

Because of the intense convection in the south, oceanic moisture coming from the Indian Ocean via the Bay of Bengal onto the Tibetan Plateau rises to very high altitudes, with accompanying very low temperatures. Accordingly, oxygen isotope ratios in precipitation are low, resulting in a weakening of the correlation between $\delta^{18}O$ and ground-level air temperatures in the southern and the middle portions of the Plateau during the monsoon. Moreover, because of the blocking action of the massive mountains at the southernmost Tibetan Plateau (e.g., the Himalayas), oceanic moisture rises to higher altitudes. Hence, the orographic uplift effect accentuates the lower $\delta^{18}O$ in precipitation in the southern and the middle portions of the Plateau. However, the monsoon precipitation causes the summer rainfall to be considerably higher than that in winter. An inverse correlation exists between $\delta^{18}O$ in summer precipitation and rainfall, accounting for an "amount effect" on $\delta^{18}O$ in summer precipitation in the south.

The Tuotuohe and Nagqu stations lie within a climatic divide, located at the northern and southern edges of the Tanggula Mountains. Accordingly, the Tuotuohe and Nagqu stations sit in a transition zone between the regions in the south dominated by the monsoon and the regions in the north dominated by the westerlies and the continental air masses. In this transition zone, the westerlies, the southwest monsoon, and continental air masses intermingle with the southwest monsoon dominating in summer and the westerlies prevailing in winter. Consequently, both air temperatures and moisture sources impact the variations of $\delta^{18}O$ in precipitation at the Tuotuohe and Nagqu stations. Furthermore, the decreasing influence of monsoon precipitation in summer from south to north not only results in gradually decreasing annual precipitation (P) (Figure 5c), but also results in increasing $\delta^{18}O$ values in summer precipitation (June–September) from south to north. Accordingly, the $\delta^{18}O$ variations in precipitation correlate both with air temperatures, and with moisture trajectories. Before the onset of the southwest monsoon, the westerlies provide most of the moisture at all four stations, and result in very similar trends of $\delta^{18}O$ and air temperature, with temperatures and $\delta^{18}O$ values increasing gradually from January to May (Figure 4). At the onset of the monsoon, $\delta^{18}O$ values in precipitation at the Lhasa and Nagqu stations decrease rapidly. During the rainy season between June and September, the monsoon activities are very strong on the southern Tibetan Plateau. These two stations located there exhibit lower $\delta^{18}O$ values in summer precipitation, while summer air temperatures remain high (Tian et al., 2001a, 2003). Because weaker convection and precipitation occur during the monsoon period at the Tuotuohe station than at Lhasa and Nagqu, the $\delta^{18}O$ values decrease only slightly after June, and the values in summer precipitation remain higher than those at Lhasa and Nagqu.

The Delingha station lies on the northern Tibetan Plateau, beyond the influence of the southwest monsoon activities. Accordingly, with little the monsoon influence, $\delta^{18}O$ values in precipitation show a strong temperature dependence (Zhang et al., 1995, Tian et al., 2003). The $\delta^{18}O$ values and air temperatures both rise in summer and drop in winter (Figure 4). Considerable evidence, based on (a) the trends of $\delta^{18}O$ values at the four stations, (b) the slopes ($d\delta^{18}O/dT$), and (c) the correlation coefficients (r) of the regressions between pre-monsoon $\delta^{18}O$ and air temperature, shows that the $\delta^{18}O$ variations at Nagqu resemble those at Lhasa, whereas the $\delta^{18}O$ variations at Tuotuohe parallel those at Delingha. We find that the $\delta^{18}O$ values in summer precipitation increase from south to north (Figure 5b). This results from the weakening of the southwest monsoon activities and the strengthening of the westerlies from south to north on the Plateau.

Based on this study, the characteristics of $\delta^{18}O$ in recent precipitation events on the south of the Tibetan Plateau (such as at the Lhasa and Nagqu stations) can explain the changes of $\delta^{18}O$ records in the Dasuopu and Far East Rongbuk ice core records from the Himalayas. According to the results from Thompson et al. (2000) and Kang et al. (2001), some short-term $\delta^{18}O$ records show that high $\delta^{18}O$ values in these two ice cores correspond to low precipitation, and low $\delta^{18}O$ values correspond to high precipitation. This inverse correlation between ice core $\delta^{18}O$ and precipitation may result from variations in the influence of monsoon precipitation. However, the changes in long-term $\delta^{18}O$ records from the two ice cores correspond directly with temperature changes over the Northern Hemisphere, and the $\delta^{18}O$ records can still be used as a proxy for temperature (Thompson et al., 2000; Kang et al., 2001).

$\delta^{18}O$ in precipitation from west to east on the Tibetan Plateau

Temperature dependence of $\delta^{18}O$ in precipitation

A positive correlation exists between $\delta^{18}O$ and air temperature for recent precipitation events at the Shiquanhe, Gaize, and Yushu stations (see Figure 1 for location).

The correlations between monthly mean $\delta^{18}O$ and monthly mean temperature at Shiquanhe, Gaize, and Yushu are stronger than those for individual precipitation events. These results suggest that temperature influences $\delta^{18}O$ values in precipitation at Shiquanhe, Gaize, and Yushu. The relationship between monthly mean $\delta^{18}O$ and air temperature for individual precipitation events at Gaize is weaker than that at Shiquanhe.

The close proximity to the monsoon region at Nagqu results in the variations of $\delta^{18}O$ in precipitation being similar to the $\delta^{18}O$ variations on the southern Tibetan Plateau (Tian et al., 2003; Yu et al., 2008). Hence, we also analyzed isotopic data from Nagqu, south-central Tibetan Plateau, and found an *inverse correlation* between $\delta^{18}O$ in precipitation and air temperature. However before the monsoon onset, a positive correlation still exists between $\delta^{18}O$ and air temperature for recent precipitation events at Nagqu; and air temperature remains the controlling factor for the variations of $\delta^{18}O$ in this area.

Temporal and spatial variations of $\delta^{18}O$ in precipitation

As mentioned above, the region of 32°N–33°N (the west to east extending Tanggula Mountain range) forms an important climatic divide. The Shiquanhe, Gaize, Tuotuohe, and Yushu stations lie within this climatic divide. All these stations fall in the transition belt between the regions dominated by the "temperature effect" in the north and the "amount effect" in the south. Hence, all these stations experience similar variation patterns of $\delta^{18}O$ in precipitation. In this zone, the westerlies and monsoon intermingle with the monsoon dominating in summer. The rest of the year, the westerlies mainly control the moisture sources at the four stations. Consequently, $\delta^{18}O$ in precipitation shows a temperature dependence at the annual scale. The monsoon activities in summer weaken the correlations between $\delta^{18}O$ and air temperature. Except at Nagqu, $\delta^{18}O$ variations in precipitation relate closely to the variations of temperature on an annual basis, despite the $\delta^{18}O$ values being low in summer as a result of the monsoon precipitation (Tian et al., 2003; Yu et al., 2004). As mentioned above, the closer the proximity to the monsoon region, the more similar the results in the variations of $\delta^{18}O$ in precipitation at Nagqu become to the $\delta^{18}O$ variations on the southern Tibetan Plateau. However, before the monsoon onset, air temperature remains the dominant factor that controls the variations of $\delta^{18}O$ in this area (see Table 2). Table 2 also shows that the correlations of $\delta^{18}O$ and air temperature at these stations before the monsoon onset are more significant than those on an annual basis. Furthermore, the slopes ($d\delta^{18}O/dT$) are also higher for the pre-monsoon period than those for the entire year. Clearly, the monsoon activities in summer have an impact upon the relationships between $\delta^{18}O$ in precipitation and air temperature in the transition zone.

Figure 6 shows the seasonal variations of $\delta^{18}O$ in precipitation with air temperature at the Shiquanhe, Gaize, Nagqu, and Yushu stations. Before the onset of the southwest monsoon, the $\delta^{18}O$ values increase gradually, consistent with the trends of air temperature. Apparently, temperature effects control the $\delta^{18}O$ values in precipitation in this area before the monsoon onset, when the westerlies control the moisture origins, the frequency of precipitation events remains very low, and precipitation events yield little rainfall (Figure 6).

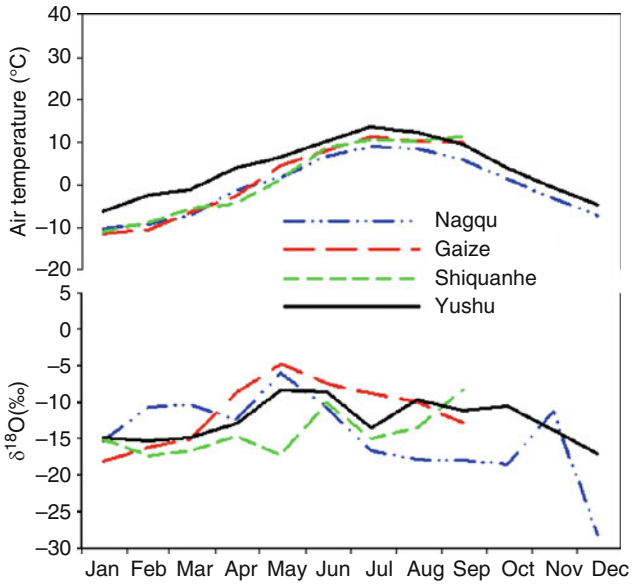
During the rainy season between late May and August, strong monsoon conditions exist at all four stations, and $\delta^{18}O$ values decrease (the $\delta^{18}O$ values fall to a minimum at the end of July or early August), while summer air temperatures remain high. The southwest monsoon in summer causes the frequency of precipitation events to increase rapidly. Compared with the pre-monsoon period, rainfall amounts increase significantly during the monsoon (Figure 6).

With the retreat of monsoon precipitation, temperature remains the dominant factor controlling the variation of $\delta^{18}O$. With air temperatures lowering gradually, the $\delta^{18}O$

Isotope Analysis, Table 2 Relationships between $\delta^{18}O$ in precipitation and air temperature before the summer monsoon

Station	Period	$d\delta^{18}O/dT$	R	n
Yushu	January–May	0.47	0.70	46
Nagqu	January–May	0.57	0.51	128
Gaize	January–June[a]	0.74	0.75	25
Shiquanhe	January–June[a]	0.77	0.72	21

[a]The rainy season starts around July at the Gaize and Shiquanhe stations.



Isotope Analysis, Figure 6 Seasonal changes in weighted-averaged $\delta^{18}O$ and air temperature at the Nagqu, Gaize, Shiquanhe, and Yushu stations.

values decrease correspondingly. Furthermore, $\delta^{18}O$ reaches its lowest value in December, when air temperatures also attain their lows at Nagqu and Yushu. After the monsoon retreat, the westerlies mainly control the moisture sources in the area and the content of atmospheric water vapor rapidly decreases, resulting in sparse precipitation in this region.

Overall, the temperature effect controlled the variation of $\delta^{18}O$ over the measurement period at the four stations. However, the southwest monsoon transports oceanic moisture with low $\delta^{18}O$ into the regions in summer, especially from June to August, resulting in the lower $\delta^{18}O$ values than would be predicted from air temperature alone. Accordingly, the monsoon activities weaken the correlation between $\delta^{18}O$ and air temperature. Before the monsoon onset and after the monsoon retreat, the periods when the westerlies dominate the moisture sources, the $\delta^{18}O$ values correlate significantly with air temperatures.

ISOTOPIC CHARACTERISTICS OF ICE, SNOW, AND GLACIERS

Bhism Kumar
Hydrological Investigation Division, National Institute of Hydrologyl, Uttarakhand, India

Definition and introduction

The isotopic methods are based mainly on analyses of environmental isotope contents (primarily ^{2}H, ^{3}H, ^{18}O). The stable isotopes particularly deuterium and oxygen-18 are useful as tracers in hydrologic systems. They are naturally present as part of the water molecules and their concentration is influenced by physical processes operating within the hydrologic cycle. In many cases the isotopic profile of snow cover gives information about the isotopic variation of those snowfalls that have contributed to snow cover accretion.

Historical background

Dansgaard (1954) first proposed that the ^{18}O content in glacier ice might reflect climatic conditions of the past. Since then, extensive work has been carried out in this field, on both of the large polar ice sheets. The most successful work that has been done in this field is undoubtedly the establishment of the $\delta^{18}O$ profile for the camp century ice core that is 1,390 m deep (Dansgaard and Johnsen, 1969). Another deep ice core, approximately 2,000 m long, has been obtained by drilling through the Antarctic ice sheet at Byrd Station (Ueda and Garfield, 1969) and its $\delta^{18}O$ content measured through its entire length (Johnsen et al., 1972). Although the physical conditions of Byrd Station core are considerably better than those for Greenland (no core pieces were lost or broken), the Byrd Station ice core is much more difficult to interpret due to low accumulation rate, absence of seasonal isotope variation that made it difficult to date. Deuterium profiles in sea-ice cores are rarely described in the literature. Friedman et al. (1961) explained the negative δD values (−2 to −14‰) of ice samples collected on Ice Island T3 and on Drift Station Alpha by the presence of a relatively thin layer of deuterium-depleted water on parts of the surface of the Arctic Ocean during the summer. Gow and Epstein (1972) reported on deuterium concentrations connected with a special sea-ice growth situation in McMurdo Sound, Antarctica.

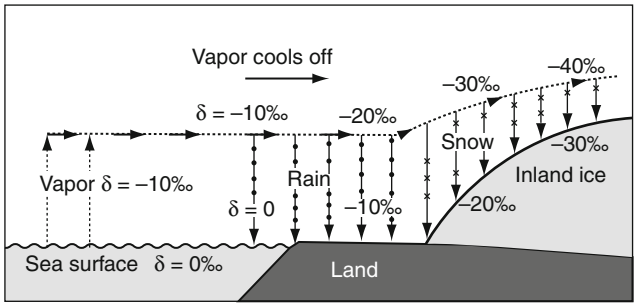
Such long climatic records as those obtained from the two polar ice cores have two main applications: the study of climatic changes as far back in the earth's history as possible and the use of this information for predicting possible climatic changes of the future.

Isotopic characteristics

The important aspect is that the heavier water tends to evaporate slower and condense faster than the lighter ones. Thus, the ratio of the heavy isotopes to the light isotopes is not constant, but changes during condensation and evaporation processes.

In ice cores, usually the ratio of ^{18}O to ^{16}O is measured. Deuterium profiles in ice cores are rarely described in the literature. Gow and Epstein (1972) reported on deuterium concentrations connected with a special sea-ice growth situation in McMurdo Sound, Antarctica. To study these isotopes in glaciers, the best method is the measurement of stable isotopic ratio (Isotopic Fingerprinting). Some other isotopes that have been found important are ^{210}Pb, ^{36}Cl, ^{10}Be, ^{39}Ar, and ^{32}Si. From the decrease in ^{210}Pb activity, firn profiles can be dated. Successful measurements have been performed in Antarctica (Picciotto et al., 1968) and in an Alpine cold Glacier (Gaggler, 1977), which have been used for determining accumulation rates for the last 80–90 years. ^{36}Cl can be detected relatively in small samples if accelerators are used. This study was first conducted in Antarctica (Nishizumi et al., 1979).

During ice ages, the oceans had a higher stable isotope ratio than today (1–2‰ for $\delta^{18}O$), because additional water depleted in ^{18}O was contained in the ice sheets. This has to be taken into account for ice core interpretation. However, for one climate period it may be assumed to be constant. On expeditions that led from the coast of Greenland or Antarctica to the interior of the continent, the mean annual air temperature and the $\delta^{18}O$ of the snow were measured. Since the altitude of the ice sheets increases toward the interior, the air temperature and the $\delta^{18}O$ decrease. It was found that there is a simple linear relationship between

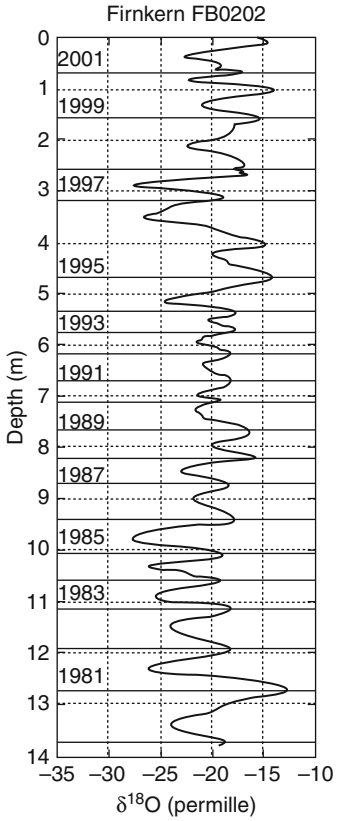


Isotopic Characteristics of Ice, Snow, and Glaciers,
Figure 1 Changes in $\delta^{18}O$ from the first evaporation to the final snow fall (Payne, 1983).

the two variables. To understand this, we have to follow the path of the precipitation from the beginning to the final snowfall. This is shown in Figure 1.

During the first evaporation from the ocean, the heavier isotopes are slower to evaporate than the lighter ones, thus the first water vapor is relatively light compared to the ocean water. The air and thus the water vapor is raised and cooled until the first condensation takes place and clouds are formed. Now the heavier molecules condensate earlier than the light ones, thus the process is reversed and the first raindrops from the clouds may have the same isotope ratio as the ocean water. Now the air mass and thus the cloud is moved, let us say, in case of Antarctica, southward, the heavier isotopes condense earlier, thus the rain or snowfall contains heavier water, whereas the remaining moisture in the cloud gets lighter and lighter. At the edge of the continent, the air is raised due to the increasing altitude of the ice sheet surface, and thus cooled even stronger. (The air temperature decreases both with altitude and latitude.) The farther inland the snow falls, the lower is the isotope ratio, since most of the heavier isotopes have fallen out already at lower latitudes. Thus, we get a relationship between the stable isotope ratio and the temperature, the air had when the precipitation was formed. Figure 2 shows the $\delta^{18}O$ profile of a "shallow" core that has been drilled close to the German Antarctic wintering base "Neumayer." It can be seen that the $\delta^{18}O$ oscillates: we find high values in summer and low values in winter. Thus, one can find the annual layers in the core. The red lines mark the borders between two annual layers. By counting the annual layers, one can determine the age of the ice. This method works only until a certain depth, because, as mentioned above, the ice is compressed under its own weight, and at some point the annual layers become so thin that it is impossible to distinguish single annual layers. Some other dating methods are used for these parts of ice cores, for example:

- Identifying horizons of known age, such as acid layers from dated volcano eruptions.
- Matching features of the $\delta^{18}O$ record with another dated climatic record, such as ocean or lake sediments.
- Radiocarbon dating of CO_2 extracted from air bubbles in the ice.



Isotopic Characteristics of Ice, Snow, and Glaciers,
Figure 2 $\delta^{18}O$ profile of a "shallow" core (Payne, 1983).

Although it is clear, that there is a strong relationship between temperature and isotope ratio, the quantitative conversion of $\delta^{18}O$ to air temperature is still a problem.

There are many different reasons for the persistent uncertainty. The $\delta^{18}O$ is influenced by many other factors apart from air temperature, such as the original isotope ratio of the ocean water (which was different from today during ice ages), the origin of precipitation and the seasonal distribution of snowfall events. Additionally to these meteorological factors, there are glaciological influences. It has to be taken into account, that the ice flows and thus the ice in the core might come from areas of higher altitude, which are cooler than the drilling site. Also, during glacial periods the altitude of the ice sheet was higher than today, thus the ice in the core might originate from a cooler area than today. Scientists have also measured today's temperature in the bore holes of the ice cores. Although the signal is considerably attenuated, one can still find the colder ice ages and warmer interglacial in the cores, and by using physical laws, the scientists can calculate the original temperature profiles, which especially for Greenland, yielded results different from the ones retrieved by measuring stable isotope ratios. So the discussion about this is still going on at present.

Applications of isotope data in glaciology

Accumulation rates

One of the most important parameters for the study of the mass balance of the glacier is the determination of the accumulation rates. The determination of the accumulation rates by the stable isotope method is relatively simple, as far as the firn and the uppermost part of the glacier are concerned. One need only count to the summer maxima down the ice profile and determine the density of the ice. At greater depths, the thickness of the annual layers must be corrected for vertical strain since the time of deposition. Since the strain also depends upon the temperature history and the thickness and slope of the ice sheets, such corrections can be quite complicated. Therefore, the stable isotope method for determining accumulation rate is mainly of importance on the uppermost part of the glaciers, where reliable results are obtained because of the simplicity of the method. The isotopic composition of snow falling in the accumulation area of glacier will differ from place to place and from time to time for the following reason: the altitude effect causes snow falling higher in the accumulation area to have a relatively lower O^{18}/O^{16} ratio. Preliminary studies show that the magnitude of this effect in terms of per mil variation for each 1,000 ft of altitude is 1.8 in Greenland, 1.7 on the west slope of the Sierra Nevada of California, and 0.6 on the Saskatchewan Glacier, Canada (Gat and Gonfiantini, 1981).

On temperate glaciers where the seasonal δ-variations are strongly modified by percolation of meltwater and where there is intensive homogenization, the stable isotope method does not work unless the conditions are favorable.

Runoff ratio

The runoff ratio indicates which part of the precipitation escapes as accumulation and is consequently an important parameter in mass balance studies of temperate glaciers. The validity of isotopic method for determining the runoff ratio rests on the fact that it only requires information about the isotopic composition of the snowpack, after the homogenization is completed, and information about the isotope content of the total precipitation. The isotopic composition of the snowpack can be measured easily in the firn.

Dating of the ice core

Dating of the ice core is closely related to determining the accumulation rate. In both cases, the results are based on counting the summer maxima of the annual *d*-variations. The stable isotope method is valid when the difference between the summer and winter δ-values is not less than 2‰ for ^{18}O and not less than 20‰ for deuterium. Thus, the method works particularly well on the high-polar glaciers where the seasonal amplitude has been found to be preserved in the ice for thousands of years.

According to Dansgaard et al. (1973), Johnsen et al. (1972), and Hammer et al. (1978), the mean thickness (λ) of annual layers depends on the distance from the bottom, that is, $(y)\lambda = f(y)$. The age, t, of a respective ice layer in years can be calculated from the equation,

$$t = \tau \int_{H}^{H-y} \frac{dy}{fy}$$

where τ being 1 year and H the total thickness of the ice sheet. Thus, the determination of λ by stable isotope measurements in different spaced increments of the core gives the age of the ice at the respective increment (Gat and Gonfiantini, 1981).

Paleoclimates

One of the dominating parameters determining the stable isotope ratio of a given precipitation is the temperature of its formation. This is reflected in the seasonal variation of the isotope content. In a similar way, it is to be expected that long-term climatic variations are reflected in the isotope content of the precipitation of the past and should be detectable in ice profiles. The use of stable isotope profiles of glacier ice to record past climatic changes is mainly of interest in relation to polar glaciers. Temperate glaciers are of less interest for this field, mainly for two reasons. First, the ice at the bottom of the temperate glaciers is very young compared with that of the polar glaciers; such a record therefore only spans a very short time period under favorable conditions possible for 2,000 years. Second, the percolating water is found to obliterate the seasonal variations and in some cases strongly to change the original isotopic content of the accumulation (Gat and Gonfiantini, 1981).

Summary

Isotopic studies have been proved useful for solving many environment-related problems. It has several applications in snow, ice, and glaciology. The methods are mainly based on the isotopes ^{2}H, ^{3}H, and ^{18}O because seasonal variations of these isotopes in snowfall can be preserved within the snow cover for a considerable time, especially in polar regions. Several studies have been conducted in this field. But there is still a great scope in studying the seasonal fluctuations and reconstruction of past climatic changes.

Isotope Analysis

ISOTOPIC FRACTIONATION OF FREEZING WATER

Martyn Tranter
School of Geographical Sciences, University of Bristol, Bristol, UK

Definition

Isotopic behavior of water molecules during freezing.

Isotopic composition of water

Water molecules with different molecular weights behave differently during freezing, with the heavier molecules showing a slight preference to enter ice, whereas the lighter molecules have a slight preference to remain as a liquid. The molecular weights of water molecules differ because hydrogen and oxygen have a number of isotopes. Hydrogen has two stable isotopes, ^{1}H and ^{2}H (or deuterium, D), and one radioactive isotope, ^{3}H (or tritium). Oxygen has three stable isotopes, ^{16}O, ^{17}O, and ^{18}O. There are nine possible molecular weights, and isotopic configurations, for water molecules, but almost all water molecules are of three molecular weights because of the low abundance of the heavier isotopes. For example, the D content of a typical water is only 0.0156% of the H content, and the typical relative ratios of ^{16}O : ^{17}O : ^{18}O are of the order of 99.763 : 0.037 : 0.2 (Greenwood and Earnshaw, 1984). The different molecular weights impart slightly different physical properties to the molecules because the vibrational energies of their bonds differ slightly (Table 1). This in turn means that the water molecules fractionate differently between ice and water during freezing. In general, the lighter molecules have bonds that vibrate more quickly, and tend to fractionate or remain in the liquid slightly more that the heavier molecules, whose bonds vibrate slightly less and have a slight preference for the solid ice.

Nomenclature of isotope fractionation

The degree to which the water isotopes fractionate into ice is defined by the Fractionation Factor, α (Equation 1):

$$\alpha = \frac{R_i}{R_w} \tag{1}$$

where R is the ratio of the heavy to light isotope (e.g., $^{18}O/^{16}O$ and $D/^{1}H$) in ice, i, and water, w (Faure, 1986; Hoefs, 2004). Values of α are dependent on the rate of freezing in particular, and are quite close to 1 see (Table 2), showing that there is only a slight fractionation of the isotopes between ice and water. However, these small changes are relatively easy to measure both accurately and precisely by mass spectrometry. The values of R usually differ only slightly between many different ices and waters, and so their R values are expressed by the δ notation to make comparison of the R values easier. The δ value is defined by reference to the R value of Vienna standard

Isotopic Fractionation of Freezing Water, Table 1 Some physical properties of the three most common isotope combinations of water (Hoefs, 2004)

Property	$^{1}H_2{}^{16}O$	$^{2}H_2{}^{16}O$	$^{1}H_2{}^{18}O$
Density @ 20°C (g/cm^3)	0.997	1.0151	1.1106
Boiling Point (°C)	100.0	101.42	100.14
Temperature of maximum density (°C)	3.89	11.24	4.30

Isotopic Fractionation of Freezing Water, Table 2 Typical values for the fractionation factors (α) of the stable isotopes of hydrogen and oxygen in water and ice during freezing

Comment	α D	$\alpha^{18}O$	Source
Equilibrium values	1.0171–1.0235	1.0026–1.0031	(Ferrick et al., 2002)
Fast – slow freezing rates	1.007–1.015	1.0005–1.0027	(Ferrick et al., 2002)
River ice values	1.0212	1.00291	(Ferrick et al., 2002)
Subglacial lake Vostok values	1.0208	1.00310	(Jouzel et al., 1999)

mean ocean water (SMOW), as shown in Equation 2, and gives rise to positive or negative values. Positive values denote samples enriched in the heavier isotope and are often referred to as "heavy" values, whereas negative values denote samples enriched in the lighter isotope and are often referred to as "light" values (Faure, 1986).

$$\delta_{\text{sample}} = \frac{(R_{\text{sample}} \div R_{\text{SMOW}}) - 1}{1000} \quad (2)$$

Isotope fractionation during freezing

The heavier isotopes fractionate into ice during freezing, and so the remaining water becomes enriched in lighter isotopes. At equilibrium, the ice has δD and $\delta^{18}O$ values which are +17.1‰ to +23.5‰ and +2.6 to +3.1 more positive or "heavier," respectively, than the water. These differences can be derived from the first line of Table 2, using Equation 3, which is derived from Equations 1 and 2.

$$\delta_i - \delta_w = 1000(\alpha - 1) \quad (3)$$

The extent of fractionation critically depends on the rate of freezing. Rapid rates of freezing prohibit the fractionation, so giving rise to the smaller α values given in the second line of Table 2, whereas slower rates of freezing give rise to α values that approach equilibrium values (Ferrick et al., 2002).

The $\delta^{18}O$ and δD of most natural precipitation, including snow, have values that lie on or near to the Global Meteoric Water Line (GMWL), defined as (Craig, 1961)

$$\delta D = 8\delta^{18}O + 10 \quad (4)$$

The values of the mean annual $\delta^{18}O$ of precipitation are positively associated with mean annual air temperature, and hence snow typically has relatively low (or light) values, particularly at high latitude (Dansgaard, 1964). A particular consequence of the progressive freezing of a closed body of water, such as at the bed of a glacier, is that the water and ice samples have an isotope composition that moves off the GMWL (Jouzel et al., 1999). The slope of the association is lower (i.e. <8) because condensation processes in clouds determine the slope of the GMWL, which enhance the fractionation effects of water molecules with different molecular weights more so than freezing does (Faure, 1986). Finally, progressive freezing of a closed water body drives the isotopic composition of the remaining water increasingly lighter, and very light isotope values can be produced in the residual waters. This process is called Rayleigh Fractionation (Faure, 1986; Hoefs, 2004).

Synonyms

Isotopic fingerprinting

Definition

An isotopic signature (also isotopic fingerprint) is a ratio of stable or unstable isotopes of particular elements found in an investigated material. The atomic mass of different isotopes affects their chemical kinetic behavior, leading to natural isotopic separation process.

Expression

Stable isotope ratios are normally reported as δ values in units of parts per thousand (denoted as ‰, i.e., per mill) relative to a standard of known composition.

$$\delta = \left(R_{\text{sample}} - R_{\text{reference}}\right)/R_{\text{reference}}$$

where R's are the ratios of the $^{18}O/^{16}O$ and D/H isotopes in case of water.

The difference between samples and references are usually quite small, δ values are, therefore, expressed in per mille differences (‰), that is, per thousand, δ(‰) = δ × 1,000.

$$\delta(‰) = [(R_s - R_r)/R_r] \times 10^3 = [(R_s/R_r) - 1] \times 10^3$$

If δ value is positive, it refers to the enrichment of the sample in the heavy-isotope species with respect to the reference whereas negative value corresponds to the sample depleted in the heavy-isotope species. The reference standards normally considered are SMOW (Standard Mean Oceanic Water) and VSMOW (Vienna Standard Mean Ocean Water).

K

KAME AND KETTLE TOPOGRAPHY

Amit Kumar
Department of Geology, Centre of Advanced Study in Geology, Panjab University, Chandigarh, India

Definition

A kame is a stratified geomorphologic feature which is created by deposition action of glacier meltwater, an irregularly shaped hill or mound composed of sand, gravel, and till, commonly associated with end moraine. A kame may occur as an isolated hill but in general each kame is one mound in a low-lying terrain of many hummocks, terraces, ridges, and hollows. Kames are often associated with kettle holes. Kettles are depressions in the outwash plains, which formed due to the melting of large ice blocks and this is referred to as kame and kettle topography. Kame and kettle topography is an indicator of a high-discharge supraglacial and englacial drainage system of a glacier in the final stages of melt, and large quantities of glacially derived debris associated with meltwater.

Origin

Glacier meltwater that exists in the ablation area of glaciers during the melting season flows down on the glacier surface, in the ice, or on the bedrock, making complex systems of drainage channels. Deformation of ice, movement of glacier, freezing, and melting processes influence on the position and form of channels. Meltwater escapes through numerous small and temporary streams. These streams carry sediments for longer distances and deposit them in various forms. Sometimes, these streams also carry some ice. Thus, the deposition of sediments after the ablation (melting of glacier) is called glaciofluvial deposits and the landforms resulting from such deposits are called glaciofluvial landforms. The sediments are deposited in the form of low alluvial fans (if deposited on land) or deltas (if deposited in standing water).The glaciofluvial landform include kame, kame terrace, kettle, kettle holes, outwash plains, etc.

KATABATIC WIND: IN RELATION WITH SNOW AND GLACIERS

Amit Kumar
Centre of Advanced Study in Geology, Department of Geology, Panjab University, Chandigarh, India

Synonyms

Drainage wind; Fall winds; Piteraq and williwaw

Definition

Katabatic wind (Greek: *katabaino* – to go down) is the common name for downslope winds flowing from high elevations of mountains, plateaus, and glacier down their slopes to the valleys or planes underneath. Such winds are sometimes also called fall winds. Particularly, it is a wind that carries high density air from a higher elevation down a slope under the force of gravity. This occurs on the largest scale as the outflowing winds from Greenland and Antarctica. In Greenland these winds are called Piteraq

Vijay P. Singh, Pratap Singh & Umesh K. Haritashya (eds.), *Encyclopedia of Snow, Ice and Glaciers*, DOI 10.1007/978-90-481-2642-2,

and in South America as well as in Alaska, it is wind known as a Williwaw.

Alpine valleys produce their own local wind systems as a result of thermal differences. The cold air slides down the slope under gravity during night. The radiative cooling of the ground surface under clear and calm conditions during night provides colder air near the surface. The nighttime downslope movement of the colder air is referred to as katabatic winds. The anabatic wind is developed prior to the daytime, whereas katabatic drainage is developed in the night. The katabatic winds usually flow gently downslope with low speed, but greater speeds are also experienced when the depth of cold air is large and the slope is higher.

KILIMANJARO

Douglas R. Hardy
Climate System Research Center and Department of Geosciences, University of Massachusetts, Morrill Science Center, Amherst, MA, USA

Definition

Kilimanjaro is Africa's highest mountain (5,895 m), located in northern Tanzania just south of the Kenya border (3°4′S; 37°21′E). At the seasonally snow-covered summit, the extent of glacier ice is now less than 2 km^2, roughly half of that remaining on the continent.

Overview

The cryosphere is sparsely represented in Africa, primarily on a small handful of the continent's highest mountains. Among these is Kilimanjaro, the "white roof of Africa," whose glaciers have achieved notoriety far out of proportion to their size (miniscule), importance as a water resource (negligible), or potential contribution to sea-level rise (zero). Yet, Kilimanjaro's summit mantle of *Snow* (qv) and *Ice* (qv) is starkly beautiful, and thus among the mountain's most fascinating, distinctive, and best-known attributes. Thousands of international visitors are attracted annually, bringing valuable tourism revenue to Tanzania.

Geographic setting

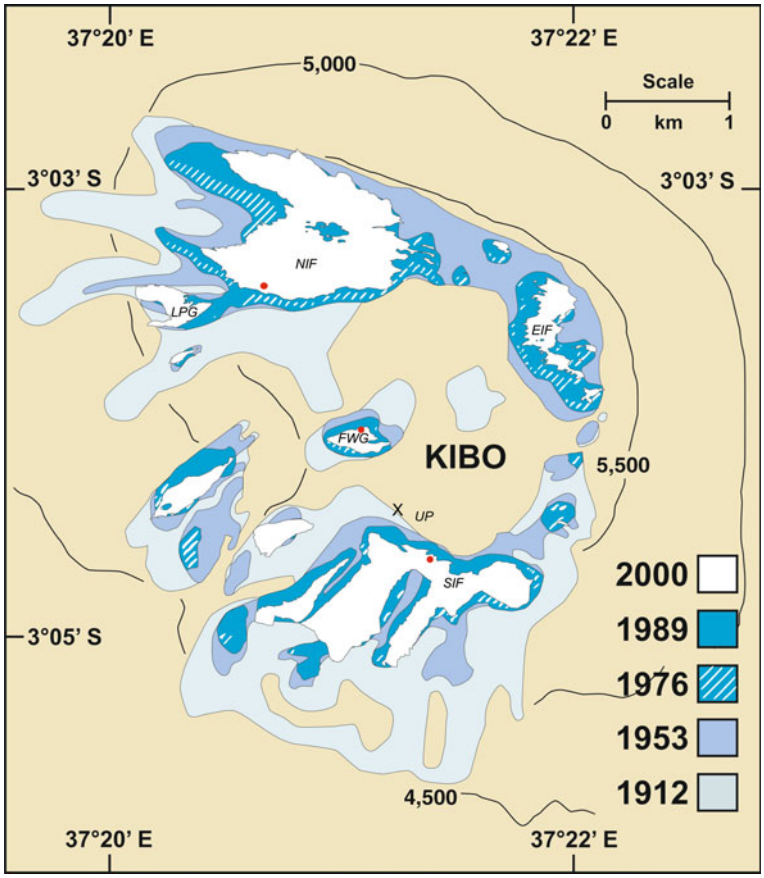
Kilimanjaro is a massive, dormant volcano in Tanzania, built up of both lava flows and pyroclastic material, situated roughly equidistant (~300 km) south of the Equator and west of the Indian Ocean. Three primary volcanic centers are thought to have been active sequentially since the Pleistocene, which together form the Kilimanjaro massif: Shira (4,005 m), Mawenzi (5,140 m), and Kibo (5,895 m). At the apex of Kibo is a relatively flat caldera measuring 1.9 by 2.7 km (Figure 1); Uhuru Peak is the highest point along the southern scarp, ~180 m above the caldera floor.

History of cryospheric research on Kilimanjaro

The earliest scientific discussion of snow and ice on Kilimanjaro began with the initial European "discovery" of the snowcap by Johannes Rebmann in 1848. English Geographers were incredulous, and dismissed Rebmann's report for more than a decade (Meyer, 1891). Hans Meyer climbed nearly to the crater rim in 1887, reaching the summit 2 years later on 6 October 1889 (Meyer, 1891). Additional European scientists soon reached the summit area and published their qualitative findings. Logistical constraints rendered ascents and fieldwork considerably more difficult than at present, yet virtually every account describes features and processes not unlike those of today. Most also discuss the decreasing extent of ice, and many predict disappearance – within decades – of either individual glaciers or all of the mountain's ice.

Mid-twentieth-century perspectives on Kibo's summit and slope glaciers were provided by Humphries (1959), Downie and Wilkinson (1972), and Hastenrath (1984). Henry Osmaston (1989) then published an analysis of glacier *Moraine* (qv) as mapped from aerial photographs, which for the first time quantified the nineteenth century extent of glaciers on the mountain. Hastenrath and Greischar (1997) built upon Osmaston's work and provided the first cartographic documentation of ice recession. Thereafter, a resurgence of research on Kibo began in February 2000 with *Ice Core* (qv) drilling, aerial photography, and installation of an automated weather station (AWS) on the Northern Icefield (Hardy, 2002; Thompson et al., 2002). A *Network of Stakes* (qv) has expanded steadily since 2000 to represent most of the glacierized area at the summit, and two additional AWS are now operating on summit glaciers (Mölg et al., 2008).

Today, as during the nineteenth century, snow and ice on Kilimanjaro are again controversial. A new ice-extent map released in 2001 was accompanied by a prediction that the glaciers could disappear within 20 years (Irion, 2001). Kilimanjaro was quickly employed to symbolize the impacts of global warming (e.g., Greenpeace, 2001). However, cautious statements by scientists such as Kaser et al. (2004, p. 337) that ". . . mass loss on the summit . . . is little affected by air temperature," or Mote and Kaser (2007, p. 325) that ". . . loss of ice on Mount Kilimanjaro cannot be used as proof of global warming," were eagerly



Kilimanjaro, Figure 1 Kibo peak of Kilimanjaro, with remnants of the *ice cap* (qv) that once encircled the summit. The crater is the area surrounded by ice and labeled "KIBO." Contours are in meters. Solid circle symbols indicate location of 2000 ice-core drilling sites (Thompson et al., 2002), and the ice extent is shown for five epochs (1912–1989 after Hastenrath and Greischar (1997), 2000 after Thompsen et al. (2002)). NIF, EIF, and SIF are the former Northern, Eastern, and Southern Ice Fields (respectively), *FWG* Furtwängler Glacier, *UP* Uhuru Peak (5,895 m), and *LPG* Little Penck Glacier. Automated weather stations currently operate near the NIF and SIF drill sites.

embraced by those seeking to cast doubts about global warming (e.g., GES, 2004). Resolution of the modern-time controversy awaits a comprehensive understanding of how Kilimanjaro's summit climate has been impacted by large-scale atmospheric circulation changes; this effort is well underway (Mölg et al., 2009; Thompson et al., 2009; Winkler et al., 2010).

Climate

Kilimanjaro rises 5,000 m above the surrounding plains, extending halfway through the tropical atmosphere to ~506 hPa. Climate varies dramatically and sharply with elevation, causing the mountain's dramatic ecological zonation. Whereas air temperature drops steadily and uniformly with elevation, the annual precipitation amount increases and then decreases with elevation. Southern and southwestern slopes reach a maximum annual total at ~2,200 m (Hemp, 2006), but northern slopes are drier (Coutts, 1969; Hemp, 2006). This precipitation pattern accounts in part for the asymmetrical distribution of glaciers on Kilimanjaro.

Precipitation at the summit annually totals only ~10% of that received by the forest below, and snow is the predominant form of precipitation at elevations above the mean annual freezing-level altitude, roughly 4,700 m (Hastenrath, 1984). Snowfall can occur at any time of year, but is primarily associated with northern Tanzania's two seasonally-wet periods, the November–December "short rains," and the "long rains" of March to May. Summit climate is thus best defined by seasonal humidity fluctuations, and by strong diurnal cycles driven largely by the tremendous daily fluctuation in incoming solar radiation; the following synopsis is based on AWS measurements made on the Northern Ice Field (NIF) since 2000 (Hardy, in prep.).

Summit climate is most stable through an extended dry season centered on July and August. This interval is

characterized by annual minima of humidity, snowfall, air temperature, and wind speed, and by increasing solar irradiance after the solstice minima.

By the middle of September, the beginning of an important seasonal change is marked by rapidly increasing wind speed, and an increase in air temperature. Solar irradiance gradually reaches an annual maximum as the sun moves into the southern hemisphere. Humidity increases slowly during September, rapidly into October, and continues climbing steadily into December. The "short rains" typically begin in mid-October, although the timing and magnitude vary from year to year – with important implications for glacier mass balance. For example, September and October (and even November) can be a time of considerable ablation (e.g., Hardy, 2003), when net solar irradiance remains high in the absence of snowfall, accompanied by increasing turbulent energy transfer as wind speed, air temperature, and humidity are increasing.

By mid-January the short rains are usually ending, with both humidity and snowfall dropping quickly to early February minima and a brief secondary dry period. The long rains then typically begin in early March, with humidity and snowfall continue increasing into April, and snow accumulation typically continues into May. Then, air temperature decreases rapidly, wind direction backs slightly from east toward north, and humidity drops drastically. By June, another dry season is beginning.

Mean annual temperature at the summit is approximately −7°C, with monthly means ranging only 1.3°C. On the NIF, daily temperature ranges between an average low of −9° and an average maximum of −4°C. Thus, air temperature on the glaciers is consistently below freezing; extreme radiational cooling at night brings surfaces temperatures below −15°C (to −27°), so a considerable cold content must be overcome each day before ablation of the snow or ice surface can occur.

Kilimanjaro glaciers

Currently, there are roughly eight glaciers on Kibo, some distinct and some in clusters as formerly larger bodies break up (Figure 1). These are all remnants of a once tenfold larger *ice cap* (*Ice Caps* qv) that encircled the volcano's summit in the mid-nineteenth century, filling at least portions of the crater itself while also spilling outward and down the slopes. The areal extent of this earlier ice cap – likely the maximum *Holocene* (*Holocene Glacier Fluctuations* qv) extent – was 20 km^2, as determined by mapping moraines (Osmaston, 1989). Subsequent ice recession through the twentieth century was "dramatic and monotonic" (Hastenrath and Greischar, 1997, p. 459), based on four area determinations averaging 26 years apart and with unknown errors; updated maps show continuing retreat (Figure 1; Thompson et al., 2002; Cullen et al., 2006; Thompson et al., 2009).

By the beginning of the twentieth century, many of the ice cap's broad lobes had been named after early explorers (see Hastenrath, 1984 for list). These names remain in use, despite morphological changes. On the south-facing slope below the crater's sharp southern rim, a Southern Ice Field has encompassed what are now or will soon be separate entities, the Heim, Kersten, Decken, and Rebmann Glaciers. Within the crater, the Furtwängler Glacier has been the only ice entity for several decades, splitting into two parts by 2007. Straddling the crater rim's north side, the Northern Ice Field (NIF) comprised slightly more than half of Kibo's total ice area until the 1970s, when an Eastern Ice Field (EIF) became distinct. Although the EIF has since broken into numerous entities, the NIF remains Kibo's largest body of ice. Extending down north- and northwest-facing slopes below the NIF are what remains of the Credner, Drygalski, and Great Penck Glaciers. The Little Penck Glacier, prominently visible today from western ascent routes, separated from the NIF during the 1990s (Figure 1) and has considerably decreased in area since 2000.

All ice masses on Kibo are here termed glaciers for discussion purposes, although most ice is now static and some entities are just tiny fragments. Ice thickness is poorly known due to limited measurements, with a probable maximum of ∼50 m for the Northern Ice Field.

Little was known of energy and mass balance details on Kibo's glaciers until 2000, other than that the total ice area had been decreasing for over a century. However, early observations were astute; Geilinger (1936, p. 9), for example, recognized that glaciers on the outer slopes and those of the crater behaved differently "... with regard to the melting process." Building upon this distinction, Kaser et al. (2004) subdivided summit glaciers into (1) horizontal glacier surfaces, the typical glacier regime studied; (2) slope glaciers; (3) near-vertical margins; and (4) basal surfaces.

Horizontal glacier surfaces

Most glaciers on Kibo's summit have horizontal or nearly horizontal upper surfaces, unbroken by crevasses. At times the surfaces are flat and smooth, but this changes from year to year. On a whole-glacier scale, the surfaces are often comprised of "massive steplike features" (Gillman, 1923, p. 17); at smaller scales one sometimes sees "fantastic ice-shapes" (Sampson, 1965, p. 121) or ice "honeycombed in many places to a depth of over 6 ft, and weathered into countless grooves and ruts and pointed spikes" (Meyer, 1891, p. 147; see also Figure 2). Since 2000 this regime has been the focus of measurements and modeling (e.g., Mölg and Hardy, 2004; Mölg et al., 2008), and is today the best known of the four regimes. Mass balance here governs glacier thickness, and balance fluctuations are largely independent of ice area, in the absence of flow. Although details of mass exchange at this surface remained unknown until 2000, historical accounts suggest that twentieth century ice thickness probably never averaged more than about twice that of today.

Kilimanjaro, Figure 2 Three views of Kibo summit glaciers, taken: (**a**) September 28, 2008, (**b**) January 30, 2009, and (**c**) October 7, 2007. Note fluting of vertical walls (**a**, **b**) and horizontal-surface penitentes (bottom of image **a**, **c**). For scale, note people in image (**b**) and ablation stake at ice surface in image (**c**) (~0.5 m visible; upper right-hand corner of image).

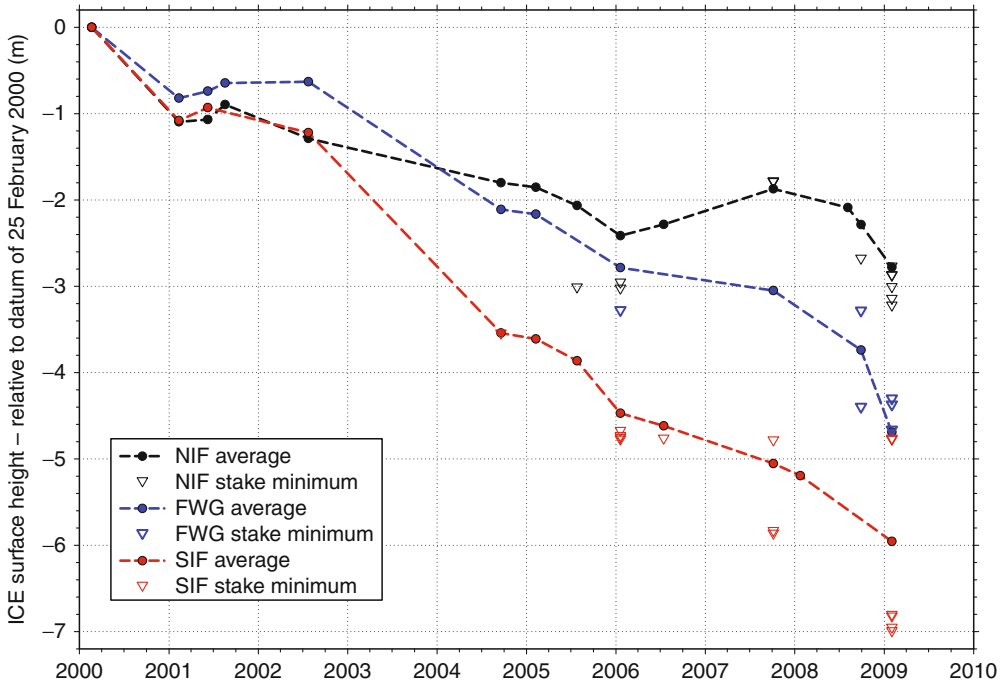
Horizontal and slope glacier surfaces on Kibo are typically comprised of hard glacier ice, appearing and behaving as expected for ablation-zone ice of density approaching 900 kg/m^3. A thin mantle of *Seasonal Snow Cover* (qv) blankets the ice during most wet seasons. Snow – or snow transitioning to superimposed ice – persists from one wet season to the next when snowfall is above average.

In the current climate at Kibo's summit, the horizontal surface, multiyear mass balance is negative – and the glaciers are thinning (Figure 3). Indeed, the hypothetical ELA has probably been above summit-level for some time (Humphries, 1959; Kaser and Osmaston, 2002). Nonetheless, speculation continues as to whether the ELA might be lower on the south slopes (e.g., Kaser and Osmaston, 2002; Mölg et al., 2009), despite little evidence.

Mass loss on horizontal surfaces is resulting from a predominance of negative energy balance, due to net radiation receipt as controlled by *Albedo* (qv; Mölg and Hardy, 2004; Mölg et al., 2008). Field measurements of mass balance support these modeling results. Mass is being lost from surfaces through both *sublimation* (*Sublimation from Snow and Ice* qv) and *melting* (*Melting Processes* qv); for a 1-year period March 2001 through February 2002, sublimation accounted for 86% of mass loss at the NIF AWS site. Yet, some areas clearly experience a higher proportion of melting, as a high degree of both spatial and temporal variability exists in surface characteristics and processes (Figure 3). Accordingly, simple generalizations based on point-scale modeling (e.g., Mote and Kaser, 2007) are questionable.

One important suggestion of recent field measurements is that the rate of mass loss from horizontal surfaces may be increasing (Thompson et al., 2009), even without a demonstrable change in forcing. Continuing ablation is concentrating particulate matter (i.e., dust) on an increasingly older surface, decreasing albedo and thus increasing net radiation receipt and accelerating ablation. Indeed, in the vicinity of the NIF weather station and *Ice Core* (qv) sites, the glacier surface is almost certainly older than 57 years, a figure based on ^{36}Cl measurements in the ice cores (Thompson et al., 2002). More recent ^{14}C-dating of organic material indicates that the surface could be over 300 years old (D. Hardy, 2004, 2009), although it is unlikely that the surface age is uniform, given the considerable spatial variability in accumulation and ablation patterns (e.g., Figure 3).

Understanding horizontal-surface processes and mass balance is important, because these control what is revealed by ice cores penetrating through layers of accumulation, and previously exposed ablation surfaces. Six cores were drilled on Kibo through three different ice entities (see Figure 1). In the absence of reliable ^{14}C dates from the core, the resulting chronology was developed – necessarily – by assuming an invariant accumulation rate



Kilimanjaro, Figure 3 Ice surface height change on three Kibo summit glaciers, from measurements at mass balance stakes. In general, only one stake per glacier was monitored through 2004, and 3–19 stakes each subsequently; average values shown. Triangles symbolize minimum height change at individual stakes that ablated out and fell over between measurements (values were used in averages). Punctuating the overall thinning trend are intervals of positive mass balance due to superimposed ice formation. Resolution of height fluctuations between these discrete stake measurements is not possible.

(Thompson et al., 2002). This record, however uncertain (e.g., Gasse, 2002; Kaser et al., 2010), will endure until an alternative chronology is provided by better dating.

Slope glaciers

Glaciers currently extend down from Kibo's crater rim in only a few cases (Figure 1). These include the Kersten and Decken Glaciers on the south side, along with the Rebmann Glacier to a minor extent, all inclined at 30–40° and all remnants of the former Southern Ice Field. The Credner Glacier still extends down the northwest flank. Additional glaciers and small ice bodies remain on the slopes but are no longer connected to ice at the crater rim. These include the Heim and Great Barranco Glaciers on the southwest flank, and the Little Penck remnant on the west side. Even by the mid-1930s, Geilinger (1936, p. 12) referred to such ice as "... independent dead glaciers of the outer slopes."

At their late-nineteenth century maximal extent, revealed by moraines, slope glaciers extended down as low as 4,400 m (Osmaston, 1989), and as recently as 1971 there were seven tongues reaching below 4,870 m (Messerli, 1980). Today, glacier ice is scarce below 5,000 m, likely with an increasing proportion buried under a mantle of debris (Humphries, 1959; Downie and Wilkinson, 1972; Young and Hastenrath, 1991; Kaser et al., 2004).

To an even greater extent than for horizontal ice surfaces at the summit, some slope glacier surfaces are today quite dirty, due to deposition of wind-blown dust (e.g., Figure 2c). This inorganic matter is being concentrated, due to a prolonged period of negative mass balance, and is accelerating mass loss by changing the energy balance.

Slope glacier meteorological measurements begun in 2005 have allowed energy balance modeling for these surfaces. To date, energy and mass balance characteristics appear similar to those on the NIF horizontal surface, with even a slightly higher proportion of mass loss to sublimation (Mölg et al., 2008).

Near-vertical ice margins

Vertical or near-vertical margins are a special characteristic of Kilimanjaro's summit glaciers (Figure 2; Winkler et al., 2010). Typically, the vertical surfaces are fluted, and "sometimes slightly undercut at the base" (Downie and Wilkinson, 1972, p. 40). Such margins have been reported since the earliest observations (e.g., Meyer, 1891; Gillman, 1923).

Ablation at the vertical margins is driving the areal recession revealed by mapping (e.g., Hastenrath and Greischar, 1997). Although ice retreat is probably the best-documented environmental change occurring high on the mountain, our understanding of vertical-wall ablation processes remains incomplete, despite the important

contribution of Mölg et al. (2003) confirming early speculation that retreat is governed by energy from direct solar radiation (e.g., Geilinger, 1936). Melting is the primary mechanism by which vertical walls retreat (lose mass), and measurements confirm that the ice temperature often reaches 0°C during the day when seasonally irradiated (Winkler et al., 2010). In addition, collapse features (calving) can be observed around most summit glacier margins, and must also be considered a mechanism of vertical margin ablation, as speculated by Downie and Wilkinson (1972).

Vertical ice exposures on Kibo nicely illustrate stratification, or the sedimentary banding associated with accumulation over time, and these can often be traced laterally for considerable distances. Notably, especially from the perspective of ice-core interpretation, some bands appear to represent buried surfaces that suggest a break in snow accumulation (i.e., missing time intervals), or at which ". . .there appears to have been marked erosion of the ice surface before further accumulations of snow" (Humphries, 1959, p. 477). Such unconformities are sometimes marked by dirt bands, which Downie and Wilkinson (1972, p. 42) described as locally common but "almost nonexistent" on a larger scale. Especially at the upper end of the southern glaciers, unconformities sometimes illustrate an angular discordance with the overlying stratigraphy, a phenomenon awaiting explanation.

Basal surfaces

Kibo glaciers rest primarily on volcanic sand, and to a lesser extent on bedrock. During February 2000 ice-core drilling (Thompson et al., 2002), the NIF basal temperature was −0.4°C, and 0°C was measured within the SIF. The NIF 10-m-depth temperature of −1.2°C suggests that meltwater is transporting heat energy into the glacier, given the −7°C mean annual air temperature.

Little is known about the spatial variability and magnitude of geothermal heat flux on Kilimanjaro, especially relative to that beneath the glaciers. However, fumeroles are present within the inner crater, and even prior to their first observation by W.H. Tilman in 1933, Jäger (1909), Gillman (1923), and Geilinger (1936) all speculated that volcanic heat might be influencing ice recession. Local-scale glacier impacts, apparently due to steam venting, have been observed and reported (e.g., Kaser et al., 2004).

Kilimanjaro snow

Snow on Kibo is ephemeral, meaning that within a relatively short period of time (i.e., minutes to months) it either ablates and disappears, or is transformed into glacier ice. Here, the term snow refers exclusively to solid precipitation, or that which has accumulated as snow cover on either glacier or crater surfaces. Although glaciers are a perennial and long-term feature of Kilimanjaro, snow cover is not – and the historical literature indicates that snow has always come and gone at high frequency (∼annual).

Few early explorers or mountaineers made snow depth measurements, but a seasonal absence of snow has been noted since the first observations. For example, Meyer (1891, p. 316) remarked that in October ". . .when all the snowfields had disappeared, there was likewise comparatively little snow to be met with on the ice-cap." Sampson (1965, p. 123) wrote that from August to October "the chances of finding any snow patches. . . are very poor at heights over ∼4,000 m." Additional evidence for the seasonal absence of snow in the past comes from historical photographs, which cannot easily quantify snow depth but nicely document times when snow is absent.

Snowfall events can be brief, such as those associated with afternoon convection (e.g., graupel), or can persist for multiple days. Wet-season events are typically of longer duration and yield the greatest accumulation. Within the past decade, seasonal snow accumulation on the glaciers of ∼1 m has been noted at least twice (early in 2001, 2007; D. Hardy, 2004, 2009), with lesser accumulations on unglacierized portions of the crater. Anecdotal accounts from guides suggest that snowfall magnitude has diminished in recent decades, although no reliable long-term station data for precipitation exist from above ∼1,800 m on Kibo. The greatest documented accumulation is that reported for the 1961–1962 combined wet seasons, involving "snowfall of over six feet," much of which ". . .was still present more than a year later" (Segal, 1965, p. 126). The extent to which this interval was unusual remains unknown, as summit visitation is much less frequent during the wet seasons.

Once deposited, ablation of snow cover from glacier and crater surfaces involves both melting and sublimation, based on observations and energy balance modeling (Mölg and Hardy, 2004; Kaser et al., 2004; Mölg et al., 2008, 2009). Of these two processes, melting is the more readily observable, both on and off the glaciers. Although sometimes difficult to distinguish from ice melt, evidence for snowmelt includes icicles, supraglacial meltwater ponds, areas of thin, water-saturated snow, and rarely, meltwater runoff. Melting at the summit is not a recent development, for Humphries (1959, p. 477) observed "melting ice and pools of melt water at the summit during the day." Sublimation of snow is often indicated by the presence of penitentes (Figure 2a, c), which form over both ice and crater surfaces in the intense radiation environment on Kibo (cf. Lliboutry, 1954). With fully developed penitentes, melting ice or wet crater sand may be present between the spikes. Although present recently in sufficient density and height to impede glacier travel, penitentes are transient features, today and in the past. Gillman (1923, p. 18) for example, did "not come across penitents" on his single trip to the summit, yet their presence in 1929 was noted by Geilinger (1936). As with other aspects of the cryosphere on Kibo, spatial and temporal variability render generalizations difficult.

Lastly, recent research highlights the extreme sensitivity of horizontal glacier surfaces to the variability of snowfall frequency and amount. By governing albedo

variability, and thus net receipt of solar radiation, snowfall has emerged as the key atmospheric variable controlling ablation and mass balance (Hardy, 2003; Mölg and Hardy, 2004; Mölg et al., 2008, 2009). Figure 3 illustrates that the system is especially sensitive to the interannual variability of snowfall during the short rains (November–December).

Summary

Currently, there are ~8 distinct ice entities on Kibo, together covering a total area of less than 2 km^2 and all remnants of a once larger ice cap. The summit glaciers are relatively flat, with near-vertical margins, and the slope glaciers today are concentrated on the mountain's southwest- and northwest-facing flanks. Glaciers on Kilimanjaro are a product of climatic conditions at the summit that no longer exist, as no area of accumulation has existed for many decades and perhaps since the current recession began. Today, as in the past, snow cover on the mountain is seasonal and subject to considerable interannual variability. Measurements and modeling in recent years have demonstrated that the mass and energy balances on horizontal ice surfaces are very sensitive to the magnitude and frequency of snowfall events – perhaps increasingly so as dirt concentration increases on exposed, ablating ice surfaces.

KUNLUN MOUNTAINS

Jingshi Liu
Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Haidian district, Beijing, China

Definition

Kunlun Mountains extend about 2,500 km from the Pamirs/China in the west to the Mount Yuzhu in Sichuan, China, in the east, and have an average elevation of 5,000 m. Their highest mount, Muztag, is 7,723 m. In this region there are 6,580 glaciers with a total area of 10,844 km^2, and an ice volume of 1,175 km^3, which corresponds to about 72% of the glacier area in the whole Kunlun (Liu, 2000). The West Kunlun Mountains lies in the western part of the Tibetan Plateau; the largest glaciers mostly 20–30 km long are distributed in the high mounts between Tianshuihai Pass and the southern Yurunkax River basin; and the alpine type glaciers are usually developed on the West Kunlun where the lands are severely cut and highly shadowed. Ice cap (flat-topped glacier), slope glaciers, and the valley glaciers are mainly developed on the south slope due to advantageous topographical and climatic conditions.

Introduction

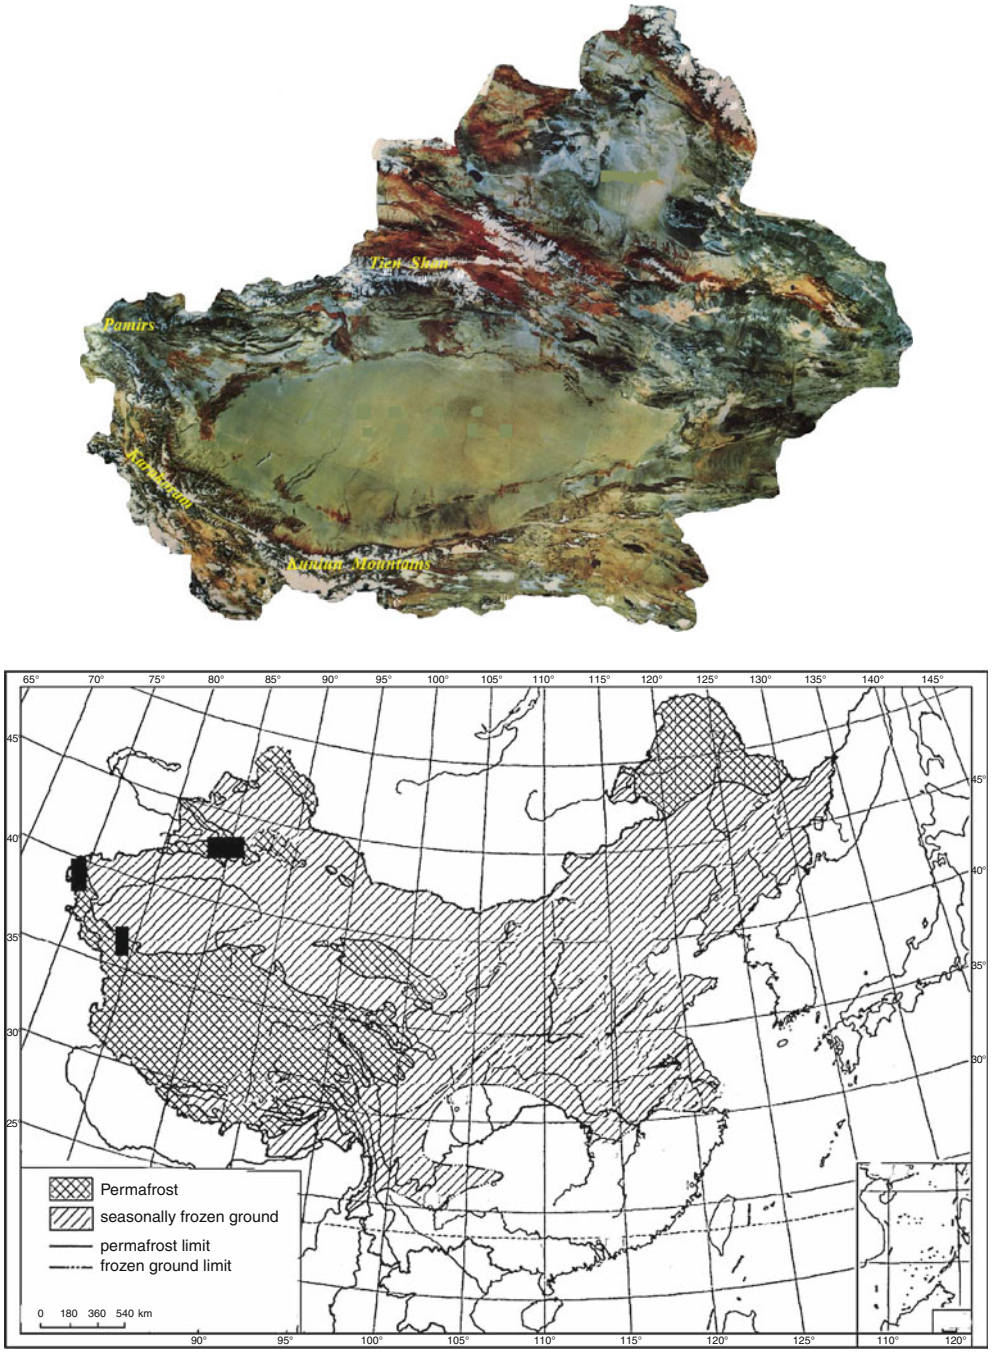
Researchers have estimated increasing greenhouse gases which can cause change in regional temperature and precipitation. The change in climate may have affected the hydrological cycle, such as precipitation form, snow accumulation and meltwater, evapotranspiration, streamflow, and its recharge to groundwater as well (IPCC, 2007).

The landform of the southern Tarim basin is characterized by the three huge mountains: the Pamirs/China, the West Kunlun, and Karakoram Mountains; all rivers originate from the mountains and drain into their basins (Figure 1). Typical snow and glacier-fed rivers, the Hotan and Keriya, are from the glaciated center at the largest icecap, and Guliya from the West Kunlun flow into the Tarim basin.

The land surface on the upstream of the watersheds is characterized by snow and glacier cover and a little grassland, and on the downstream by Gobi and desert where rainfall seldom produces runoff due to strong evaporation except for storm rainfall. Since their upper streams are covered by a great number of glaciers and snowpacks where there is much precipitation in summer, stream flow occurs also in the summer (June–September), and there is a close linear relationship between summer flow and air temperature, as the former contributes 70–90% of stream water annually. With the rise in temperature and increase in rainfall, the maximum monthly runoff in July contributes about 30% of the annual runoff, and the minimum in February or March contributes only 1.2–1.8%. Eighty percent of their drainage areas are over an altitude of 3,000 m; it means streamflow is closed to the exchange between heat and water within the glacier system in the high mountains. Meanwhile, due to hot weather and rainy season in July and August annually, their combined role causes annual maximum floods. According to hydrological records, more than 90% of the maximum floods occur during the period of late July to early August.

The Hotan River basin is the largest basin in the west Tibet Plateau and includes parts of the Karakoram and the south territories of the Tarim basin in the west China. The basin covers an area of approximately 34,558 km^2, which encompasses a wide variety of climatic conditions, including the periglacial, the alpine permafrost, and desert zones. Glaciers, snow cover, and patterned ground features associated with continuous and discontinuous permafrost are found in the south, while agriculture and stock raising are important economic activities in the northern part. Figure 1 shows the features of permafrost regions in west China and in the Hotan River basin. The drainage area is located in the seasonal frozen ground and alpine permafrost region. The elevation ranges from 1,860 to 7,167 m with an average altitude of 4,200 m estimated by the DEM, and the low limit of alpine permafrost is about 4,400 m, thus approximately 45% of the basin lies within the continuous and discontinuous mountain permafrost zones (Zhou et al., 2000).

The Hotan River consists of two large subbasins: the Yurungkax in the east and the Karakax in west. There are a great number of glaciers in the upstream above 4,800 m, with a total area of 5,127.15 km^2 (Yang and An, 1990). Hydrometeorological records indicate a simple



Kunlun Mountains, Figure 1 Snow and glacier distribution in the Kunlun Mountains (*top graph*) and Permafrost regions in the west China (*bottom graph*).

pattern of streamflow under an extreme continental climate. During mild and rainy summer, weather is influenced by the westerlies, the streamflow from snow and glacier meltwater is the main supply to the oasis. The precipitation distribution in the mountains is extremely heterogeneous ranging from 70 mm in the valleys to 350 mm of the glaciated areas up to 5,800 m (Nakawo et al., 1990). The annual mean air temperature at 1,860 m is 7.9°C, the estimated annual air temperature over the alpine permafrost is below −2.7°C, and ranges from −5.6°C to −14.6°C according to a lapse rate of air temperature with −0.75°C/100 m in cold season from

observations for 6 years along an eastern neighboring valley (Abe and Wang, 2004).

The ablation period of the glacier is about 120 days from June to September according to an investigation on the glacier Gozha (5,200 m) in the headwaters, and shorter and shorter eastward due to higher glacier terminus (Cao and Aseit, 1992). The seasonal distribution of runoff, therefore, is quite variable as recharged mainly by summer meltwater and the monsoonal rainfall accounting for about 80% of the annual runoff, and the maximum is 34% of the annual in July, and the minimum is only 0.95% in February (Liu et al., 1999).

In long and cold winter from October to March, periodic events of soil freeze and thaw frequently occur. Meanwhile snow cover exists from November to May and increases snow thickness in high mountains. The river in winter, therefore, drains into the recessive period recharged only by groundwater, which is greatly affected by the freeze–thaw cycle of both the seasonally frozen ground and the active layer of permafrost.

Glaciers in the West Kunlun develop at the elevation over 5,200 m. Only individual large glaciers can extend downward at a lower elevation below 4,800 m on a southern slope. The glacier coverage and meltwater contribution, being mainly hydrological index for such rivers recharged by meltwater in China, can reflect the role of meltwater and floods to streamflow.

Change in air temperature and precipitation

Climate in the West Kunlun indicates period of both cold and warm temperature (Figure 2). The annual and winter temperature has been consistently fluctuating from the mid-1950s to the mid-1980s, and then it shows an abrupt rise after the late 1980s, the annual average in two recent decades since 1987 is 0.8°C higher than that of the previous 40 years. The highest annual temperature during 53 years was recorded in 2006 and 1994. However, the rise in monthly temperature is nonuniform – the greatest rise in winter. The monthly temperature in December to February has increased about 1.8–1.9°C since the 1980s; whereas, the summer temperature since the 1950s has kept consistent, although it is warming since 1990s.

Precipitation during the 1950s–1970s had been gradually decreasing in the mountains; however, it has started increasing since the 1980s. The maximum precipitation has increased by 10–30% more than that for the previous 40 years, a little increase in at Keriya, the maximum before 1980, for example, was 188.5 mm (1963), now once exceeded 200 mm. Precipitation might have a more dramatic increase in the high mountains.

It is interesting to note that the annual and summer flow did not respond to the climate warming since the 1980s as above. River flow only in Keriya, however, indicated a little increase by 9% after 1985 with a delay of 5–6 years to the increasing precipitation, but meltwater in Hotan River still kept rather stable or decreased a little. It is not coincidental with favorable water and heat both for rainfall and meltwater runoff since the 1980s.

Winter streamflow

The change in winter streamflow is related to permafrost degradation in cold regions (Liu et al., 2003; Qin et al., 2005). Graphical and numerical analyses of winter monthly discharges are given in Figure 3, where winter streamflow during October to March showed a strongly upward trend since 1997, the monthly flow increased by 47.4%, 32.2%, 18.8%, 32.7%, 33.5%, and 31.5%, respectively. The remaining months generally did not exhibit any significant trend. For example, an insignificant number of trends were found for the summer flow from June to September. According to the detection of the change point for monthly temperature, there was a statistically significant upward year (change point) after 1986. For winter streamflow, a statistically significant upward year was observed since 1995, but the earliest one was in January 1985. Winter streamflow in all 6 months were much more sensitive than the seasonal air temperature; trend changes were found in 4 monthly discharges with a significance

level at 99%, the most sensitive with the maximum variability was in January discharge (Huang et al., 2008; Liu et al., 2009).

Summary

In the Kunlun Mountains, snow cover, glacier, and permafrost are the various reservoirs of water. The seasonal meltwater from this region supplies most important resources for the oasis life along the downstream area in the extremely arid desert basin, but the annual flood can cause loss of human life and property and eco-environment as well. From the point of the hydrological scale, the response to the climate fluctuations from snow and glacier-fed drainage basins with less glacier cover and in lower elevation seems to be more sensitive to the change in precipitation and air temperature than that with more glacier cover at higher elevations. The hydrological regime of these rivers in the Kunlun is developing in an advantageous direction in winter to the local economy and eco-environment of the oases.

Introduction

Subglacial Lake Ellsworth is located near the Ellsworth Mountains in West Antarctica at 78.9°S 90.6°W. The lake basin is in the center of the West Antarctic Ice Sheet (WAIS) in the Pine Island Glacier drainage basin, 20 km from the ice divide with the Institute Ice Stream. The lake is approximately 15 km long and over 3 km across at its widest point. Seismic surveys have revealed that the lake is over 100 m deep in places. The ice sheet above the lake is between 2.9 and 3.3 km thick, with the lake surface over 1 km beneath present sea level within a distinct topographic hollow, ~1.5 km deeper than the surrounding subglacial bed. The basin is fjord-like in its topographic setting, and is one of a series of fjord-like over-deepenings on the western flank of the Ellsworth Subglacial Highlands.

This summary of our current knowledge will document the series of radio-echo sounding (RES) transects and field campaigns from which the lake has been identified. Basal thermal regime and ice-flow conditions, which are believed to control the lake will then be described. The final section will describe future plans for the exploration of Lake Ellsworth (Lake Ellsworth Consortium, 2007).

Radio-echo sounding data

Subglacial lakes can be identified on radio-echo sounding (RES) records. RES utilizes VHF radio-waves to measure the thickness of ice sheets and suggests the presence of subglacial lakes in three ways: (1) reflections from a water surface beneath the ice are at least an order of magnitude stronger than from ice-rock contacts; (2) reflections are of constant strength across the lake, rather than the more common variable strength that returns from bedrock; (3) the surface of a subglacial lake is smooth and flat compared with the rough surrounding topography. Using these criteria enables the identification of subglacial lakes and, where more than one RES transect is available, their surface extents to be measured. Two independent airborne and two ground-based RES campaigns have identified Lake Ellsworth:

1. The first knowledge of Lake Ellsworth is reported in Siegert et al. (2004), and is restricted to one RES line, acquired in 1977–1978 (Figure 1a and b). Later RES profiles (described below) suggest that the sounding line is near-parallel to the lake long-axis, and is also near parallel to ice flow over the lake. Preliminary modeling of the lake environment suggests that the mean gradient of the lake surface reflector is 0.02, about ~11 times the ice surface slope, suggesting the lake is in hydrostatic equilibrium with the overriding ice. The slope of the ice base across Lake Ellsworth is not entirely constant; being concave over the lake's upstream side and convex across its downstream side. In other words, the ice sheet "sags" as it flows onto the lake, and buckles against the sidewall as it re-grounds. The same features have been identified over Lake Vostok and are an expected characteristic of deep-water subglacial lakes. In the cases of both lakes, the strength of the reflections from the ice-water

interface varies near the shores, as a consequence of the reflector's shape (Siegert et al., 2004).

2. In austral summer 2004–2005, the British Antarctic Survey flew a sounding line, using a 150 MHz ice-sounding radar, across Lake Ellsworth in the form of a bow. Part of a 35,000 km grid pattern being collected over Pine Island Glacier also crossed the lake, and identified other lake-like reflectors in the surrounding area (Vaughan et al., 2007). This suggests the lake is part of a wider subglacial drainage system. The new radar lines confirm the bright specular nature of the reflector and show a much shorter reflector than the 1977–1978 survey, of between 1.5 and 2.3 km in length. This suggests that the lake is long relative to its cross-profile, occupying a fjord-like basin on the flanks of the Ellsworth Subglacial Highlands (Figure 1c). Analysis of the RES data suggests that the ice is floating on a fluid whose density is 950–1,013 kg m^{-3}, possibly indicating that the lake is composed of fresh water (Vaughan et al., 2007).
3. In January 2006, a ground-based Chilean expedition traversed the Institute Ice Stream to Lake Ellsworth and acquired several RES transects over the lake (Vaughan et al., 2007). A 150 MHz RES system was used to collect nine lines, totaling 15 km over the lake-like reflector (Rivera et al., 2006). These lines bound the lake to the north and west, though do not constrain its upstream margins to the south and east. Here, transitional zones indicated by Rivera et al. (2006) show areas around the lake where off-line radar reflections from steep bedrock surfaces prevent the lake surface being imaged.
4. In 2007/2008 a 3-month field season, using ground-based RES and seismics, revealed the lake to be in excess of 100 m deep and confirmed it as an ideal candidate for in situ measurement and sampling. An over-snow 1 MHz ice-penetrating radar was used to acquire new radar data from Lake Ellsworth and its surroundings during 2007/2008. The survey was designed to acquire data in a grid pattern, to allow: (1) the refinement of the lake outline mapped by Vaughan et al. (2007); (2) the imaging of internal layering within the ice; and (3) the development of a digital elevation model (DEM) of the lake and the surrounding subglacial terrain. The new radar and seismic data confirms the general form of the lake outline established by Vaughan et al. (2007), but shows that Lake Ellsworth is wider and slightly longer at its downstream end than previously mapped. Internal layering is apparent within the topmost 2 km of the ice sheet overlying the lake. Localized buckling of these layers can be used to infer the direction of long-term ice flow over the lake as these structures can be traced, through a sequence of radar profiles, back to their point of origin; an area of high subglacial topography identified up-flow. Internal layering data have been integrated with the DEM of the subglacial bed to facilitate 3D numerical modeling of ice flow and basal melting over Lake Ellsworth, work that is currently in progress.

Basal thermal conditions and ice flow modeling

The basal heat flux calculated in West Antarctica from temperature gradients in boreholes is around 70 mW m^{-2} (e.g., Hulbe and MacAyeal, 1999). Numerical thermodynamic evaluations suggest that the subglacial environment above Lake Ellsworth is warm, that is, at the pressure melting point (Siegert et al., 2004). Due to increased ice thickness at the last glacial maximum (LGM), it is expected that the ice sheet was also warm based at the LGM. This indicates that Ellsworth may have existed during both the present interglacial and the LGM.

Preliminary ice flow modeling of the lake environment using internal layer architecture to invert for basal melting also suggests that the dominant process at the basal boundary condition is one of melting (Siegert et al., 2004). The model predicts that as ice flows over the lake, basal melting is expected at a rate comparable to the surface accumulation rate (which near the ice divide is $\sim$17 cm $year^{-1}$) (Siegert et al., 2004). This melt rate is significantly greater than that calculated for Lake Vostok, though is comparable to the situation in Lake Vostok in terms of its value as a proportion of the surface accumulation rate. As melting is the driving force behind water circulation (Mayer et al., 2003), the enhanced rates of melting predicted by the model may lead to circulation in Lake Ellsworth being stronger than Lake Vostok (and many other subglacial lakes). Upstream of Lake Ellsworth, a small region of basal accretion is modeled at a rate of 20 cm $year^{-1}$. It is not yet known whether this freezing rate is real, or whether three-dimensional flow of ice (not accounted for in the model) complicates ice flow upstream of the lake and influences the internal layer structures. As the rate of water supplied to the lake is considerable, it is likely that Ellsworth is part of a wider subglacial hydrological network, feeding water into the basal environment of the Pine Island catchment.

Exploration of Lake Ellsworth

It is a well-established hypothesis that Antarctic subglacial lakes house unique forms of life and hold detailed sedimentary records of past climate change. Testing this hypothesis requires in situ examination. Of the >145 subglacial lakes known in Antarctica, Lake Ellsworth stands out as a candidate for first exploration for the following reasons (Lake Ellsworth Consortium, 2007):

- The base of the West Antarctic Ice Sheet has been accessed, sampled, and measured. Accessing Ellsworth would, therefore be less environmentally sensitive compared to accessing an East Antarctic subglacial lake.
- Lake Ellsworth is located close to the ice divide, so drilling from the ice surface into the lake will not be complicated by ice flow.

- Lake Ellsworth has been meaningfully characterized by geophysical methods.
- The sediments across the floor of Lake Ellsworth may contain a record of West Antarctic Ice Sheet history.
- The geological setting of the lake is better understood than any other Antarctic subglacial lake, as there is substantial outcrop of rock in the nearby Ellsworth Mountains.
- The ice-sheet surface elevation over Lake Ellsworth is 2,000 m above sea level; more than a kilometer lower than the ice surface over East Antarctic subglacial lakes. Altitude related problems encountered by scientists at the center of the East Antarctic Ice Sheet would not be an issue during the study of Lake Ellsworth.

A consortium of over twenty scientists from eleven institutions has been assembled to plan the exploration of Lake Ellsworth. Lake Ellsworth will be accessed using clean technology hot water drilling. Once lake access is achieved, a sterile probe will be lowered down the borehole and into the lake. The probe will contain a series of instruments to measure the lake water and sediments, and will be tethered to the ice surface through which power, communication, and data will transmit. The probe will be dropped down the water column to the lake floor. The probe will then be pulled up and out of the lake, measuring its environment continually as this is done. Once at the ice surface, any samples collected will be taken from the probe for laboratory analysis. The duration of the science mission, from deployment of the probe to its retrieval, is likely to be between 24 and 36 h. Measurements to be taken by the probe include: depth, pressure, conductivity, and temperature; pH levels; biomolecules (using life marker chips); anions (using a chemical analyzer); nitrogen isotopes (using a tuned laser diode); visualization of the environment (using cameras and light sources); dissolved gases (using chromatography); and morphology of the lake floor and sediment structures (using sonar). After the probe has been retrieved, a sediment corer will be dropped into the lake to recover material from the lake floor. The consortium plans to access Lake Ellsworth in 2012–2013.

LAKE ICE

Rajesh Kumar
School of Engineering and Technology, Sharda University, Greater Noida, NCR, India

The lake ice formation takes place when the daily temperature is below the freezing point. Lake ice cover is normally

Lake Ice, Figure 1 Synoptic view of the lake ice formed on the upper surface of lake water in the Baralacha La region of Himachal Pradesh, India.

Lake Ice, Figure 2 Close view of above lake showing liquid water underneath the thin lake ice.

a seasonal phenomenon and once formed the lake ice gets thicker and thicker over the course of the winter as the temperature gets colder and colder. It starts melting in spring. The surface water of the lake freezes at 0°C while the bottom layer of water maintains at above freezing temperature.

The occurrence of lake ice is primarily a function of air temperature. Once meteorological conditions provide colder breeze over warmer water, it forms ice on the surface of water due to advection cooling. But the water below the surface of ice is not much cooled so it exists in liquid phase. Hence the lake ice is found at the lake surface only (Figures 1 and 2).

Definition

Subglacial Lake. A lake covered by an ice sheet or glacier.

Introduction

Subglacial Lake Vostok is the largest of at least 370 (Wright and Siegert, 2010) subglacial lakes in Antarctica, and it was the first to be discovered. A lot of our knowledge about Antarctica, about the Earth's climate history, and about the subglacial lakes has been descended from the research station built at this location. This contribution summarizes some of the knowledge gained after more than 50 years of research in the heart of Antarctica, on top of, within, and below the ice.

On top of the ice: discovery

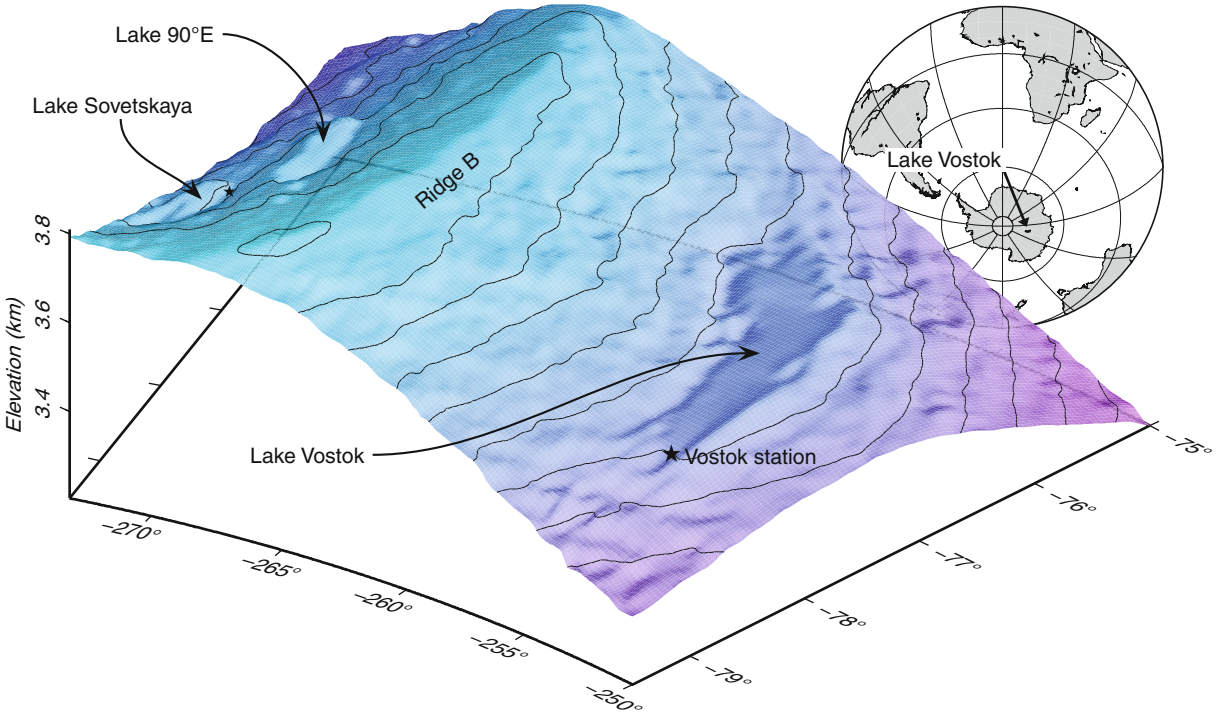
During the *International Geophysical Year*, the *Second Soviet Antarctic Expedition* encountered a quite plain area in the center of Antarctica. For the intended permanently manned station far away from any human settlement, airborne transport is indispensable, and hence this location was chosen to establish *Vostok Station*, on December 16, 1957. It is located close to the *Southern Pole of Inaccessibility* and the *South Geomagnetic Pole*. Many scientific experiments have been carried out at Vostok Station. Analyzing the results of seismic soundings, Soviet scientists had speculated about water beneath the 3,750 m thick ice sheet even in the 1960s. Further evidence of the existence of a lake was provided by radio echo sounding in the 1970s, which was confirmed later by satellite altimetry and seismic sounding (Kapitsa et al., 1996).

Subglacial Lake Vostok's area of about 16,000 km^2 can be estimated from airborne measurements and satellite imagery (Figure 1). The lake is surrounded by a bedrock-based ice sheet, and the ice flow approaches Subglacial Lake Vostok from Ridge B in the west, but is deflected southward over the lake (Figure 2). As the lake's surface is flat, it is reasonable to assume an isostatic equilibrium, that is, the ice floats on the water like an ice shelf. The observed ice surface slope over the lake is only 0.02%, leading to an elevation difference of about 50 m. However, because of the density differences between water and ice, surface ice slopes are enhanced approximately ten times at the lake–ice interface. This results in a lake surface elevation difference between the northern and southern tip of about 500 m.

In the ice: drilling and indications of life

In the 1970s, Soviet scientists started to drill ice cores in the vicinity of their station. These early boreholes were less than 1,000 m deep, but nevertheless they provided a unique climate archive. Deeper cores were drilled in 1984 and in the 1990s. The deepest core reached a depth of 3,623 m and penetrated the boundary between meteoric ice and refrozen lake ice at 3,539 m. From this ice core, a climate archive dating back 420,000 years was revealed. According to the seismic soundings, the water interface below Vostok Station is about 3,750 m deep, which means that below Vostok Station a layer of about 210 m refrozen lake water exists (e.g., Jouzel et al., 1999). Today, the deepest borehole is less than 100 m away from the lake's surface.

Subglacial Lake Vostok is an oligotrophic environment: Temperatures of about −3°C, permanent darkness, low nutrient supply, and a supersaturated oxygen level provide a hostile environment, which has been separated from any atmospheric influence since the Antarctic Ice Sheet formed millions of years ago. However, analyses of the refrozen water reveal that potential nutrients and even viable microorganisms exist in Subglacial Lake Vostok (e.g., D'Elia et al., 2009). If this is verified in the future, a so far undiscovered ecosystem on Earth can be explored. Subglacial Lake Vostok may be an extraordinary example of how life may develop under such extreme

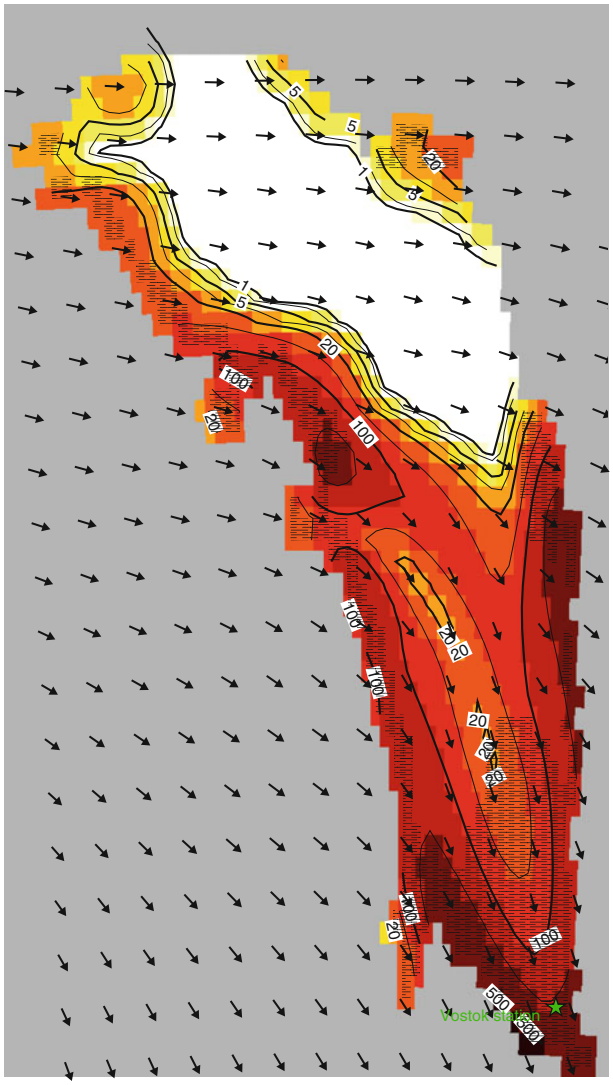


Lake Vostok, Figure 1 Lake Vostok, East Antarctica. Subglacial lakes can easily be identified by means of their flat ice sheet surface. Vostok Station is located in the southern tip of Lake Vostok. Two other major lakes can be identified across Ride B in central Antarctica: Lake 90°E and Lake Sovetskaya, named after another Russian Research station.

conditions, and this nourishes speculations about extraterrestrial life on the ice-covered Jovian moon Europa in our planetary system.

Besides life in the lake water itself, remnants of preglacial life might be stored within the sediments at the lake's bottom – at least if the lake did exist before the ice sheet formed, which is still a matter of debate (Siegert et al., 2004). After the ice formed over the preglacial lake, the supply of light, oxygen, and nutrients from the atmosphere was intercepted, leading to mass extinction. If the sediments at the lake's ground are probed, a new climate archive will be opened and information about life million years before present will be available. However, it will be problematic to probe Lake Vostok without contaminating it. According to the *observer effect*, it is impossible to sample something without changing it. In the closed subglacial system, any contamination released by a drilling equipment will permanently and irreversibly modify the lake's composition. In this sense, Lake Vostok can be interpreted as a macroscopic example of the uncertainty principle.

Because of these well-founded worries of the scientific community against a probing, Russia agreed in the late 1990s to delay the penetration of the lake until further risk assessments have been made. It is undisputed that the Russians' drilling project does not violate the *Antarctic Treaty*. Therefore, they already have filed an *Initial Environmental Evaluation*, and only the obligatory *Comprehensive Environmental Evaluation* is pending. Hence, the drilling will be legitimate. The Russians are not the only ones who have interest in probing Lake Vostok. The American Space Agency NASA has announced that they would like to test their equipment to be used on missions to other planets and moons on Earth beforehand, and that Lake Vostok would be an ideal location for this. Meanwhile, a British consortium of scientists has launched an already accepted proposal to explore and penetrate a subglacial environment at the much more accessible and tiny Antarctic Subglacial Lake Ellsworth (e.g., Woodward et al., 2010) This has stirred the somewhat calmed plans to unlock Lake Vostok again: Despite the worries and protests of scientists (e.g., Hobbie et al., 2007) and the *Antarctic and Southern Ocean Coalition* (ASOC, an environmental organization), Russian scientists reinitialized drilling during the field season 2005/2006 with an overhauled equipment and stopped the drilling only a few tens of meters close to the lake. The Russian scientists claim that they are capable of sampling lake water without infecting it with modern microbes. However, this will be quite a task as their drilling hole is filled with kerosene and other noxious fluids necessary to prevent the borehole from refreezing or from closing due to pressure forces. Technical and legal reasons have postponed the penetration of the lake so far, but the Russians have announced that after 2010 they plan to go where no man has gone before (Schiermeier, 2008).



Lake Vostok, Figure 2 Modelled accreted ice distribution and its thickness (m) at the lake–ice interface (indicated by *color*) and areas where freezing takes place (*white shaded*). The surface ice flow direction (After Tikku et al., 2004) is indicated by *black arrows*.

Below the ice: modeling

The lake's area can be estimated from the surface topography, and a lot of valuable information about Lake Vostok can be gathered from the accreted refrozen lake water in the ice core. But until the lake is directly probed, detailed information about circulation and water mass exchange under the ice can only be derived from numerical modeling. From airborne gravity data and assumptions about the densities of ice, water, sediment, and rock, the lake's geometry and its water depth can be estimated (Studinger et al., 2004). In addition, seismic sounding can be used to constrain the derived geometry model (Filina et al., 2008). According to these studies, the lake's largest depth exceeds 1,000 m, the volume is about 5,000 km^3, and a sedimentary layer at the lake's bottom is several hundred meters thick.

The surface temperatures in central Antarctica are, on average, about −65°C during winter, and even in the brief summer, they barely reach −35°C. This is well below the freezing point of water, and hence ice never melts in this region of the Earth – at least not at the ice sheet's surface. Nevertheless, water does exist in its liquid form below about 4,000 m of ice. At this depth, the freezing point of fresh water is about −3°C. A small geothermal heat flux of about 50 mW/m^2, as estimated for the area of Lake Vostok, is therefore responsible (and sufficient) for melting the ice's base. Additional hydrothermal energy sources are not expected to provide energy for the melting. The meltwater is collected in the topographic basin (a rift valley according to Bell et al., 2006) forming Lake Vostok.

With this valuable information, a lake-flow model can be set up to calculate the average water circulation, the basal mass (im)balance, and the distribution of melting and freezing at the lake–ice interface (Thoma et al., 2008). These simulations show a ceaseless melting-induced ice loss of about 5×10^{-2} km^3/a, which is not balanced by freezing, and a horizontal (vertical) water velocity on the order of 1 mm/s (10 μm/s). However, the modeled low vertical velocity is a spatial average; heating from below results in upwelling of plumes that rise significantly faster (about 0.3 mm/s) to the lake's surface (Wells and Wettlaufer, 2008). The combination of the modeled basal mass balance and ice flow information allows for estimating the distribution and thickness of the accreted ice at the ice sheet base from which samples have been drilled at Vostok Station. According to Thoma et al. (2010), about 65% of the lake–ice interface is covered with accreted ice (Figure 2).

Most probably, Lake Vostok is not an isolated lake but is connected to other lakes via a subglacial network like other lakes have proven to be before (Wingham et al., 2006; Fricker et al., 2007). The water collected in the Lake Vostok basin will finally reach the Southern Ocean. The age of the lake water is estimated to be between a few thousand years and more than 100,000 years, and a more recent model-based study (Thoma et al., 2010) indicates a mean water age of about 50,000 years. However, these timescales are short compared to the Antarctic Ice Sheet's age of several million years, which means that the lake water has been replaced several times since its inception.

Conclusions

After more than 50 years of research in the heart of Antarctica, some of Lake Vostok's mysteries are revealed (like the dimension of the lake), some are depreciated (like the theory of an isolated, sealed environment), but a lot is still unknown about the massive water basin beneath the 4,000 m thick Antarctic Ice Sheet. Within the next few years, we can expect more insights to be gained from the subglacial environment, perhaps by direct sampling through an access hole.

LAMINATED SEDIMENTS

Rajesh Kumar
School of Engineering and Technology, Sharda University, Greater Noida, NCR, India

The laminated sediments have traditionally been considered by geologists as strata with a thickness of about less than 1 cm (Berthault, 1988). This is one of the characteristic features in the sedimentary rocks. The deposition of sediments for several years or at different geological time might have slight difference in their mineralogical composition. This exhibits different shades of colors even if they are belonging to the same area. After consolidation, these depositions in the sedimentary rocks exhibit them in the form of thin layers. Each laminated sediments or the thin layer/band represents a different phase of deposition. Lamination clusters together signify all the structures characterizing sedimentary rocks within a bed or stratum. One of the most common examples for the laminated sediments is the medium-grained reddish sandstone that possesses thin bands of red shades due to difference in iron content at each depositional phase. The ticker laminated sediments are called as bedding planes.

LANDFORMS OF GLACIAL DEPOSITION

John F. Shroder
Department of Geography and Geology, University of Nebraska at Omaha, Omaha, NE, USA

Definition

Glacial erosion occurs in the upper, dominantly accumulation area whereas farther down near the terminus

the ice produces areas and landforms of deposition. This entry describes some of the common depositional landforms under one umbrella. For detailed description of Jökulhlaups, Moraine, and Till, please see the respective entries *Hydrology of Jökulhlaups*; *Moraine*; *Till* in this Encyclopedia.

Landforms produced by deposition of glacier materials are mainly differentiated on the basis of whether or not they are primarily ice contact or meltwater in origin. Ice contact generally means that the landform is composed dominantly of unsorted, unstratified tills, which are generally mixtures of all clast sizes from clay, silt, and sand, to cobbles and boulders. Till deposits form as *lodgement tills* through the pressure of overlying ice that consolidates them and plasters them onto the substrate beneath; the under-melt and over-melt *ablation tills* that melt out both beneath and above the ice; and *flow tills* that form from any prior tills that become water saturated and flow over other deposits and landforms. Meltwater deposits tend to be sorted and stratified. In the waning phases of the Pleistocene ice age many glaciers melted away to leave complex mixtures of various kinds of tills and glaciofluvial sediments and landforms that are collectively known as *kettle and kame topography.*

Moraine is the general term used for almost all of the landforms composed of till, and there are many kinds of moraines, depending upon where the moraine occurs in relation to the original ice that formed it and how it was formed. Thus *lateral moraines* are the long ridges that develop alongside glacier edges where sub-, en-, and supra-glacial till debris accumulates. At the terminus or front of the glacier where the mass balance of accumulation versus wastage has allowed the glacier front to remain in place for a while, some of the same processes pile up masses of till in arcuate ridges that become the *end* or *terminal moraine*. As the glacier retreats back from its farthest extent, it can form recessional moraines where the terminus holds its position for a few years. The common medial moraines that form on the surface and down inside glacier ice commonly does not hold its long, commonly sinuous landform shape once the ice melts away; instead together with other miscellaneous sources of sub-, en-, and supra-glacial debris, it becomes undifferentiated *ground moraine* that tends to be scattered about formerly glaciated landscapes. Some ground moraines become *fluted moraine* where the basal tills are scraped, squeezed, and streaked out into lineations known as "flutes."

Push moraines form where a thick glacier terminus overrides preexisting tills or glaciofluvial sediments and forces the materials bulldozer-like, up into apparent morainal forms in front of the glacier, even where some are not made only of till. Other types of moraines that are formed transverse to ice flow are *ribbed* or *Rogen moraines* that are rather irregular in shape. They can form as the result of pushing or overriding of materials reactivated by the ice, or perhaps as a transition between streamlined features up-ice and transverse forms down-ice, or where thermal transitions occur in deglaciation along the sub-ice line that can perhaps migrate on some temporally controlled basis between cold-based ice frozen to its bed and warm-based ice further toward the terminus.

De Geer moraines are much more fine or more delicate than the Rogen type and are successions of discrete narrow ridges, thought possibly to be the result of till sediments dropped out along an ice-contact sublacustrine grounding line where icebergs calved off into a lake or the sea, or where till was squeezed up. Similar *Kalixpinmo hills* or *moraines* also may be where subglacial materials are squeezed up into cavities or deformed by glacier flow.

Smooth *drumlin* forms can form from prior deposited tills that are swept over by a new ice advance that selectively erodes away surrounding tills to leave the streamlined hills behind. Drumlins are thought to form when sub-glacial meltwaters also erode the streamlined shape. Some drumlins can also have internal glaciofluvial deposits that are sorted and stratified. Together with erosional rock drumlins, it is clear that drumlin landforms are polygenetic. Finally, various crag and tail forms can occur where a glacially overridden hill can have a mass of streamlined debris drawn out behind it down-ice in a streamlined form.

Kames are a common glacial hill or ridge landform composed dominantly of glaciofluvial sediments that are deposited in a variety of meltwater environments, such as englacial, supraglacial, and proglacial environments where conditions are appropriate for accumulation of sediment. Supraglacial lakes, crevasses, the bottoms of moulin (glacial water mills), and other miscellaneous depressions are all possible localities for establishment of kames. No particular shape is implied in the designation of the polygenetic term, although those flat-topped ones that form along the margins of glaciers or across the top of the glacier by meltwater streams or lakes, commonly become *kame terraces*.

Eskers are polygenetic also and can form as long, winding ridges of glaciofluvial sediments, commonly as a result of deposition in linear subglacial and englacial streams in tunnels, as well as in supraglacial streams. In some cases, however, the depositional processes can involve deposition of glaciofluvial sediment in a series of deltas into ice-contact lakes, which as the ice front retreats, allows the delta to retreat as well, leaving behind a series of long- or short-beaded eskers.

Glacier-fed deltas associated directly with meltwaters are classified on the basis of water depth and gradients of the feeder river. Shoal or shallow water types form Hjulström types of deltas with gently sloping fronts. Steeper and slightly deeper forms are the "classic" Gilbert-type deltas with clear topset, foreset, and bottomset bedding forms. As the water deepens and the slopes vary, various subaqueous debris cones, submarine ramps, and lobes develop, commonly as a result of subaqueous mass movement.

The regions out in front of glaciers that are washed over extensively by braided meltwater streams are replete with widespread fluvioglacial sediments that in mountainous regions form *valley trains,* and in more open regions spread out as *outwash plains* or *sandars* (singular – *sandur*).

Such regions may be the product of the slow melt of glaciers in the region, or the more spectacular breakout floods due to breakage of an ice dam or because of subglacial volcanic eruptions that result in abrupt, high-discharge floods or *jökulhlaups*. Valley trains and outwash plains are commonly pocked with kettle holes result where blocks of ice melted out leaving a remnant, commonly water-filled, depression behind.

LANDFORMS OF GLACIAL EROSION

John F. Shroder
Department of Geography and Geology, University of Nebraska at Omaha, Omaha, NE, USA

Definition

Landforms produced by the glacial erosion. Glacial erosion occurs in the upper, dominantly accumulation regions beneath the ice of glacierized valleys and ice sheets and ice caps. For detailed description of various aspects, please see the following entries: *Glacial Erosion*; *Landscapes of Glacial Erosion*; *Sediment Entrainment, Transport, and Deposition*.

The characteristics of glacially eroded landforms are primarily classified into four main categories of bedrock, topography, glacial processes, and time. Bedrock controls include the actual lithologies themselves, the character and spacing of the joints, the degree of preglacial weathering, and the overall rock structure. Topographic controls of glacial erosion are constituted by the relative relief, the shape of the relief, its alignment in relation to ice flow, and the overall altitudes involved. The morphology of the ice mass and its thickness help to control landform production, as does the direction of the ice flow, the velocity of the basal ice, and the character and amount of glacial debris. The temperature of the basal ice is essential because cold-based glaciers frozen to their beds do not erode their substrates, whereas warm-based ice in association with plentiful meltwater is a highly effective erosive agent. Change of any of these factors over time will affect the character of the eroded landforms, just as does the overall length of time that the region is glacierized.

Glacial erosion occurs by a number of processes that commonly generate sequences of scale-dependent landforms as a result of direct ice contact through crushing and fracturing, plucking or quarrying, and abrasion, as well as through fluvial erosion beneath the ice. The processes of *crushing* and *fracture* of the rock beneath a glacier produce chattermarks and crescentic fractures. *Plucking* or *quarrying* occurs during regelation slip wherein meltwater migrates to the downglacier side of an obstruction and refreezes to also incorporate fractured rock into the regelation layer that the glacier then carries away. *Abrasion* occurs where small to large grains of rocks and minerals are held by the ice and dragged over the substrate to grind away at it. At the very smallest level, fine clastic abrasives beneath the ice cover can polish the rock; at slightly larger scales, *striae* or scratches result, and above that even larger grooves are cut into the rock. *Plastically molded surfaces* or *P-forms* are eroded into bedrock as sinuous rounded forms possibly formed by the action of water-saturated tills, which are forced out under pressure beneath the ice. Fluvial erosion occurs beneath warm-based glaciers that are not frozen to their beds where meltwaters can be under pressure and where they can entrain large quantities of clastic particles that act as effective erosive tools. *Subglacial channels* and *potholes* can be developed, as well as large *tunnel valleys* that can be kilometers in width and tens of kilometers in length.

Glacially eroded valleys are easy to recognize because they so commonly have a U-shaped cross section, in contrast to the more V-shaped valleys produced by running water alone. *Glacial troughs* most closely conform to a caternary curve that forms primarily through plucking and abrasion on the lower sidewalls and bottoms of the valleys. In the course of its movement down valley, the glacier commonly exploits valley-wall constrictions, differences in rock hardness, closer joint spacing directly below where a tributary glacier added to the ice discharge to enhance its erosional ability.

Glacial troughs can be carved out of winding river valleys that have interlocking spurs, in which case they will be eroded away to leave *ice-faceted spurs* or *truncated spurs* that align between the lateral valleys. Where tributary ice streams have joined the trunk ice stream, the floors of these smaller glacier troughs are generally above the floor of the main glacier valley and *hanging troughs* or *hanging valleys* form, commonly with waterfalls once the ice has melted away.

As glacial troughs are blocked by moraines, they can fill with *glacial trough lakes* that drown the valley floor. Similarly, where glaciers descended close to or below sea level, a subsequent postglacial rise in sea level has generated *glacial fiords* invaded by an arm of the sea into the submerged glacial trough.

At the head of a glacial trough commonly exists a steep-headed, half-bowl-shaped basin or *cirque* scooped out of the bedrock that forms as a consequence of intense frost action and nival processes adjacent to the ice. The flow lines in the ice in the zone of accumulation carry rock fragments down to the bedrock beneath the glacier where it becomes deeply abraded and even overdeepened through abrasion and plucking. Once the ice has melted away, a *tarn* lake can result where the water is dammed up behind the rock sill at the lip of the cirque.

As cirques and glacial troughs dissect a mountain range, the upland remnants between three or more back-to-back

cirques erode rectilinear glacial monuments, generally in flat-lying rocks, or triangularly faced *horns* in other rocks or in places where the monuments have been reduced by headward erosion from the opposing cirques. A saw-toothed ridge or divide between cirques or glacier troughs consists of low *cols* and sharp knife-edged ridges that can form an *arête*. Multiple cirques along a mountain range can form a *scalloped upland* or *biscuit-board topography*, in analogy to a layer of prepared bread dough on a pastry board with arcuate pieces cut out for biscuits that leave the cirque shape behind.

Landform eminences produced primarily by plucking and quarrying at the smaller end of the scale form streamlined *roche moutonnée* of a few meters to a few decimeters in size that tend to be plucked and rough and jagged on the down-ice or lee side, and rounder, smoother, and abraded on the up-ice or stoss side. At the large end of the scale, the same sort of streamlined landform is hundreds of meters in size and generally stands as an isolated and asymmetric rocky crag or mountain *flyggbirge*. In a few cases of completely streamlined erosional forms, *whalebacks* or larger *rock drumlins* can form. Finally, jagged mountain peaks that protrude through a surrounding ice sheet are *nunataks*, which is an Inuit word for "place of refuge."

Summary

Glacial erosion occurs most prominently in association with warm-based ice that is not frozen to its bed and in abundant association with meltwaters. Glacial erosion is accomplished primarily by subglacial abrasion from other rock fragments entrained in the moving ice, as well as by plucking in which basal meltwater refreezes beneath the ice to pull off blocks of bedrock. A wide variety of small-scale and large landforms are produced in the bedrock.

LANDFORMS OF GLACIAL TRANSPORTATION

John F. Shroder
Department of Geography and Geology, University of Nebraska at Omaha, Omaha, NE, USA

Definition

Landforms produced due to the movement of glacier.

All glacial deposits were transported from other sources but landforms specific only to transportation can be considered where the mechanism of motion and its results are the most important factors to be considered. Thus features such as *erratics*, *boulder trains*, or glacial erratic *indicator fans* or *dispersal fans* are the chief landforms of glacial transportation. Such landforms are commonly recognized as exotic blocks far from their original source that will reveal paleo-flow directions of the ice once the course of transport is determined by finding the original outcrop from which they were derived.

For an erratic to be incorporated within a glacier, it is necessary either for the ice to exert enough tractive force on a block to pick it up from the bed over which it is flowing, or for the block to fall from high cliffs to the glacier surface and be carried along passively thereafter. Small blocks are brought into ice streams both ways constantly but very large blocks require unusual sets of circumstances in order to become transported landforms. A possibility can be that huge erratic blocks might be moved by cold-based glaciers if the 0°C isotherm moves down reasonably close to the glacier bed so that the block is frozen onto the overlying ice. Then, if the friction at the frozen ice/rock interface exceeds that occurring on the lower unfrozen plane of weakness in the rock or that of the substrate below, the whole block can be picked up and dragged along. Subsequently as is characteristic of cold-based glaciers, the block can rise in the ice stream as ever more material and ice is added underneath it by regelation refreezing at the glacier base.

A huge such erratic in Germany measures 4 km by 2 km by 120 m thick. Elsewhere large quartzite blocks of the Foothills Erratic Train occur on the prairie underlain by Cretaceous bedrock in Alberta, Canada, more than 375 km from their source in the mountains of Jasper National Park. The largest of these erratic blocks, the Okotoks erratic near Calgary, is thought to weigh about 16,000 t.

Erratic trains can be divided into two chief types: the *Dubawnt type* in which erratic blocks are spread as a plume down-ice from a relatively restricted source outcrop; and the *Boothia type*, which on the other hand is a boulder train characterized by erratic plumes that extend out from small parts of large source areas by ice streams of more rapid flow within an ice sheet. In general, no matter which type of erratic train is involved, the dispersal patterns of the erratics can be used to reconstruct former ice transportation pathways. Care must be exercised in interpretation, however, because debris transport histories may involve several cycles of glaciations during which time ice divides and ice-flow vectors may shift altogether from one direction to another, even as much as 90° or more. In general, most boulder trains are fan-shaped down-ice, although some may be rather rectilinear in the shape of their edges.

In those rare cases where a medial moraine from a glacier is preserved on the ground after the glacier has melted away, a clear transportation landform results.

For example, in the case of medial moraines that derive from a nunatak mountain that projects through an ice sheet, the erratic debris spread out from that nunatak while the ice is in place will form a more-or-less vertical debris septum within the ice that exists as a medial moraine on the surface of the ice. If the ice melts away without too much meltwater removal of the debris, a linear pile of boulders and moraine hills will show the original transportation direction.

Summary

All glacial deposits were transported from somewhere else but only a few show clear evidence of transportation that sets them apart from the others. Thus, glacial landforms of transportation include single erratics, boulder trains of erratics, and indicator fans or dispersal fans. More rarely, medial moraines may be preserved.

Glacier Motion/Ice Velocity

LANDSCAPES OF GLACIAL EROSION

Martin P. Kirkbride
Geography, School of the Environment, University of Dundee, Dundee, Scotland, UK

Definition

A landscape of glacial erosion is one in which a large part of the landscape comprises exposed glacially molded bedrock, evidence of the net removal of rock by glacier abrasion and quarrying. Landscapes comprise erosional landforms at scales from centimeters to kilometers. This entry discusses the significance of these landscapes and their role in landscape evolution beneath ice sheets and alpine glaciers. For detailed description about landforms and glacier erosion, please see following entries: *Glacial Erosion*; *Landforms of Glacial Erosion*, etc.

A new realization of the significance of glacial erosional landscapes

Glaciers have been recognized as potent agents of landscape modification since the earliest days of classical Glacial Theory. At the landscape scale, understanding glacial topography was for many decades limited to sterile descriptions of form, because a physical understanding of subglacial erosion processes was insufficiently advanced to explain landform assemblages at landscape scales. Furthermore, the impossibility of deriving direct chronological information from denuded bedrock landscapes precluded any empirical attempt to construct evolutionary models of erosion-dominated landscape development. All this changed in the late twentieth century due to advances in four areas of science: (1) the development of powerful numerical models of glacier and ice sheet behavior; (2) application of new techniques for estimating denudation rates in eroded landscapes, notably thermochronometry and cosmogenic isotope analysis; (3) better understanding of subglacial erosion, notably the integration of basal water pressure variations into explanatory models, and (4) high-resolution proxy records of global climate history from ice cores and marine sediments, which could be used to drive computer models of glacier and ice sheet behavior. Recent research attempts to integrate glaciological and geomorphological models to "recreate" glacial erosional landscapes. Their outputs can then be measured against real landscapes and empirically calculated rates of glacial erosion and topographic change. These advances allow long-standing questions in glacial geomorphology finally to be addressed, such as:

What do the preserved landscapes of former ice sheet beds tell us about the life cycles of ice sheets?
How long does it take for glacial topography to form on a previously unglaciated landscape?
What are the relative rates of fluvial and glacial erosion at landscape scales of space and time?
What role do glaciations play in the uplift and evolution of mountain ranges?

Modeling glacial landscape evolution using coupled ice-bedrock models takes two approaches. Forward modeling shows how an initial unglaciated landscape is modified by ice cover (e.g., Jamieson et al., 2008): reverse modeling starts with current terrain models and works backward to "recreate" the preglacial landscape (e.g., Jamieson et al., 2005). Armed with these techniques, studies of glacial landscape evolution are now contributing to wider debates involving the roles of ice sheets and of alpine mountain building in global climate change.

Classification and origins of erosional landscapes under ice sheets

Sugden and John (1976) classified glacial erosional landscapes at continental scales according to the role of thermal regime in promoting or inhibiting erosion, and to the consequent character of the deglaciated terrain (Table 1). The main landscape types of areal scouring, selective linear erosion, and little or no erosion, are primarily related to spatial variations in thermal regime (Sugden, 1974, 1978). Areal scouring creates distinctive landscapes of exposed bedrock in the form of rock basins, roches moutonées, and other more-or-less streamlined forms reflecting former ice flow. Though often limited to low-relief landscapes, areal scouring of uplands (including summits) should also be included in the landscape type where the terrain was inundated by an ice sheet moving across the area from a distant source.

Landscapes of Glacial Erosion, Table 1 Classification of landscapes of glacial erosion (After Sugden, 1974; Sugden and John, 1976; Summerfield, 1991; Benn and Evans, 1998)

Landscape type	Thermal regime	Topography	Examples
Areal scouring	Warm-based	Landscape dominated by exposed, plucked, and abraded bedrock forms whose scale depends on joint and fault density. Rock basins, roche moutonées, streamlined erosional forms, and striated pavements. Negligible glacial sediment cover and disorganized post-glacial drainage. Erosion aided by impermeable bedrock.	NW Scotland W Baffin Island, Canada
Selective linear erosion	Warm-based over valleys, cold-based over interfluves	Glacial modification of pre-existing fluvial valleys into troughs. Largely unmodified plateaux and interfluves may retain delicate non-glacial landforms (patterned ground, regolith)	Cairngorm Mountains, Scotland Trollaskagi Peninsula, N Iceland Beartooth Mts, Montana, USA E Greenland
Little or no erosion	Cold-based	Preglacial slope forms survive with regolith cover. Presence of former glacier cover may itself be contentious. Limited evidence of meltwater activity during deglaciation. Erosion may partly be suppressed by permeable bedrock.	NE Scotland W Sweden E Baffin island (Canada)
Alpine landscapes	Warm-based in valleys	Cirques line sharp-crested mountain ranges above glacially modified troughs, with periglacial morphogenesis on high ice-free slopes. Predominance of steep terrain with avalanche couloirs supplying much glacial accumulation.	Southern Alps (New Zealand) European Alps Southern Alaskan coast ranges

Landscapes of selective linear erosion are specific to mixed-regime ice sheets under which thin ice over uplands remains cold-based while thick ice over valleys slides under a warm-based regime, often aided by flow convergence from surrounding uplands. Valleys are deepened and reshaped to "U"-shaped trough forms, often exploiting geological weaknesses. Landscapes of little or no erosion may be controversial, because evidence of former cold-based glaciation may be elusive, and preservation of preglacial landforms and sediments may suggest ice-free conditions throughout the Quaternary.

This classic partitioning of glacial landscapes underpins all the more recent research exploring the thermomechanical controls on glacial erosion at large spatial scales. The modern challenge is to upscale process explanations of abrasion and plucking (Boulton, 1979; Hallet, 1979, 1996) to provide models of landscape evolution under ice sheets at continental scales. The challenge has been approached both empirically (Sugden, 1978; Li et al., 2005; Phillips et al., 2006; Swift et al., 2008) and theoretically, using coupled ice-sheet-erosion computer models (Hildes et al., 2004; Jamieson et al., 2008). An up-to-date summary of the fundamental controls on glacial erosion is provided by Jamieson et al. (2008). In summary, effective abrasion and quarrying require that ice is moving over the glacier bed, in turn requiring water to be present at the bed. This requires a temperate thermal regime, due to an excess heat supply to basal ice from some combination of geothermal heat flux (especially under insulating very thick ice), frictional heating by flowing ice, and heat advection by flow convergence. How effectively the resulting basal water then promotes sliding depends on another set of factors including substrate properties, water pressure variations, bed permeability, and the connectivity of the subglacial drainage network and its seasonal evolution. These factors interact on glacier beds of widely differing lithology and topography to give a challenging modeling environment. Thus, empirical observations of former ice sheet beds are vital for defining boundary conditions and geomorphological outcomes.

Former ice sheet beds show strong patterns in the distribution of glacial erosion, evidenced by landscape types, and indicative of past ice sheet thermal regime and flow structure. Earlier representations of ice sheets as defining first-order radial zones of thermal regime, erosion, and deposition (Sugden and John, 1976; Sugden, 1978) have been refined to integrate the role of dynamic ice streams evacuating ice from ice-drainage basins within ice sheets. These operate, perhaps intermittently, when thermal, substrate and hydrological conditions combine to provide conditions facilitating optimum sliding and erosion. Such palaeo-ice streams are now being recognized from their distinct geomorphological signatures. For example, in Scotland, the late Pleistocene Minch ice stream drained much of NW Scotland out to the continental shelf edge (Stoker and Bradwell, 2005) and the Strathmore ice stream concentrated ice discharges from the south and east Highlands (Golledge and Stoker, 2006). The erosional landscapes of the hinterlands and main axes of such ice streams are important evidence of their significance for the dynamics of Pleistocene ice sheets.

Alpine glacial erosion and the height of mountains

Alpine landscapes of glacial erosion are assemblages of familiar (though sometimes poorly understood) forms

including cirques, horns, arêtes, and troughs, with the common characteristic of local accumulation sources and erosion by partly or entirely warm-based cirque and valley glaciers. As a result, alpine landscapes are best developed in mid-latitude mountain ranges.

The significance of alpine erosional topography for tectonic-isostatic modeling of mountain uplift highlights another example of a renewed scientific interest in "old-fashioned" glacial landscapes. Molnar and England (1990) highlight the feedbacks between the glacial denudation of mountain ranges and their uplift. Isostasy compensates for the majority of the crustal thickness lost to erosion of the mountains. Thus, removing 60 m of crust from range crests would lower the mountains by only c. 10 m. Molnar and England provocatively suggest that if the erosion was focused along valleys, and the isostatic response was areally distributed, this could lead to an increase in summit elevations, greater ice cover, and more erosion. Paradoxically, deepening of glacial troughs during glacial cycles could thereby increase the maximum height of alpine mountains even if average relief did not change. They hint that the initiation of Quaternary glaciations could thereby have accelerated mountain-building processes due to climatic change.

This controversial idea has been countered by the "glacial buzzsaw" hypothesis (Brozović et al., 1997). This depends on a premise that glacial erosion in alpine terrain is more effective than fluvial erosion, as several authors including Montgomery (2002) have argued. As a mountain massif is uplifted above the glaciation threshold, trough cutting will accelerate mass loss from the uplifting crust while cirque development and periglacial slope mass-wasting will "shave off" the summits to limit range heights. Where summits intersect the glaciation limit by only enough to produce cirque glaciers, cirque evolution primarily by lengthening more than by deepening or widening (Brook et al., 2006a) means that retreating headwalls on opposing slopes may lower the ridgelines. A negative feedback is hypothesized, in which the taller and steeper the mountains, the more erosive the glaciers, so that the height of mountain ranges becomes self-limiting. This mechanism has been suggested to explain range hypsometry and/or long-term sediment yields in the Himalaya (Brozović et al., 1997) the Andes (Montgomery et al., 2001), Alaska (Spotila et al., 2004), and the Western Cordillera of North America (Mitchell and Montgomery, 2006; Foster et al., 2008). Evidence for the buzzsaw also includes systematic relationships between both equilibrium-line altitudes and range crests (Porter 1964), and between ELA and maximum ice flux and erosion (Foster et al., 2008). The buzzsaw hypothesis can be criticized for an overreliance on the hypsometric (area-altitude) distribution of relief. In the European Alps, for example, uplifted preglacial valley floors below glacially modified peaks could be mistaken for "buzzsaw" planation. The applicability of the buzzsaw hypothesis to different tectonic and climatic settings is an area for further research.

Landscape modification over multiple glacial cycles

How long does it take to establish a glacial erosional landscape on initially unglaciated terrain? Modeling of trough cross-sectional development showed that a mature "U"-shaped valley can develop within a single glacial cycle of c. 10^5 years (Harbor et al., 1988). In New Zealand's Southern Alps, empirical verification for this estimate is provided by examining the erosional geomorphology of mountains in which trough-and-arête topography evolved on uplifting ranges exposed to glaciations for only the last 200,000 years of glacial duration (Kirkbride and Matthews, 1997; Brook et al., 2006b). These studies imply that mature troughs can be established early in a succession of glacial cycles in tectonically active maritime mountain ranges, where glacial erosion rates are of the order of at least several millimeters per year. Glacial landscape evolution would be correspondingly slower where low erosion rates (c. 0.01–0.1 mm/year) occur in dry climates and on durable crystalline rocks. On geological timescales, erosive alpine glaciers can impose glacial landscapes on the Earth's crust very rapidly. Later glaciations presumably contribute little to further topographic evolution once valley cross sections are adjusted to efficiently evacuate ice discharges. Long-term feedbacks between glacial landscape evolution and ice extent are suggested by Kaplan et al.'s (2009) observation that Patagonian glaciations were of successively smaller magnitude over the last 1.1 million years, in spite of favorable climate, as glacial erosion reduced potential ice accumulation areas and provided a topography favoring low-gradient fast ice flow.

Conclusions

Glacial modification of topography is important in two main respects. First, understanding how glacial erosion operates at landscape scales allows reconstruction of past basal processes beneath continental ice sheets, helping to understand ice sheet evolution and response to climate change. Second, erosional landscapes in alpine mountain ranges have a characteristic hypsometry and elevated sediment yield that feeds into models of mountain uplift and denudation. The study of landscapes of glacial erosion has progressed remarkably over several decades from bland description of form and topography to being an integral component of modeling climate-tectonic interactions in Earth system science.

LAST GLACIAL MAXIMUM GLACIATION (LGM/LGP) IN HIGH ASIA (TIBET AND SURROUNDING MOUNTAINS)

Matthias Kuhle
Department of Geography and High Mountain Geomorphology, Geographical Institute, University of Göttingen, Göttingen, Germany

Synonyms

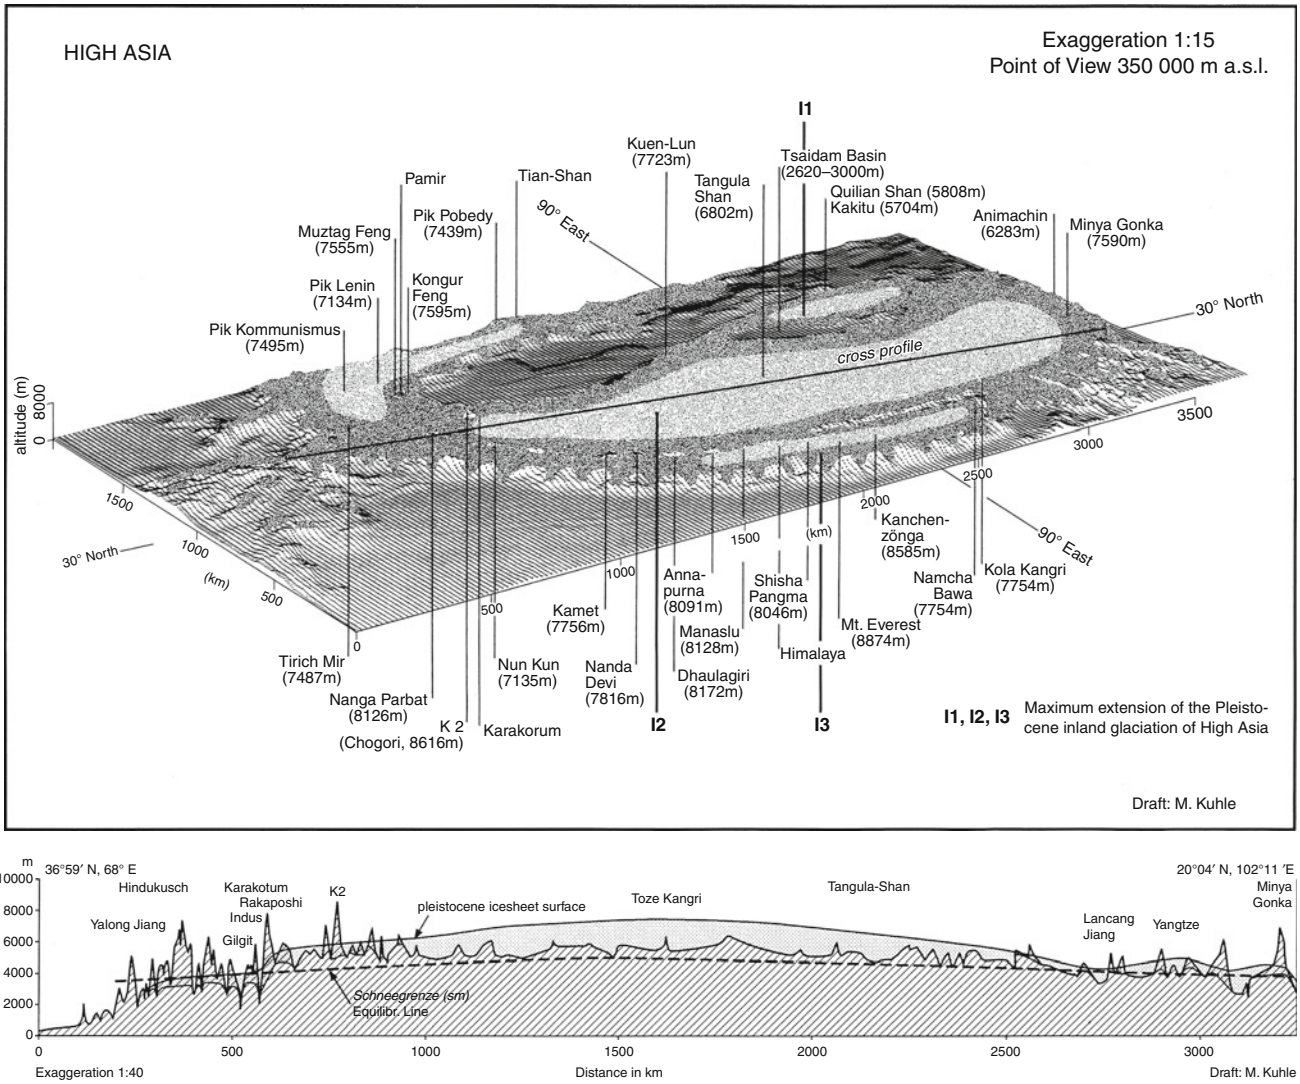
Pleistocene glaciation of High Asia during the last ice age; Quarternary glaciation of High Asia during the MIS 3-2

Definition

Reconstruction of the maximum extent of the ice cover in High Asia.

Introduction: The state of research up to 1973

A synopsis of older results and views on the Pleistocene glacier cover in High- and Central Asia has been provided by Wissmann's (1959) compilation. Glacier cover of Tibet is discussed in the Chinese literature by Shi and Wang (1979), and has also been reproduced by CLIMAP (Cline, 1981, entitled "Last Glacial Maximum"). These authors speak of a 10% to maximum 20% ice cover of the mountains and plateaus of Tibet. Even in the "Quaternary Glacial Distribution Map of Qinghai-Xizang (Tibet) Plateau" (Shi et al., 1991), this opinion is to a great extent repeated and supported. However, there was a first restriction: Zhou Shangzhe, a member of this group, agreed with the author's reconstruction of an inland ice as for the Tibetan plateau area on Animachin (cf. Figure 1) (Kuhle, 1987, 1988a). In this map, he put down a plateau glacier area of still 400 × 300 km in size. But time and time again, from as long ago as the turn of the nineteenth to twentieth



Last Glacial Maximum Glaciation (LGM/LGP) in High Asia (Tibet and Surrounding Mountains), Figure 1 *Top*: The reconstructed 2.4 million square kilometres ice sheet or ice stream network covering the Tibetan plateau (Kuhle, 1987, 1988a, b, 1989, 1995, 1998, 2001, 2004, 2005, 2007, 2011), with the three centers I 1, I 2, I 3. Only peaks higher than 6,000 m rise above the ice surface. *Figure 1. Bottom*: Cross profile of the central ice sheet from Hindu Kush in the west to Minya Gonka in the east.

century, there have been single investigators, such as Oestreich (1906), Dainelli and Marinelli (1928), Norin (1932), and others (see Kuhle, 1988b:416–417), who described ancient ice margin sites scattered throughout the high regions of Asia. According to the author's calculations, the above work represents ELA (equilibrium line altitude) depressions of more than 1,000 m and indicates, locally, significantly more glacier cover than the Wissmann scheme had acknowledged. However, these authors neither drew nor gave voice to such conclusions. Other early researchers, such as Huntington (1906), Tafel (1914), Trinkler (1932), Zabirov (1955), and others (see Kuhle, 1988b: 416–417), making more or less direct use of the data they obtained by observation, reconstructed larger glacier areas which, depending on the altitude of the mountains of plateaus, had built up only a few hundred meters of ELA depression.

The author has been fortunate in being able to carry out about 37 expeditions and research visits since 1973, some of which extended to 7 months, with the purpose of reconstructing the extent of glaciers in Asia during the glacial periods. The location and large number of areas under investigation permit reconstuction of the glacier areas to be made for the whole Tibet and parts of Central Asia. Reconstructions are supported by data from some earlier authors (see above) and are in glaring contrast to the negligible ice cover published by CLIMAP as late as 1981 (Cline, 1981) and the "Quaternary Glacial Distribution Map of Qinghai-Xizang (Tibet) Plateau" (Shi Yafeng et al., 1991). For example, the extent of glaciation of Tibet

during the Last Ice Age is given as approximately 2.4 million km² and is estimated to include a central thickness of about 2 km. Breaking up on the edges, ice discharged through the surrounding mountains as steep outlet glaciers (a.o., Kuhle, 1989, 1998, 2005).

Synopsis of the extent of the inland-ice in Tibet since the earliest Last Glacial Period (LGP)

Figure 1 shows the reconstruction of the maximum glaciation in Tibet, with an area of about 2.4 million km². In the central part, it formed a compact inland ice sheet with outflows that descended through the surrounding mountains and terminated at the steep edges of the high plateau.

To err on the safe side, the 50–70 m high, glaciofluvial gravel terraces east of 84°–85°E, which lie there on a valley floor at 3,800–3,900 m a.s.l, are classified as High Glacial deposits (Kuhle, 1989, 1998, 2004). They indicate a glacier-free Tsangpo section, which separates glacier complexes I3 and I2 as far west as 84°E (Figure 1, top).

Further in the west, the complexes I2 and I3 join again during the maximum of the Last Glacial Period (LGP) (Figure 1, top). With an equilibrium line as low as 600 m below the average plateau altitude (Figure 1, bottom), glaciation seems likely, even in the case of the more easterly Tsangpo section. This would place the gravel terraces and varved clays of the deepest parallel valleys in the late Last Glacial Period (LGP). Thus until now, at least for one time-interval during the LGP, this valley section is regarded as free of ice. A precise dating of the terraces is to be done (Figure 1, top, from north of Shisha Pangma to near Kola Kangri; cf. Kuhle, 2004). The second ice free area is the Tsaidam Depression. In the block diagram of Figure 1 (top), it shows up as narrow strip below I1 (cf. Kuhle, 2004).

Dates of lake sediments in the area of the former ice sheet are all younger than 13,000 years old because they developed only after the glaciers had melted (Gasse et al., 1996, and others). By contrast, lakes in nearby, nonglaciated areas such as the Tsaidam basin (Figure 1) and the Gobi desert display continuous sediment records going back more than 40,000 years (Pachur and Wünnemann, 1995; and others).

In a north-westerly direction from Mt. Everest to K2 (Figure 1), and from Dhaulagiri to the western Kuen Lun (Figure 1), the cross section shows that the Last Glacial Period (LGP) Equilibrium Line Altitude (ELA) runs parallel to the present ELA (in the area of southern Central Tibet the ELA attained an altitude of over 4,700 m a.s.l. (Figure 1, bottom)) (Kuhle, 1998, 2004). Nonetheless, a Last Glacial Period (LGP) Equilibrium Line Altitude (ELA) depression of at least 1,200 m means that 83–86% of the plateau surface was above the ELA. The accumulating ice necessarily led to the filling of valleys that incised the Tibet plateau. The remainder accounts for the remaining 14–17%.

Last Glacial Period (LGP) glaciers attained an approximate thickness of 2,700 m. Glacier thicknesses, ascertained by means of abrasions, polishings, and erratics, reach 1,600–2,000 m in the Himalaya and 700–1,200 m in Central and North Tibet. In the northern, southern, and western Karakorum, thicknesses of 1,750–2,600 m have been observed (Kuhle, 1987, 1988a, b, 1989, 2004, 2005) and in some places confirmed by Hewitt (2009a, b). However, these are probably minimum values. The ice may well have risen to 2,500–3,000 m in Central Tibet owing to a compact ground plan that extended over 1,500 × 3,000 km. The high viscosity of cold, continental glacier ice with annual temperatures of around −6°C to −10°C at the ELA (Kuhle, 1998) supports the build-up of ice, provided that there is sufficient precipitation. An average thickness for all of the Tibet ice of approximately 1,000 m implies that 2.2 million km³ of water was bound in the ice sheet of Tibet. This corresponds to a lowering of sea level of about 5.4–6.5 m (Kuhle, 1998).

Earlier it has been shown (cf. Kuhle, 1998, Figure 22) how the glaciated area in Tibet and in the Karakorum relates to an ELA depression or an uplift of the plateau- and mountain relief of only 500 m. At the same time, it permits an estimation of conditions if the equilibrium line drops by 1,200 m and makes the cupola-shaped build-up of the inland ice to a considerable thickness plausible. With the ice held back by mountain barriers, build-up was assisted by the low run-off, and initially by freezing to the subsurface. At a later stage, due to ice build-up, the pressure-induced melting point was reached. Run-off from the central inland ice sheet gradually increased until an equilibrium had been achieved. This was the end of ice build-up.

Meanwhile the Tibetan ice is confirmed by different disciplines. This will be shown by only three selected items

Breakdown of the summer monsoon, strengthening of the winter monsoon, and pioneering role of the subtropical inland ice

A Tibetan inland ice must have prevented the development of a low-pressure cell, a heat low, as it exists today over the heated debris covers of Tibet. Accordingly, the summer monsoon weakened. In the meantime, deep-sea cores from the Arabian Sea prove the glacial breakdown of the SW-Indian summer monsoon via dust fall (Sirocko et al., 1993). Loess-palaeosol sequences in China showing the fluctuations of the East-Asian monsoon also confirm the dramatical weakening of the summer monsoon during glacial phases (Rutter and Ding, 1993). At the same time, however, the winter monsoon strengthens during the ice ages like a mirror image of the summer monsoon. The winter monsoon was the result of differences in temperature, in this case between cold continental and catabatic winds of the Tibetan ice and the relatively warm air over the Pacific and Indian oceans. The resulting cold/dry anticyclonic wind blew loess out of the Inner-Asian glaciolimnical meltwater pits and deposited it on the Chinese loess plateau. Due to grain-size measurements in loess–palaeosol sequences, evidence was provided of

monsoonal variations and a special intensity of the winter monsoon during the glacial period (Xiao et al., 1995). Modeling has shown that the Nordic inland ices have nearly no effect on monsoon circulation whose intensity is primarily controlled by direct insolation at low altitudes (Felzer et al., 1998). Hence, the weakening of the summer monsoon and simultaneous strengthening of the winter monsoon is a clear pointer to a large-scale subtropical glaciation on the Tibetan plateau (Anderson and Prell, 1993). At the same time, this enormous climate-ecological influence on the monsoon makes clear that the Tibetan inland ice must have had a central influence on the global atmospheric circulation and energy balance. Probably, this climate-ecological signal is even strong enough to recognize a decisive influence on the global tendency towards glaciation. Tibet may have been the pacemaker and trigger for the ice ages (Kuhle, 1988a; cf. Ice age development theory, in this volume). Tibet's key role is confirmed by computer models showing that the Tibetan ice sheet is not only the first to be built up at the onset of a glacial cycle, but that when the build-up of the Tibetan inland ice had already come to an end, only half of the Nordic lowland ices were built up, i.e., that they develop much more slowly. The global ice volume then measured only 50% of the maximum ice volume during the LGM (Marsiat, 1994).

Glacial isostasy

Glacial-isostatic rebound during inter- and postglacial periods is an indicator of a High Glacial inland ice cover. The very high uplift rate of 12 mm per year measured on the Tibetan plateau (Hsu et al., 1998) is such a glacio-isostatic indicator because its value lies far above that of normal tectonic uplift. Just within the short Pleistocene period (1,000,000 years), it would lead to an unrealistic uplift of 12 km. These measurements confirm corresponding uplift calculations of the applicant due to meanwhile self-glaciated end moraines N of Shisha Pangma (S-Tibet) (Kuhle, 1995). The thickness of the inland ice of 2,000 m led to a glacio-isostatic lowering of the plateau by 600–700 m down to c. 4,300 m a.s.l. At the same time, this is the cause of the interglacial deglaciation of Tibet (Kuhle, 1995). On the basis of changes of geoid anomaly in relation to gravity anomaly – a method that allows to distinguish glacio-isostatic from tectonic uplift – also Kaufmann and Lambeck (1997) and Wang (2001) have shown a glacio-isostatic uplift of Tibet and thus have confirmed a Tibetan glaciation (Nesje and Dahl, 2001:127). Obviously, the effects of an up to 2,000 m thick ice sheet on the height of the plateau are so profound that the satellite missions CHAMP and GRACE were able to identify them (Kuhle, 2001).

Computer models and tests of general circulation models

Up to now, the general circulation models made up and tested by computer modeling were based on the global inland ice configurations of CLIMAP (1981) and COHMAP (1988), i.e., they did not include the glaciation of Tibet. These climate models unanimously show the tendency of Tibet to develop a permanent snow cover and thus to form a large-scale glaciation of the Tibetan plateau (Kutzbach et al., 1998). All sensitive experiments also indicate the growth of an ice sheet in Central Tibet which is much more likely and the development of which must have set in much earlier than that of the more northern Laurentide- and Fenno-Scandinavian ice sheets (Verbitsky and Oglesby, 1992; Marsiat, 1994). Marsiat also shows that on conditions of a reduced glaciation of Tibet, the development of the Nordic lowland ices is insignificant, too (Marsiat, 1994). This independent modeling result has been considered to be an unexpected mistake of these climate models (Verbitsky and Oglesby, 1992; Marsiat, 1994; Kutzbach et al., 1998). Actually, however, it is a clear confirmation of the terrestrial field data (Kuhle, 1987, 1988a, b, 1989, 1995, 1998, 2001, 2004, 2005, 2007, 2011).

Dating

In the area of the Tsangpo bend in SE Tibet (Figure 1, left-hand side of Namcha Bawa), a last strong glacier advance is proved about or after 9.820+/−350 YBP. In addition, seven datings of trees from an 80 m high opening (1989) have been analyzed (Kuhle, 1998:83 Table 2: 99; 2004: 190 Figure 37). The eight ^{14}C-samples stem from the lower 32 m of the opening. These limnic basal sands, in which the trunks were embedded, have been overlain by 8 m thick varved clays. They provide evidence of an ice-dammed lake in this lower section of the Tsangpo valley at merely c. 3,000 m a.s.l. Accordingly, this ice-dammed lake is of the same age or younger than 48.580–9.820 YBP. Therefore, it is classified as being of the Last Glacial Maximum up to Late Glacial. The counting out of the varves yielded that the lake existed c. 1,000 years. It was situated between the ice complexes I2 and I3 (Figure 1, left-hand side of Namcha Bawa) and was dammed up by the Nyang Qu Glacier. The Nyang Qu Glacier, which was an outlet glacier of the ice complex I2, followed the Nyang Valley, reaching the Tsangpo Valley 17.5 km down-valley from the opening. Ground and lateral moraines confirm that the glacier bended into the Tsangpo Valley, and thus the ice-dammed lake came into being. These are several of the datings which establish an immediate genetic connection to the inland glaciation of Central Tibet and thus provide evidence of the Ice Sheet during the Last Glacial Period (LGP).

Discussion of datings

For several years, TCN-dating in High Asia has been carried out by some authors. However, a methodically fundamental mistake is that the astrophysical metric of cosmic radiation has not been sufficiently explored so far, and that the TCN-dating method therefore is not considered to be a reliable dating technique. In the critical remark (Kuhle and Kuhle, 2010), however, it is referred to the, at least up to now, unsolved astrophysical problem which states that one cannot assume constancy of cosmic radiation; the constancy assumption is, however, the indispensably

most important prerequisite for both TCN- and OSL-dating techniques.

As has been shown in other areas of the Himalaya, Karakoram, and Tibet, up to now, only ^{14}C-datings are glaciogeomorphologically safe, while the OSL- and TCN-datings carried out so far because of the high sea level are fourfold to tenfold overestimated, i.e., they led to too old ages. Thus, by means of ^{14}C-datings of moraines in the Khumbu Himal, a snowline (ELA)-depression up to 500 m has been evidenced during the Neoglacial period c. 2.1 and 4.2 ka ago; while the same ELA-depressions according to OSL- and TCN-ages were dated to c. 16–23 ka, i.e., they were overestimated by a factor 6.5. More OSL- and TCN-overestimations are evidenced for S- and Central Tibet and the Karakoram (Kuhle and Kuhle, 2010).

Probably the age of the TCN-data that so far have not been calibrated with regard to the high sea level of High Asia has been overestimated on the following grounds:

1. Obviously, the correction factors underestimate the amount of cosmic rays that really hit the surfaces of very high altitudes.
2. Due to magnetic field excursions, the amount of cosmic rays (CR) was additionally strengthened during the Late and High Glacial. This must have had a special effect at high altitudes, so that the age overestimation exponentially increases with moraine age.

This means that the Late Glacial moraine stages can already be extremely overestimated as to their age and thus differ from the Holocene stages in a clear age leap, while the glaciogeological findings do not confirm this great difference in age.

Actually there are already several independent proofs with regard to an "age leap" like this of the TCN-dating in High Asia (ibid. and Kuhle, 2011).

With regard to this deficiency of TCN-dating – that unfortunately has come into fashion – it is scientifically extremely important to take the complete glaciogeological and glaciogeomorphological setting into consideration and give to it the primary importance it deserves (Kuhle and Kuhle, 2010).

Summary

Since 1973, new data were obtained on the maximum extent of glaciation in High Asia. Evidence for an ice sheet covering Tibet during the Last Glacial Period means a radical rethinking about glaciation in the Northern Hemisphere. The ice sheet's subtropical latitude, vast size (2.4 million km²), and high elevation (6,000 m a.s.l.) are supposed to have resulted in a substantial, albedo-induced cooling of the Earth's atmosphere and the disruption of summer monsoon circulation. Moraines were found to reach down to 460 m a.s.l. on the southern flank of the Himalayas and to 2,300 m a.s.l. on the northern slope of the Tibetan Plateau, in the Qilian Shan region. On the northern slopes of the Karakoram, Aghil, and Kuen Lun mountains, moraines occur as far down as 1,900 m a.s.l. In southern Tibet, radiographic analyses of erratics suggest a former ice thickness of at least 1,200 m. Glacial polish and roches moutonnées in the Himalayas and Karakoram suggest former glaciers as thick as 1,200–2,700 m. On the basis of this evidence, an 1,100–1,600 m lower equilibrium line (ELA) has been reconstructed, resulting in an ice sheet of 2.4 million km², covering almost all of Tibet. ^{14}C ages classify this glaciation as MIS 3-2 in age (Würmian = Last Glacial Period (LGP), c. 60.000–18.000 years ago).

LATENT HEAT OF CONDENSATION

Prem Datt
Research & Design Center (RDC), Snow and Avalanche Study Establishment, Himparishar, Chandigarh, India

The condensation is the opposite process of evaporation. Latent heat of condensation is energy released when water vapor condenses to form liquid droplets. The latent heat of condensation is defined as the heat released when one mole of the substance condenses. The temperature does not change during this process, so heat released goes directly into changing the state of the substance. It is expressed as kg/mol or kJ/kg. The energy released in this process is called heat of condensation. The heat of condensation of water is about 2,260 kJ/kg, which is equal to 40.8 kJ/mol. The heat of condensation is numerically exactly equal to the heat vaporization, but has the opposite sign. In the case of evaporation, the energy is absorbed by the substance, whereas in condensation heat is released by the substance. For example, as moist air is lifted and cooled, water vapor eventually condenses, which then allows for huge amounts of latent heat energy to be released, feeding the storm.

LATENT HEAT OF FUSION/FREEZING

Prem Datt
Research and Design Center (RDC), Snow and Avalanche Study Establishment, Himparishar, Chandigarh, India

Fusion is a physical process in which a solid converts into a liquid. The latent heat of fusion at a particular temperature is the amount of heat required to convert a unit mass of solid into liquid. For example, when ice melts into water the amount of heat required at 0°C is estimated equal to 334 kJ/kg, which is the latent heat of fusion of ice at 0°C. *This process is opposite to the process of freezing.* In a natural snowpack the fusion process generates melt-freeze polycrystals and melt-freeze clusters of the small rounded grains. A hard crust within snow results after multiple melt-freeze processes.

LATENT HEAT OF SUBLIMATION

Prem Datt
Research and Design Center (RDC), Snow & Avalanche Study Establishment, Himparishar, Chandigarh, India

Sublimation is a physical process in which a solid directly converts into a gaseous (vapor) state without going through a liquid state. The latent heat of sublimation at a particular temperature is the amount of heat required to convert a unit mass of solid into gas. For example, when ice sublimates into vapor, the amount of heat required at 0°C is estimated equal to 2,838 kJ/kg, which is the latent heat of sublimation of ice at 0°C. In the crystal growth of ice and snow in atmosphere, this process plays a dominant role. This process is opposite to the process of deposition.

LATENT HEAT OF VAPORIZATION/CONDENSATION

Prem Datt
Research and Design Center (RDC), Snow and Avalanche Study Establishment, Himparishar, Chandigarh, India

When a substance changes phase, the arrangement of its molecules changes, but its temperature does not change. If the new arrangement has a higher amount of thermal energy, then the substance absorbs thermal energy from its environment in order to make the phase change. If the new arrangement has a *lower* amount of thermal energy, the substance releases thermal energy to its environment.

Latent heat of vaporization is a physical property of a substance. It is defined as the heat required to change one mole of liquid at its boiling point under standard atmospheric pressure. It is expressed as kg/mol or kJ/kg. When a material in liquid state is given energy, it changes its phase from liquid to vapor; the energy absorbed in this process is called heat of vaporization. The heat of vaporization of water is about 2,260 kJ/kg, which is equal to 40.8 kJ/mol.

The vaporization is the opposite process of condensation. The heat of condensation is defined as the heat released when one mole of the substance condenses at its boiling point under standard pressure.

LATEROGLACIAL

Lasafam Iturrizaga
Geography/High Mountain Geomorphology, Institute of Göttingen, University of Göttingen, Göttingen, Germany

Synonyms

Ice-marginal

Definition

The term "lateroglacial" defines the ice-marginal areas along the lateral sides of the glacier. The lateroglacial environments grade downglacier into the latero-frontal and proglacial environments. They are composed of specific geomorphological and glaciological landform assemblages, such as ablation depressions, lateral moraines, breach lobes or earth pyramids. Lateroglacial landforms are mostly developed between the glacier and the adjacent valley flank in high mountain landscapes. However, they occur as well in the mountain forelands, especially along dam glaciers or outlet glaciers (e.g., in Iceland), but to a more limited extent. Relict lateroglacial sediments may serve as important geomorphological evidence for reconstructing the extent and ice thickness of former glaciations.

LATEROGLACIAL LANDFORM SYSTEMS

Lasafam Iturrizaga
Geography/High Mountain Geomorphology, Institute of Göttingen, University of Göttingen, Göttingen, Germany

Synonyms

Ice-marginal landforms

Definition

Lateroglacial landforms are located at the lateral margins of the glaciers and belong to the glacial landscape systems. Down glacier they pass over into the laterofrontal and proglacial sediment environments. Lateroglacial landforms show characteristic landform sequences and assemblages (i.e., lateroglacial valleys, ablation depressions, earth pyramids) and are classified as a specific geomorphologic unit of the glacial environment.

Distribution

Lateroglacial landforms may occur at any glacier, preferentially at valley glaciers in mountain regions with sufficient debris supply areas and their associated forelands (i.e., in the European Alps, the Andes, and the Himalayas). They are best developed in the Karakoram Mountains (72°–79°E; 35°–36°N), where they have been investigated systematically as a specific geomorphological unit along 53 glaciers in regard to their distribution, evolution, and morphodynamics (Iturrizaga, 2001, 2003, 2007). The Karakoram shows the highest concentration of large valley glaciers outside of the polar regions with glacier lengths of up to 72 km. In combination with a surrounding high mountain relief of over 8,000 m, the Karakoram provides large-sized debris supply areas for the formation of a heterogeneous lateroglacial environment. Lateroglacial sediment complexes may attain a length of up to several to tens of kilometers and can be referred to as lateroglacial valleys. Besides their large horizontal distribution, they are spread over a considerable vertical range in the Karakoram and occur between altitudes of about 2,500–5,000 m. The upper limit of lateroglacial sediments deriving from the glacier is theoretically given by the altitude of the snow line. Due to the fact that a major part of the glaciers are avalanche-fed glaciers and therefore show steep inclined head walls of up to 3,000 m in absolute height, the distribution of lateroglacial sediments starts usually 1,000–1,500 m lower than the snow line.

Types of lateroglacial landforms and their processes of formation

The transition from the valley flank to the glacier emerges in different morphological variations. One of the most well-known and prominent landforms are the lateroglacial valleys, which are ice-marginal depressions between the glacier and the valley flank and may be filled with sediments. They even show in some cases an own drainage system over short distances. They are not true valleys in sensu stricto, but rather glacier-marginal discontinuous depressions. Where mountain spurs stand out against the glaciated main valley, the lateroglacial valleys may be interrupted. The topographical depression can be filled up with a wide range of different types of sediments or the sediments themselves may even be the trigger for the formation of the lateroglacial valleys. One of the main characteristics of the lateroglacial sediment regime is the damming effect by the glacier, which results in a large-scaled sediment storage along the glacier margins. The lateroglacial sediments are highly polygenetic landforms.

A characteristic type of lateroglacial valleys is the *lateral moraine valley*. It is a mostly linear depression or sediment assemblage between the lateral moraine and the valley flank (Oestreich, 1906). It had been erroneously often referred to as "*ablation valley*." Visser (1938) carried

out the first systematic investigation on these landforms and postulated an insolation-controlled distribution of all lateroglacial landforms. This terminology has been widely criticized by many authors (v. Klebelsberg, 1938; Hewitt, 1993) as the lateroglacial depressions show various formation processes. Consequently, the nongenetical expression "lateroglacial valleys" has been introduced (Iturrizaga, 2001). However, the formation of a lateroglacial valley might be triggered by the presence of an ablation depression as it can provide initial sediment traps.

The formation of lateral moraine valleys is mainly a result of (a) dumping processes of the lateral moraine against the valley flank, especially during times of a comparatively smaller extent of the glacier, and (b) different type of debris inputs from the adjacent tributary valleys and valley slopes. Their width attains a size of up to 1 km. The great dimension already indicates that ablation processes only play a subordinated role in their formation. The *lateral moraine* is the most distinct depositional landform in lateroglacial environments. It may attain a height of about 250 m. Its large size has been attributed to repetitive glacier advances and accordingly to various deposition processes. The lateral moraine is often composed of an older moraine core, which has been superimposed by younger moraine layers and/or processes of moraine accretion. The time period of their formation goes in general back to the Neoglacial and Little Ice Age. Once the lateral moraine has been built up, it prevents the direct debris transfer from the glacier to the interior of the lateroglacial valleys. Consequently, the sedimentary system in the lateroglacial depression is well protected from glacial activities, unless some overspilling or breakthrough of the lateral moraine takes place. The lateral moraine also impedes the drainage of the tributary rivers into the glacier system.

The lateral moraine valleys are distinguished into two principal types: (a) The V-shaped lateral moraine valley, in which the lateral moraine is directly connected with the adjacent valley flank. Its origin goes mainly back to dumping processes occurring at the glacier margin (Figure 1). (b) The lateral moraine valley with a valley bottom floor (Figure 2). The incorporated sediments are composed of heterogeneous debris sources (Figure 3):

1. Primary processes of rock disintegration such as ice avalanches and freeze-thaw processes as well as glaciofluvial sediments from the main and tributary glaciers provide debris for the formation of lateroglacial sediments, especially for the formation of the lateral moraine.
2. A considerable part of the debris supply for the lateroglacial sediment complexes derives from the tributary valleys, in particular at glaciers framed by highly dissected mountain relief (Figure 1). The sediment cones, such as alluvial fans, debris flow cones, and avalanche cones, drain toward the glacier either into an existent ice-marginal depression or even onto the glacier. Especially large-sized, catastrophic debris flows can even initiate the formation of a lateroglacial valley. Rockslides, debris flows, and snow avalanches deposited into a lateroglacial valley frequently dam lateroglacial rivers and cause the deposition of lacustrine sediments. As a result, a considerable proportion of the lateroglacial sediments is of non-glacial origin. This fact has to be taken into consideration regarding glacier reconstruction in recent non-glaciated

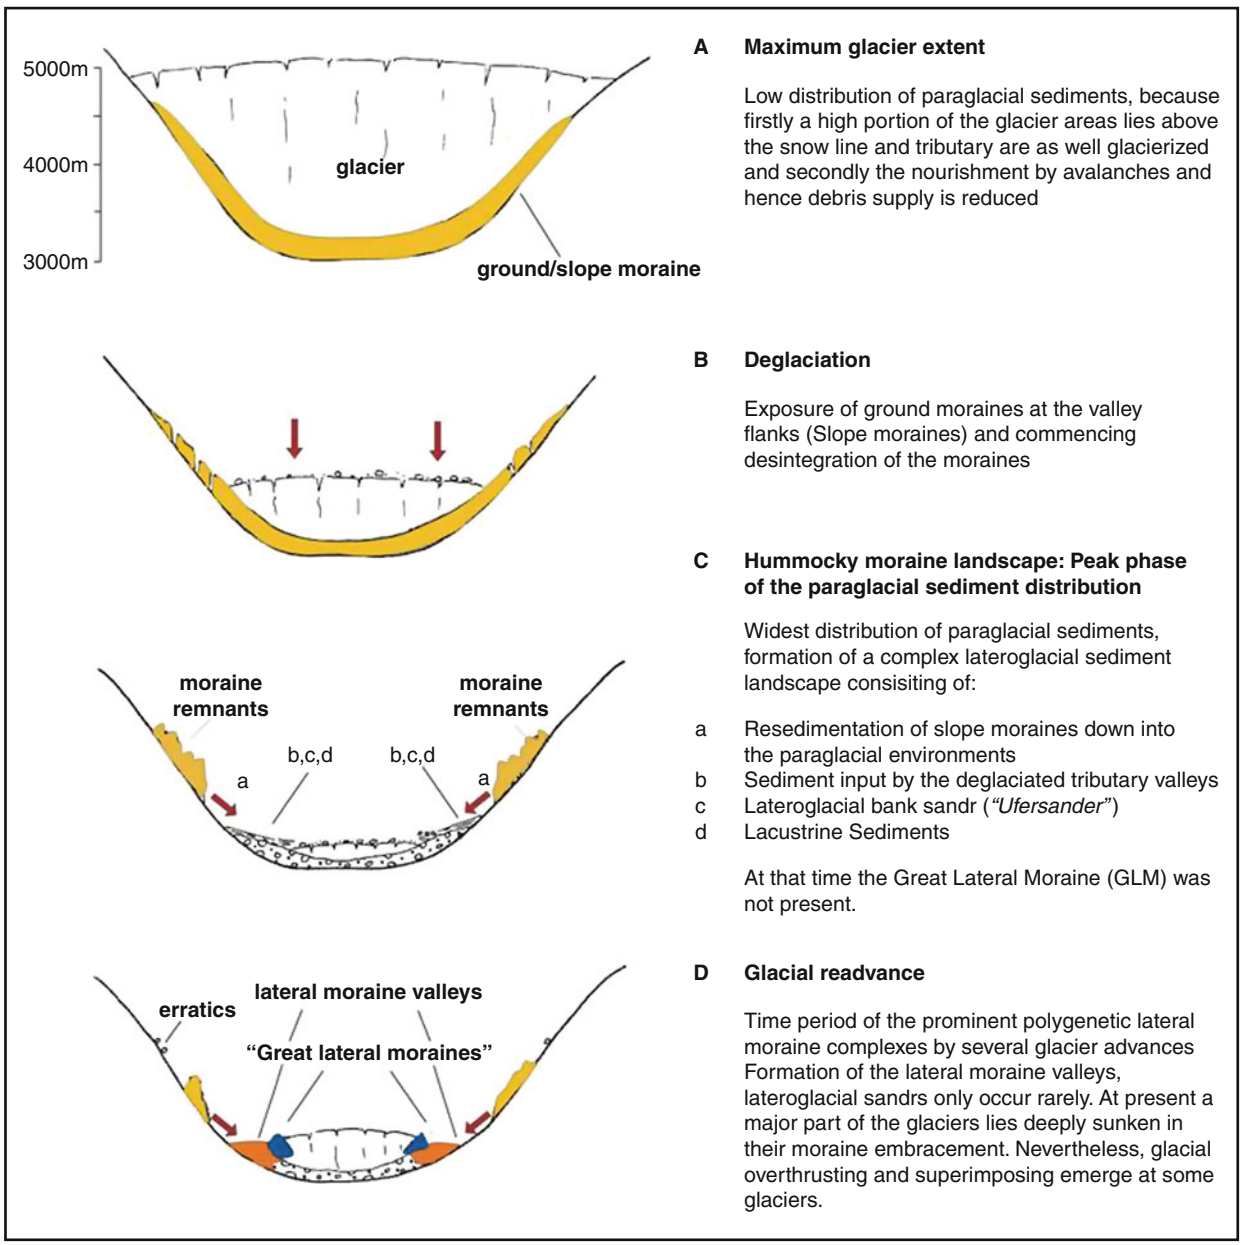
B Debris supplied by the adjacent valley sides, either by the tributary valleys (**B.1.1**) in form of sediment fans or by the slopes (**B.1.2**) in form of talus cones, avalanche cones or resedimented moraine material, **B 2** Debris supplied by the glacier margin (lateral moraine, **B.2.1**), morainic debris flows (**B.2.2**)

Lateroglacial Landform Systems, Figure 3 Source areas of debris supply for lateroglacial valleys.

mountain valleys. Dendritic glaciers in which the individual tributary glaciers recede and loose the contact to the main glacier are prone to the formation of lateroglacial sediment complexes.

3. The lateroglacial sediment landscape is built up to a great extent by the secondary debris supply in form of the reworking of older glacigenic deposits mantling the valley flanks (Figure 4). Many glaciers show a close interfingering of Late Glacial slope moraines and younger lateroglacial landforms. After the gradual down-melting of the Pleistocene glacier surface, moraine deposits remain along the lateroglacial margins, partly as terraces, partly as amorphous deposits and are dislocated into the lateroglacial valley by different types of mass movements.
4. In some parts, the sediments are deposited in the form of small-scaled *lateroglacial sandar*. These are glaciofluvial deposits which originate directly from the melt waters of the main or the tributary glacier. They are located between the glacier and the valley flank or the lateral moraine. After the deglaciation, these sediments are preserved as kame terraces.



L. Iturrizaga

Lateroglacial Landform Systems, Figure 4 Genesis of the lateroglacial valleys deduced from the glacial history.

Relict lateroglacial valleys occur as high as 1,000 m above the present glacier surfaces and are important landforms for reconstructing the Pleistocene glacier thickness.

Summary

Lateroglacial landforms are composed of a large variety of different sediment types. The higher and more spaciously the surrounding mountain relief of the glacier in general is, the more complex are the lateroglacial landform systems. In many mountain areas, i.e., the European Alps, the Canadian Rocky Mountains, and also the Himalayas, lateral moraine valleys represent rather stable landforms. However, at many locations, they are in the stage of destruction due to glacier surface lowering and the missing abutment of the glacier. In the Karakoram, lateral moraine valleys may also be destroyed by present glacier advances or lateral widening as those glaciers are even today highly dynamic in the form of short-term glacier advances or surges. Lateroglacial valleys are a major location for temporary settlements and their pasture areas. Changes in the settlement situation are valuable indicators for glacier dynamics along the lateroglacial margins.

LAURENTIDE ICE SHEET

John T. Andrews
Institute of Arctic and Alpine Research and Department of Geological Sciences, University of Colorado, Boulder, CO, USA

Definition

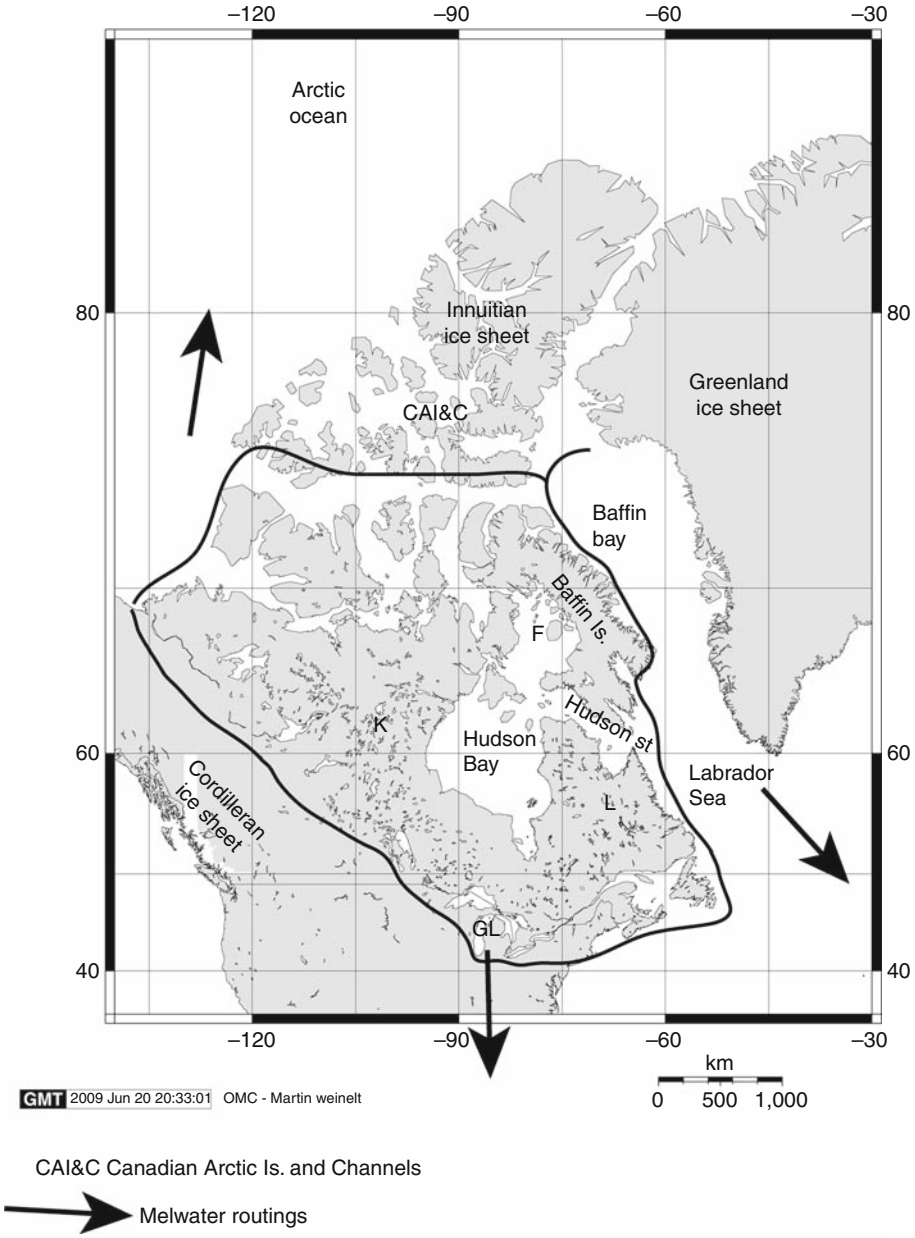
Laurentide Ice Sheet (LIS) – refers to an Antarctic-size ice sheets that extended from the general area of the Great Lakes in the USA northward to the Canadian Arctic coast, and westward from the uplands and fjords of Baffin Island and Labrador to the foot of the Rocky Mountains (Figure 1). In the west, it was at times contiguous with the Cordilleran Ice Sheet, and in the NE merged with the Innuitian Ice Sheet.

Introduction

The LIS had an area of approximately 12×10^6 km^2, a central thickness estimated to be in the range of 3–4 km, and sufficient mass to cause a worldwide fall in sea level of around 70± m, out of a total global sea level extraction of ~120–130 m due to expansion of ice sheets and glaciers worldwide (Figure 2). The term LIS should strictly be only applied to the last great ice sheet of the Wisconsinian Glaciation (Figure 2), but it is frequently used to cover a broader span of Quaternary time. Because of its area, height, and volume the LIS has to be considered a major component in the late Quaternary climate of our planet, seriously influencing ice sheet/ocean/atmospheric interactions. Waters from the ice sheet debouched into three marine basins – drainage from the Great Lakes westward were directed into the Gulf of Mexico, waters from the long eastern margin entered Baffin Bay, the Labrador Sea and the western North Atlantic, whereas the northern margin drained to the Arctic Ocean (Figure 1). The input of meltwater into the oceans has been called upon as having a significant impact of the thermohaline circulation of the oceans. Tidewater outlets and ice streams also injected icebergs into the North Atlantic and Arctic oceans. Ice-rafted debris (IRD) from the North American continent has been traced across the Arctic Ocean and in the North Atlantic as far east as the Portugal margin.

A brief history of concepts about the LIS

By the 1890s, a good deal of research had been carried out in the glaciated area of the USA and in southern Canada. In 1898, Tyrrell produced a map of the former North America ice sheets. This map is remarkably similar in many ways to present-day concepts of the LIS, that is, an ice sheet that like the Antarctic Ice Sheet, had several dispersal center with ice divides over Labrador, Foxe Basin, Keewatin, and the Patrician Center off SW Hudson Bay. This notion prevailed until the 1940s when Flint argued for the growth of an ice sheet from the mountains of the eastern Canadian Arctic to finally form a massive



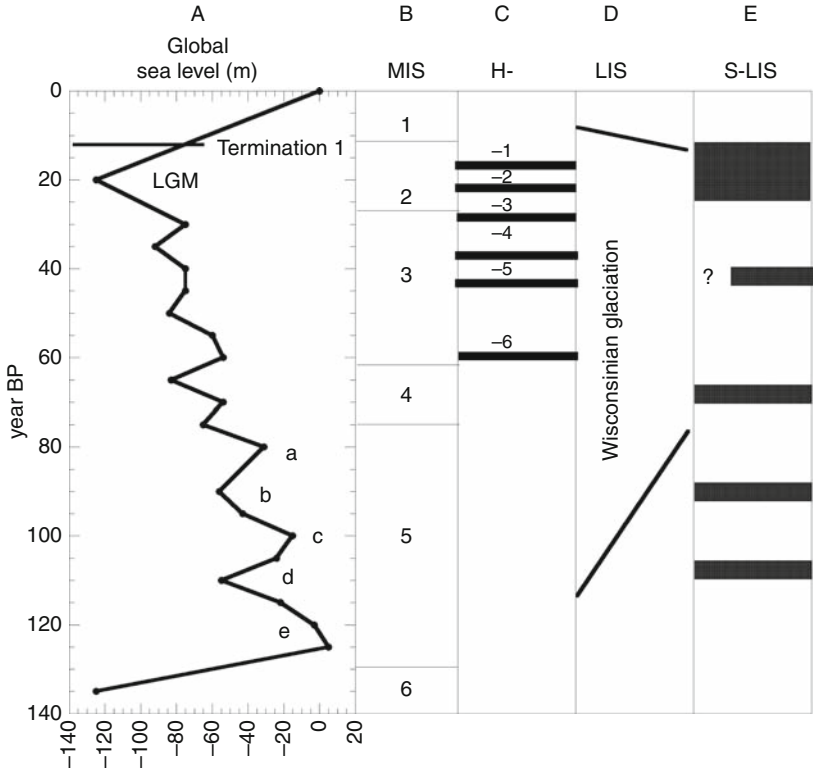
Laurentide Ice Sheet, Figure 1 North American showing the outline of the Laurentide Ice Sheet during the last glacial maximum. K = Keewatin ice divide, L = Labrador ice divide, F = Foxe Basin ice divide.

single-domed ice sheet centered over Hudson Bay. Flint's model was based on a conceptual model for the growth and development of the ice sheet. This model continued to have adherents into the 1970s and 1980s but is now largely abandoned.

Wide-ranging field observations in the Eastern Canadian Arctic in the late 1950s and 1960s, combined with adequate topographic maps, aerial photographs, satellite imagery, and increased knowledge of the tectonic evolution of the North Atlantic region during the Tertiary, resulted in an appreciation of the role that the high rolling uplands of the Eastern Canadian Arctic played in the onset of glaciation, and in the overall complex pattern of shifts in flow regimes during the Wisconsinian Glaciation.

Onset of glaciation

Our knowledge of the growth and buildup of the LIS during the interstadials of marine isotope stage (MIS) 5, namely 5d and 5b, is limited (Figure 2). The last full interglacial over North America (MIS 5e) was warmer than present, and it is possible that many of the smaller ice caps



Laurentide Ice Sheet, Figure 2 Evolution of global sea level during the last glacial (Wisconsinian) cycle. (**a**) global sea level (Shackleton 1987); (**b**) marine isotope stages (MIS); (**c**) Heinrich (H-) events; (**d**) age span of the Wisconsinian Glaciation; (**e**) glacial episodes of the Laurentide Ice Sheet (LIS) in the area of the Great Lakes (Figure 1) (Karrow et al., 2000).

and glaciers in the Eastern Canadian Arctic disappeared. On the global level, the relationship between ice volume and $\delta^{18}O$ of marine foraminifera indicate that the growth of ice sheets during MIS 5d was remarkably rapid as global sea level fell to –55 m in ~10,000 years. What fraction of this global extraction of water for ice sheet buildup is associated with the LIS is largely unknown, but on general climatic grounds it seems reasonable that a considerable fraction of the 55 m of global sea level was locked into the initial growth of the LIS.

The global pattern of changes in sea level, a proxy for ice sheet growth and decay, has been successfully linked to changes in insolation, which in turn has been linked to the orbital variations of the Earth relative to the Sun – the so-called Milankovitch orbital variations. Spectral analysis of $\delta^{18}O$ time series covering the last 700,000 years shows that the variations in sea level, hence ice sheet mass, have 100,000, 41,000, and 25,000 periodicities, and this gives an initial template for evaluating the history of the LIS. However, subsequent research has shown that the LIS is also marked by much shorter periodic events, such as Heinrich (H-) events (Figure 2).

The uplands of the Eastern Canadian Arctic, that is the largely undissected Precambrian shield that lies to the west of the Tertiary rift-margin along the Labrador and Baffin Island coast, have a large fraction of their elevation >500 m asl. Imagery and fieldwork indicate that during the Little Ice Age (LIA) ca. AD 1400–2000 large fraction of these uplands were covered with permanent snow beds or small ice caps, thus demonstrating the sensitivity of these areas to relatively small changes in net mass balance. Hence, virtually all attempts to model the development and growth of the LIS over the last 120,000 years, show the initial growth of the ice sheet over the uplands of Labrador and Baffin Island. As conditions cooled, it is also probable that ice sheets developed over the somewhat lower plateaus terrain of Keewatin, west of Hudson Bay, and an ice sheet may have developed across the High Canadian Arctic islands and Channels. Thus, the initial movement of the various accumulation centers would have been from the uplands through the fiords of Labrador and Baffin Island, and toward the large interior seas of Hudson Bay and Foxe Basin. A critical question is whether the advancing ice sheets based over Labrador and Baffin Island merged across Hudson Strait prior to glacial inundation of Hudson Bay – if that did not happen then a large glacially dammed lake would have been ponded within the Bay.

At some point, possibly in MIS 4, Hudson Bay, and Foxe Basin were filled and the LIS then became a marine-based ice sheet, somewhat similar in that respect

to the West Antarctic Ice Sheet today. Because of the mass of the LIS the bedrock under the ice sheet would be isostatically depressed – thus meaning a large fraction of the ice sheet was grounded below the sea level, and linked to the North Atlantic via the deep graben of Hudson Strait (Figure 1). Hudson Bay, Foxe Basin, and Hudson Strait are floored with Paleozoic carbonates composed of calcite and dolomite, and these rocks provide powerful tracers of ice sheet activity in the adjoining deep-sea basins of the Labrador Sea and Baffin Bay.

Glacial landscapes

The extension of the LIS along its eastern margin is limited by the presence of the adjacent ocean basins, and it is in these areas that some trace of the history of the ice sheet can be recovered in piston cores through marine sediments. The deep water connections between the ice sheet (~450 m at the Hudson Strait sill, without isostatic depression) and the Labrador Sea represent one major potential point of instability; others exist in other deep marine embayments, such as the Gulf of St Lawrence. However, on the grand scale of the LIS there is also another large spatial difference, that is between the "hard bed," glaciological speaking, of the sediments produced by erosion of the Precambrian granites and gneisses, versus the "soft-bed" younger sedimentary rocks that flank the shield rocks along the southern flank. Reconstruction of profiles of the ice sheet and its outlets in the areas of the Canadian Prairies, Iowa, and in the Great Lakes indicate that the basal shear stress was much lower and the ice much thinner than where the ice sheet was moving across the shield bedrock. Thus the configuration of the LIS and its potential response to climate and other changes are quite different from the neighboring Greenland Ice Sheet.

The effect of the combination of bedrock, elevation, and tectonics on the large-scale patterns of glacial erosion is evident on satellite imagery. The uplifted eastern rim of the Shield is dissected by fiords, and large-scale grabens extend into or toward the center of the ice sheet. On the flanks of Foxe Basin and Hudson Bay where the eastward flowing ice attained thicknesses of 2 km or more the Shield rocks have been glacially eroded along joint and fracture planes to form a landscape of glacial scour, with limited thickness of glacially derived sediments (till). Between the fiord landscape and the scoured areas there is frequently an area (usually >400 m asl) with little or no scour; this is interpreted as an area that was covered by thinner ice with basal temperatures below the pressure melting point (i.e., cold-based ice). In the flanking region along the southern margin of the ice sheet the thickness of till is greater and the underlying bedrock is masked by glacial and glaciofluvial sediments. Contrary to some theories, the area at the geographic center of the LIS, the western Hudson Bay lowlands, has a thick sequence of preserved non-glacial and glacial sediments that are a critical record of the LIS.

The LIS and Wisconsinian glaciation

The marine isotope records form a template for global changes in ice sheet volumes acting on multi-millenial scales (Figure 2). How far does the stratigraphic record from the area of the LIS match this master template, indeed how far can we express the history of the LIS in a single description versus regional differences in glacial history? This question faces several major problems. First is the fact that the stratigraphic record within the margins of the LIS is largely an intermittent record of temporal events at the best; in addition, the ice sheet has also the potential to erode evidence of past oscillations. Secondly, to place the history of the LIS into a time perspective to match with the $\delta^{18}O$ record requires (a) materials that can be dated, and (b) dating methods that span, ideally, 120,000 years or so. It should be noted that the marine time series are not without problems, in-so-far-as the main "absolute" dating method is radiocarbon dating of foraminifera, which only extends back 40,000–50,000 years BP. Thus, the chronology for MIS 4 and 5 is largely derived from a process of correlation with the astronomical (insolation) variations with links to U-series dates on raised coral reefs. Within or at the margins of the LIS implications for ice sheet growth or retreat are based on the stratigraphic sequence (including the nature of the sediments and paleobiological data) with ^{14}C dates being derived from wood, peat, shells, whalebone, or other organic materials. Often exposed sections have no material for dating or events are dated at >40,000 BP. In the last 10–20 years, a dating revolution has occurred with the advent of cosmogenic exposure age dating. This method allows, for the first time, moraines and eroded surfaces to be directly dated. This approach has shed new light on the LIS history, especially in Arctic areas, where materials for ^{14}C dating were scarce or absent, but where large surface boulders and exposed bedrock are abundant.

The LIS probably grew from its inception grounds during the interglacials of MIS 5 and expanded across the Gulf of St. Lawrence and into the Great Lakes during MIS 4 ca. 75,000 years ago (Figure 2). The history of the ice sheet during MIS 3 is proving difficult to unravel but the ice sheet may have been largely confined to the "hard bed" of the PreCambrian shield. Whether the glaciologically sensitive area of the interior basin of Hudson Bay was ever deglaciated is debatable and hinges on issues involved with dating marine sediments in the Hudson Bay lowlands and the interpretation of sediments in the Labrador Sea.

Heinrich events and LIS instability

The relatively smooth intervals of growth and retreat of ice sheets that are implied in the ocean ^{18}O records were infact punctuated by massive instabilities of the marine-based LIS. Heinrich (H-) events (Figure 2) record massive outbreaks of meltwater and icebergs into the North Atlantic, with the major source being the ice

stream in Hudson Strait. H-events have been documented in the Labrador Sea eastward toward Europe due to their distinctive mineralogical composition, mainly detrital carbonate (DC) grains. Similar, but temporally offset DC events occur in Baffin Bay, representing collapse of the LIS and Innuitian ice sheets across the Canadian Arctic channels that lead into Baffin Bay. Detrital carbonate events also occur in Arctic Ocean sediments and represent events along the Arctic margin of the LIS and Innutian ice sheets. The massive thickness of DC sediments associated with H-4 in the Labrador Sea argues that Hudson Bay was not ice-free during MIS 3.

The last glacial maximum (LGM) and deglaciation of the LIS

The LIS expanded from its more restricted, more largely unmapped, extent during MIS3 to reach its maximum last glacial extent ~20,000 years BP (Figure 1). Note that the LGM is also marked by a major H-event (Figure 2). Given the geographic and climatic extent of the LIS during the LGM, it is unlikely that every margin of the ice sheet reached its maximum extent at exactly the same time. Indeed, for much of the eastern flank of the ice sheet the exact location of the margin at ~20,000 years BP is unknown and does not appear to be marked by large moraine systems, possibly because the ice sheet was cold-based.

The deglaciation of the LIS has now been mapped and dated across thousands of sites. Viewed in the light of the previous 120,000 years the deglaciation is relatively abrupt and is termed, globally, Termination I (Figure 2). Briefly the LIS retreats asymmetrically with initial high rates of ice retreat along the southern and western margins, with little change along the long eastern margin. As summer insolation increased, meltwaters were directed into adjacent oceans (Figure 1). The stability of the ice sheet was weakened by a massive collapse through Hudson Strait during H-1 (16,000 years ago). As the ice sheet retreated in the south and west at some point the continental drainage divide was revealed and a series of large, glacially dammed lakes were formed – these lakes are often lumped under the name Glacial Lake Agassiz. The final demise of much of the LIS occurred ca 8.4 years ago when waters from the Labrador Sea, penetrating through Hudson Strait, breached the remaining ice over Hudson Bay and connected with and drained glacial lakes that had been dammed south of the ice sheet. This outburst event and earlier meltwater events impacted the thermohaline circulation.

In subsequent years, the ice retreated and disappeared from the Labrador plateaus but the last remnants of the LIS still exist across central Baffin Island in the form of the Barnes Ice Cap.

Summary

The Laurentide Ice Sheet was the largest ice sheet in the Northern Hemisphere, comparable in size to the present Antarctic Ice Sheet. Growth and retreat were controlled by periodic changes in insolation but its marine-based nature made it susceptible to major collapses with massive outflows of meltwater and icebergs.

LAYERING OF SNOW

Rajesh Kumar
School of Engineering and Technology, Sharda University, Greater Noida, NCR, India

Snow layers are formed as a tabular body of snow with younger at top and oldest at the bottom having well defined boundaries of their precipations if at certain gaps (AGI, 1960). The layers are differentiated from the surrounding one due to unique deposition and post-deposition processes. Each layer of snow forms a snow packs which differs in physical and microstructural properties from those above and below. The layering sequence and its characteristics govern thermal, physical, and mechanical properties of the snow pack. The strength of the snow pack and the transport of air, water, and heat through it are also dependent on layer's characteristics. Under natural conditions they exhibit irregular boundaries and a wide range of grain and bond characteristics when traced laterally.

The definition focuses on the fact that the microstructure (grain size, shape, and arrangement and nature of bonds) differs from one layer to another. Though the layering seems simple, the real snow layers can be complex (Matthew and Carl, 2004). The knowledge about snow mechanics is very crucial in dealing with the snow avalanche formation and hazard mitigation measures. Snow stability depends on the layering of snow. The most relevant mechanical properties like compressive, tensile, and shear strength of the individual snow layers within the snow cover vary significantly in space and time. Local observations of snow layers are used as the basis for spatial extrapolation of snow properties and for establishing a time record of snow deposition.

Introduction

The study of the Earth's glaciers and ice sheets is of tremendous importance as their fluctuation has consequences on sea level, river flow, ecosystem functioning, ocean circulation, and climate stability. Recent studies have shown that the Earth's small glaciers are in measurable decline on account of secular atmospheric warming (Kaser et al., 2006; UNEP/WGMS, 2009), and whose environmental services (e.g., hydrological regulation) vary regionally – from short-term flow augmentation to long-term decline (Bonardi, 2008; Casassa et al., 2008; Sauchyn et al., 2008). There is considerable concern regarding the state and evolution of the Earth's larger glacier systems and the ice sheets, and their effect on global sea levels (Abdalati et al., 2002; Arendt et al., 2004; Zwally et al., 2002b; Rignot and Thomas, 2002; Thomas et al., 2006; Bamber et al., 2007; van de Wal et al., 2008; Alley et al., 2009; Thomas et al., 2009; Vinther et al., 2009).

Increasingly, remote sensing tools have been used to study and understand in a more comprehensive, regional manner, the sign, magnitude, rate, and causality of the Earth's glacier and ice sheet mass balance changes. Reflecting on the Greenland ice sheet, Reeh (1999) suggested that modern observation methods in combination with trimline observations, large-scale snow accumulation and mass flux estimates, and ice sheet modeling could reduce the uncertainty associated with understanding its mass balance variation. It has also been recognized for some time that the worldwide glacier surveillance strategy has historically been biased to relatively small glacier sizes, with large glacier systems being relatively underrepresented (Haeberli et al., 1998). The application of laser-based detection and ranging strategies, including the support they provide for glacier and ice sheet mass and energy balance studies, plays a key role in addressing

these thematic concerns, methodological opportunities, and surveillance biases.

The following reviews the principle of lidar, its integration as an instrument in typical glacier surveillance applications, and important error considerations. The capability of lidar is illustrated with numerous examples from the available literature. Survey planning considerations and specific technical challenges are also discussed.

Lidar ranging/swath mapping principles

Lidar for range finding has been in use since the 1970s (e.g., Measures, 1984), and provides long-distance ranging capability to ascertain the position of planetary satellites and moons as applied to geodesy and related fields. This entry concerns laser ranging and detection of the surface of the Earth's glaciers and ice sheets from fixed points, aircraft or artificial satellites, with an emphasis on swath mapping from aircraft.

Lidar-operating principles are generally similar to those of microwave-based RaDAR (**Ra**dio **D**etection **A**nd **R**anging) systems, but instead make use of "light." This light is commonly in the form of near-infrared radiation pulses emitted by a laser. This laser energy interacts with surface features and upon scattering may then return back to a coincident detector, enabling "time of flight" (t) measurement. The range is simply:

$$r = c\frac{t}{2} \tag{1}$$

where c is the velocity of light.

In a typical scanning or swath mapping configuration, laser pulses are directed toward the Earth's surface by employing an oscillating or nutating mirror. This results in a scanning pattern of measurements. In an airborne deployment, this pattern repeats itself along-track. The ground measurement locations are in fact of finite size, and so the matter of laser beam divergence determines the effective illuminated footprint dimensions over which the detection and ranging occurs. Terrain orientation and target range are chief factors, with the spatial coherence of the light over the target surface being a function of the quality of the laser light and the influence of the atmosphere between the source and the target. While usually described as some fraction of a probability density function, aspects of the positional probability and the terrain orientation can complicate defining the footprint dimension.

A key element in a lidar-based topographic mapping system is locating the reference axes of the lidar boresite/detector relative to a spatial reference system for the Earth. For an airborne application, for example, this is enabled by continuously measuring the attitude (pitch, roll, yaw) and position of the aircraft (Figure 1). The former is generally determined with an "inertial measurement unit" (IMU) or outputs from a suitably equipped "inertial navigation system" (INS), while the later is derived from measurements obtained with the aid of Global Navigation Satellite Systems (GNSS; e.g., GPS and/or, GLONASS). Simultaneous GNSS data is collected over a known ground control point within the survey baseline to enable differential correction of the platform position data. "Mechanical offset" measurements between the reference axes, the IMU sensor and the GNSS receiver antenna phase center must also be made (Figure 1). In some systems, the entire laser sensor head is stabilized with gimbals, while other systems use attitude and position data to feedback to and control the scanner mirror directly so that the generated swath remains stable regardless of changes in the aircraft orientation.

Software is used to extract ground-point positions relative to the spatial reference system. The platform velocity, scanner rate, laser pulse repetition frequency (PRF), and IMU data rate for most airborne applications will also require the use of software to project the position of the measurement platform between those determined with the low data rate GNSS measurements (typically 1–2 Hz).

Typical laser scanning systems may employ "first-pulse" and "last-pulse" measurement modes, where the former measures the range between the initial outgoing pulse and the first return pulse detected, while the latter measures the range between the initial outgoing pulse and the last return pulse detected. This may prove useful for "surfaces" having a complex vertical structure. In many systems, the power of the laser return pulse is recorded in the form of an intensity measurement, usually expressed as a function of the percent reflectance of the measured surface. This data can be used to assess the quality of the range measurements as well as give an indication of surface properties.

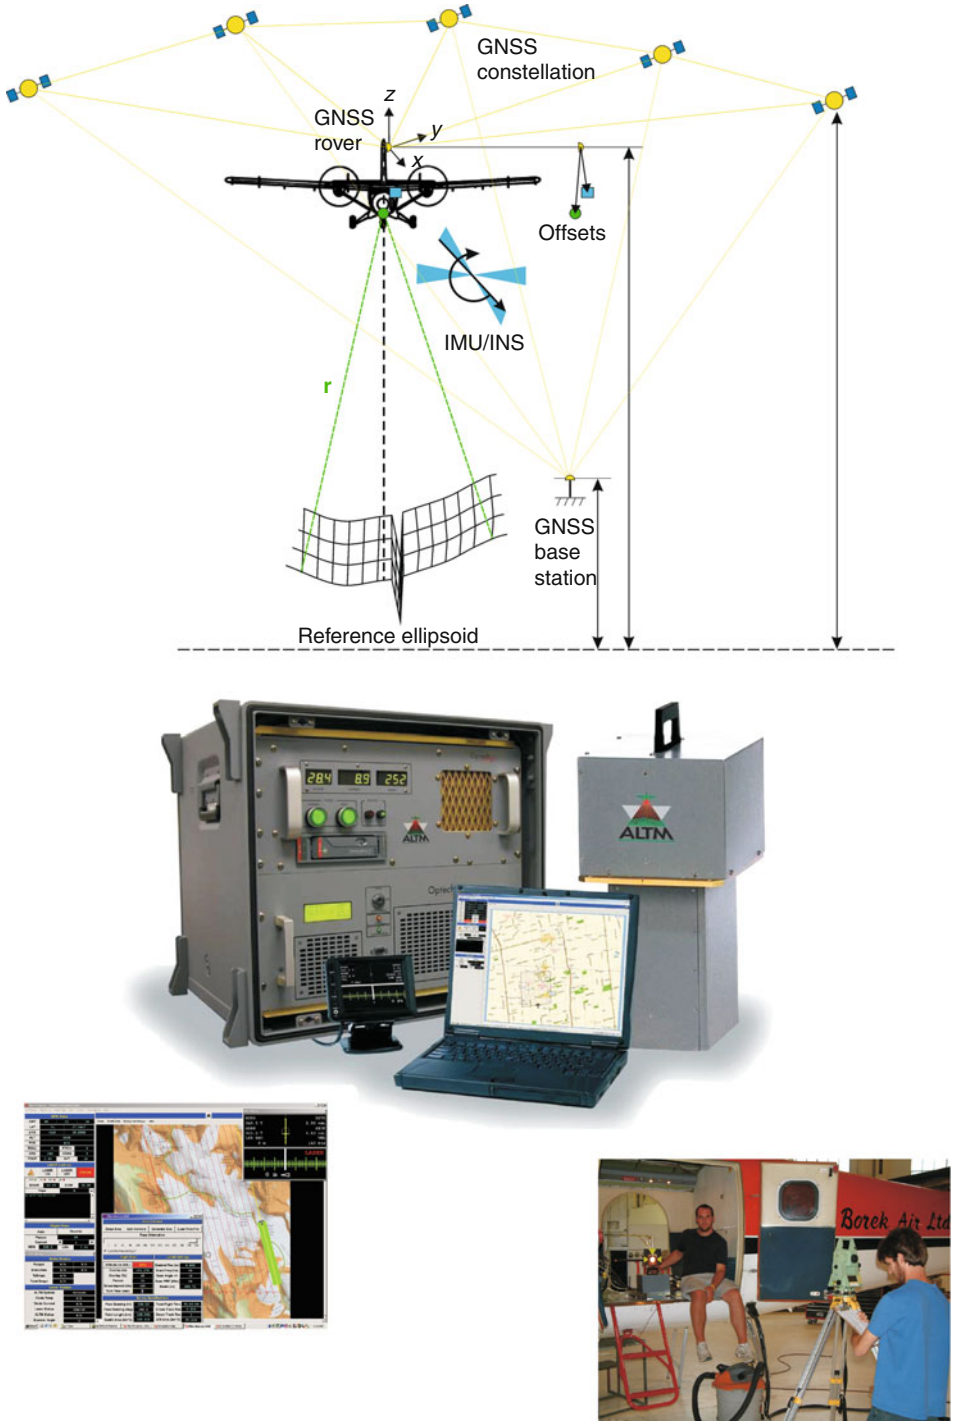
In the case of a lidar mounted onboard an artificial satellite (e.g., the Global Laser Altimeter System, GLAS, aboard the NASA/EOS Ice Cloud and Elevation Satellite, ICESat; Zwally et al., 2002a), precision orbit determination, timing and geo-location are enabled with GNSS measurements, while "star trackers" are utilized to effect platform pointing and stability control.

A comprehensive treatment of lidar ranging practice can be found in Wehr and Lohr (1999).

Error considerations

Critical to assessing the total survey error budget and the uncertainty associated with, for example, a digital elevation model (DEM) are two major sources of error in lidar data: (1) the forward propagation of individual system component errors and (2) the backward propagation of external contributions such as those manifested by terrain slope.

Starting with Favey et al. (1999) there began a number of efforts where error considerations were discussed with increasing thoroughness (e.g., Krabill et al., 2002;



LIDAR in Glaciology, Figure 1 *Top*: Schematic of the measurement and reference framework for airborne lidar mapping; *Middle*: Typical ALTM system components including, clockwise from *top left*: console containing the control module, data storage, IMU and GNSS system interface and laser power supply; laser/mirror assembly; notebook computer/operator interface; pilot display; *Bottom*: Surveying mechanical offsets for an installation in a de Havilland Canada Twin Otter (System photograph courtesy Optech Inc., Toronto Canada; photograph of mechanical offset measurement courtesy Chris Hopkinson and the Canadian Consortium for Lidar Environmental Applications Research, C-CLEAR).

Lutz et al., 2003; Hodgson and Bresnahan, 2004). This was in response to the problems associated with steep terrain, detecting small changes over large areas, GNSS ambiguity resolution, and long survey baselines. Work in other fields (e.g., Davenport et al., 2004) has benefited error assessment considerations for glaciological applications, particularly as it concerns to high point-density and surface morphology studies. Goulden (2009) provides a comprehensive treatment of terrain slope errors in which initial errors are first estimated by propagating the error of the individual measurement systems in the LiDAR system using the General Law of Propagation of Variances. These are then cast in terms of the effect of the local slope to produce a "worst-case scenario" of the actual terrain. For a variety of heights above ground level (AGL) and scan angles, Goulden and Hopkinson (2010) provide a thorough treatment of forward error propagation as it concerns the laser beam divergence, and IMU and GNSS subsystems specifically.

Vibration modes having their origin in the measurement platform can also impart errors through the nature of gimbal or scanner mechanical structures, though most of these problems can be ameliorated through control system design and structural tuning. For installations on aircraft where the location of various system components may be dictated by cable routing, power supplies, structural bulkheads, and aperture and antenna locations, aeroelastic resonance may impart particularly troublesome consequences on the final data. These can include the manifestation of surface roughness where there is none, or noise that precludes the study of surface roughness (personal communication, Robert Gurney).

A better understanding of the error budgets associated with the application of lidar has manifested the broader utility of lidar as a tool in glaciology, including determining survey expectations a priori, assessing specifications provided by commercial lidar manufacturers, establishing lidar data acquisition/mission planning standards, and the development of some novel applications.

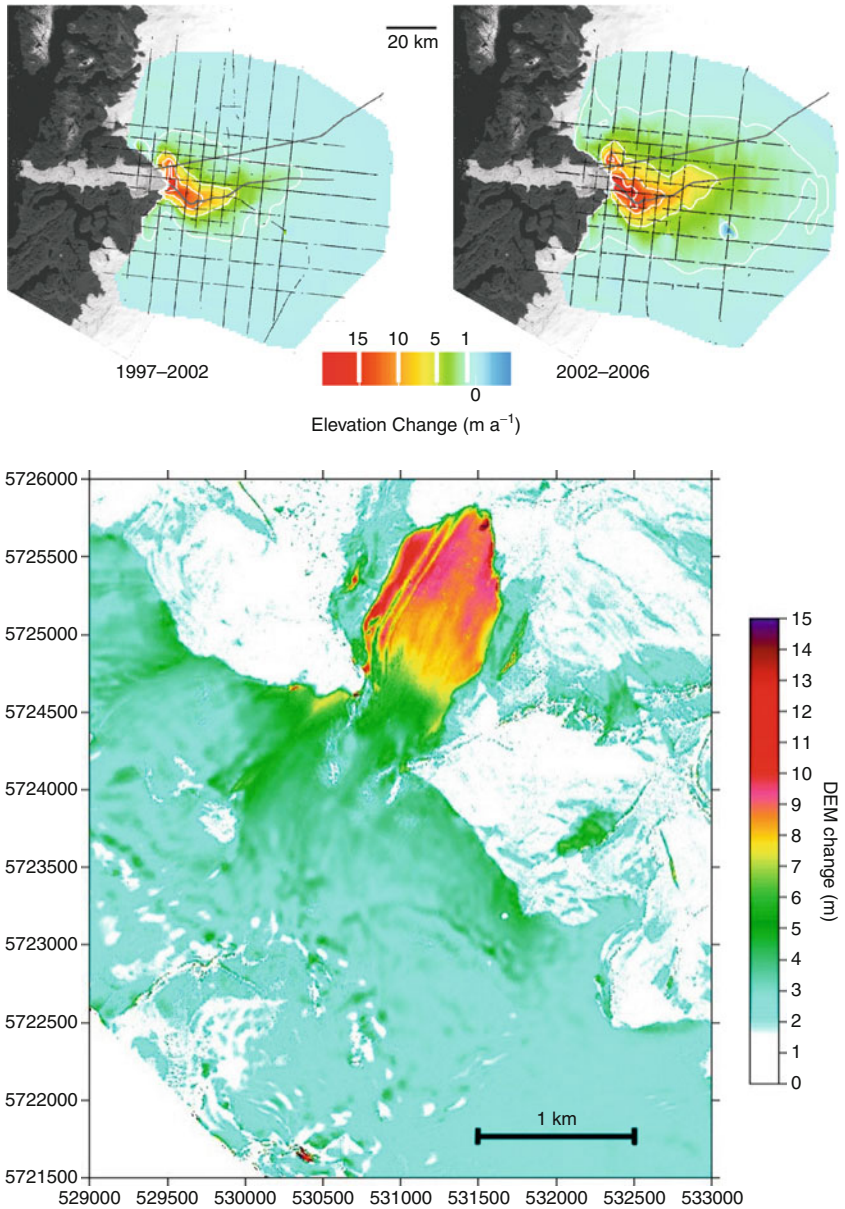
Lidar in practice

Almost all field glaciologists, young and not so young, will be familiar with laser range finding as part of simple trigonometric "theodolite" surveys or with "total station" instruments. Range measurements are made by discrete, manual repositioning of a reflector prism, though there are motorized total station systems that can follow the reflector prism continuously. Techniques employing GNSS have largely replaced this method of topographic mapping.

More recently, ground-based scanning lidar has been used to automatically map surfaces with sub-centimeter range and positional accuracy over ranges spanning several meters to more than 1 km (e.g., Intelligent Laser Ranging and Imaging System or ILRIS; www.optech.ca). Typical deployments involve locating the system over several established ground control points, with the resulting scanner data ingested by software to produce 3-D models of exceptional quality. ILRIS and similar systems are used primarily for engineering applications requiring high tolerances, but have also seen use in periglacial geomorphology studies. Because engineering applications dominate the commercial ILRIS market, and therefore must operate as "eye-safe" (e.g., urban environments), 1,550 ηm laser light is employed. For snow and ice, particularly in the presence of any melting, 1,550 ηm is considered unsuitable; because both transmission and specular reflection occur, laser return dropout rates are extremely high (personal communication, Chris Hopkinson). As such, they have not seen much use in the glaciological community. Nevertheless, the author is aware of one proof-of-concept effort that included a quantitative assessment of the range capability of an ILRIS instrument over glacier ice and snow-covered surfaces (Hopkinson, 2004).

Airborne lidar applications are now common despite the high instrument and software costs associated with commercially available systems, and the high aviation costs associated with typical surveys. Garvin (1997) reviewed the contemporary efforts of the 1990s, including the preeminent work of Krabill et al. (1995) who measured surface elevation change over the Greenland ice sheet and its outlet glaciers using the NASA Wallops Flight Facility, Airborne Topographic Mapper (ATM). This and subsequent missions have contributed to much of the Greenland ice sheet literature quoted in the introduction (Figure 2). In 1995, NASA's ATM team collaborated with the Glaciology Group of the Geological Survey of Canada (GSC) to begin repeat altimetry measurements over all of the major ice caps of the Canadian Arctic Islands (Abdalati et al., 2004), a collaborative effort that continues to this day. Echelmeyer et al. (1996) utilized a "pencil" lidar over the extensive glacier systems of Alaska, and in subsequent efforts, expanded the investigation to include the numerous accumulation areas located in the Yukon Territory, Canada that feed some of the Alaskan glaciers. With this data, Arendt et al. (2002) reported on the significant sea level contributions from this relatively little studied region. Notably, this effort was enabled by assembling a system "off-the-shelf" and installing it in a private light aircraft flown by Echelmeyer.

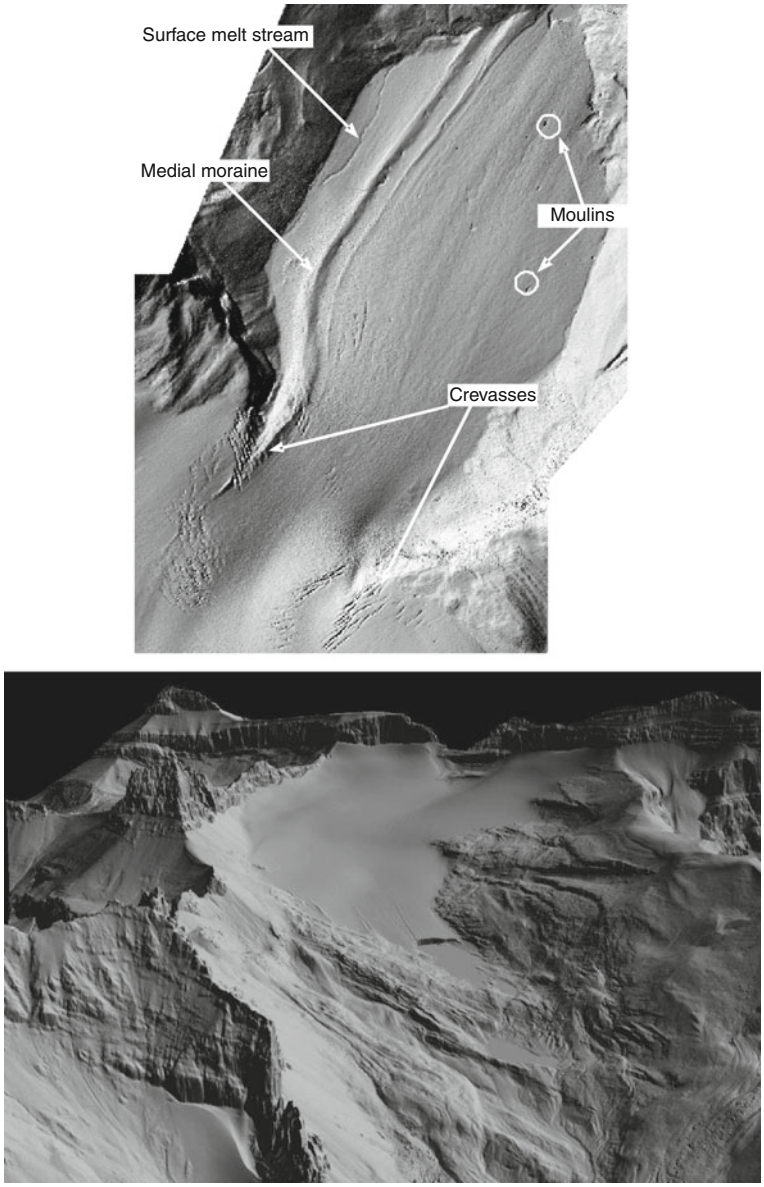
Smaller-scale efforts to map surface topography were initiated over a single small glacier in Norway by Kennet and Eiken (1997) using an early-generation commercial scanner system. They compared their results to those derived from the application of traditional stereo photogrammetry. Favey et al. (1999) reported on the utility of repeat scanning lidar surveys for estimating volume changes over a small glacier in Switzerland, as did Hopkinson et al. (2001) and Hopkinson and Demuth (2006) for a large ice field in the Canadian Rocky Mountains and its outlet glaciers (Figure 2).



LIDAR in Glaciology, Figure 2 Inferred surface elevation change determined from repeat laser altimetry. *Top*: Jakobshavn Isbræ, Greenland, 1997–2002–2006, to a point where it converges into its rapidly flowing outlet (After Thomas et al., 2009; with permission International Glaciological Society); *Bottom*: Peyto Glacier, Canadian Rocky Mountains, 2000–2002 (After Hopkinson and Demuth, 2006; with permission Canadian Aeronautical and Space Institute).

If surveys are conducted with a high enough point measurement density, mapping surface features such as meltwater channels, moulins, and other thermal or mechanical surface manifestations is possible e.g., (Figure 3; see also Hopkinson et al., 2001; Arnold et al., 2006). Repeat surface mapping can enable surface feature tracking in support of glacier motion studies (Abdalati and Krabill, 1999; Arnold et al., 2006; Hopkinson and Demuth, 2006; Hopkinson et al., 2009). Several investigators have utilized return pulse intensity values to map the distribution of seasonal snow, firn, and ice over the glacier surface e.g., (Figure 4; see also Lutz et al., 2003; Arnold et al., 2006; Hopkinson and Demuth, 2006).

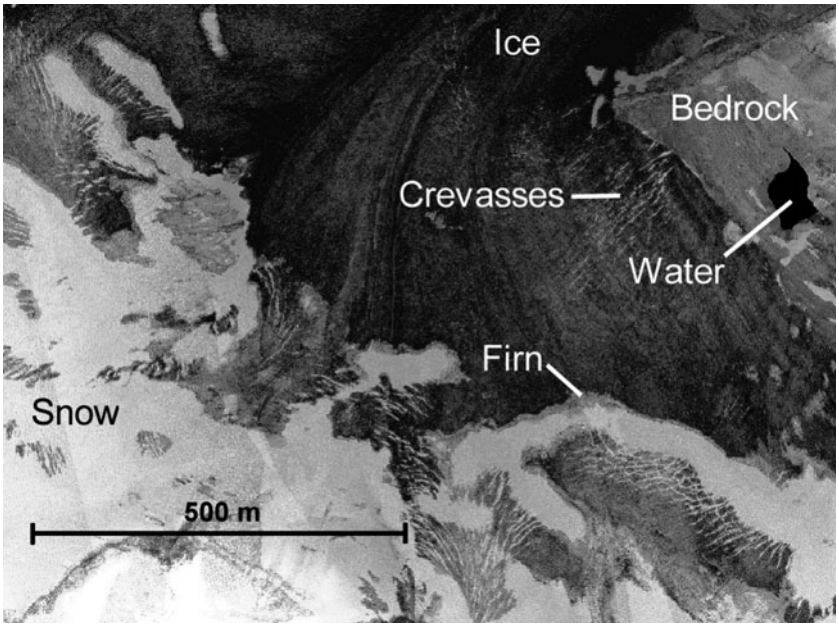
Airborne lidar has enabled detailed investigations in regions that are, for the most part, very difficult to access due to weather and terrain. These "hurry up and wait"



LIDAR in Glaciology, Figure 3 *Top*: Shaded-relief rendering of last-pulse data (gridded at 2 m resolution) collected over the terminus of Peyto Glacier, Canadian Rocky Mountains, 2002. Crevasses, meltwater streams, moulins and medial moraine forms are clearly evident. *Bottom*: Oblique rendering of the Ram River Glacier and the upper Ram River Valley, Canadian Rocky Mountains, 2002. The glacier has retreated out of an over deepened basin resulting, in this instance, in a calving terminus. Surface meltwater streams are also evident. (Data courtesy of C-CLEAR, Optech Inc. and the Geological Survey of Canada).

scenarios, where taking advantage of brief periods of fair weather is key, include studies of glacier elevation change in Patagonia (Keller et al., 2007), and assessing the mechanism and volumes of material involved in ice and rock avalanche events in the Icefield Ranges of Canada's Saint Elias Mountains (Lipovsky et al., 2008).

High-resolution ALTM has also been used in support of glacier energy-balance modeling and hydrology (Chasmer and Hopkinson, 2001; Arnold and Rees, 2003; Hopkinson and Demuth, 2006; Hopkinson et al., 2010). Lidar-derived DEMs can support satellite-based glaciological studies including the terrain-correction of SAR imagery (e.g., Wivell et al., 1992), and removing the topography effect necessary in the application of InSAR for glacier motion studies. Satellite altimetry cal/val campaigns routinely utilize lidar. For example, the CryoSat-2 (e.g., Wingham et al., 2006) calibration/validation effort will utilize ICESat low-slope crossovers, and under-flights with the NASA ATM. Lidar has also been used in the validation of glacier DEMs derived from the Shuttle Radar (SRTM)



LIDAR in Glaciology, Figure 4 Return pulse intensity image from a portion of Peyto Glacier near its equilibrium line, demarcating regions of snow, firn, and ice. (After Hopkinson and Demuth, 2006; by permission Canadian Aeronautical and Space Institute).

and the Advanced Spaceborne Thermal Emission Radiometer (ASTER) instrument aboard NASA's EOS/Terra spacecraft.

Lidar-based altimetry from artificial satellites is currently the realm of ICESat's GLAS instrument (Zwally et al., 2002a), which has seen service over both ice sheet interiors, their margins and ice streams, ice shelves, and the large glacier systems of Alaska and Svalbard (e.g., Csatho et al., 2005; and overview by Zwalley, 2005).

Mission planning

Returning again to airborne swath mapping, a few salient points related to mission planning are now provided.

Survey goals and aviation resources will, to a large degree, dictate the ground-point measurement density, which is in turn realized by adjusting survey system parameters: laser PRF, scanner angle/field of view, scanner rate; and flight variables: height AGL and ground speed. Estimating the nominal point-spacing will also vary according to the type of scanner/mirror configuration employed. High point-densities may be desirable for glacier morphological and surface facies studies, whereas, lower point-densities may be acceptable for DEM generation so long as topographic noise does not confound the survey goals. It should also be noted that due to the finite speed of light, the laser PRF will be height limited; and that "eye-safe" laser range may impose minimum flying heights in regions where, for example, recreational alpine ski touring is popular.

Notwithstanding aviation and meteorological considerations, mission planning for swath mapping typically involves determining the number of flight lines (fl) for a given width ($\overleftrightarrow{Y}$) of the planned survey area (perpendicular to the flightline direction), and the desired swath overlap fraction (olp):

$$fl = \frac{\overleftrightarrow{Y}}{sw(1 - olp)} \tag{2}$$

where sw is the swath width given by:

$$sw = 2h \tan\left[\frac{\theta_{sc}}{2}\right] \tag{3}$$

and where h is the height above ground and θ_{sc} is the scanner angle/field of view. Overlap is desirable for error checking and stitching swath data for contiguous mapping.

"Terrain following" is often employed to maintain a nominal height AGL, resulting in a more uniform swath and overlap widths and generally results in fewer laser return dropouts. Aviation considerations include flying the aircraft within gimbal and IMU tolerances and making rudder turns that prevent the loss of signal lock with the GNSS.

Challenges

Several additional technical challenges confront the user of lidar-derived terrain information, particularly as it concerns the detection and interpretation of height change data. In many glaciological applications, we are concerned with detecting small changes over large areas. Notwithstanding what has already been discussed with respect to coupled system and terrain errors, attention must be paid to the vertical reference systems used in precision height

measurement. A good overview is provided by Töyrä et al. (2003), albeit confined to the Canadian Spatial Reference System. A more general overview describing the representation of the Earth's surface undulations can be found at: http://www.kartografie.nl/geometrics/Reference%20surfaces/body.htm.

While repeat lidar mapping can lead to relatively straightforward estimates of surface elevation change, deriving surface mass balances over the accumulation area will require additional information describing the contribution to elevation change of snow densification, accumulation, and ice flow/divergence. For example, densification alone can manifest thinning, while in actuality there may have been zero mass change. Conversely, thickening may be the result of changing ice flow conditions – for example, as possibly manifested by a delayed Little Ice Age cooling having stiffened the ice near the glacier bed, therefore retarding the flow of ice (personal communication, Martin Sharp).

While alluded to previously, instrument and aviation costs are likely the largest challenge to the systematic use of lidar in the study of glaciers. To date this has been ameliorated by developing research consortia such as the Canadian-based C-CLEAR, and international cooperation founded by NASA's Wallops Flight Facility and the Geodynamics Department of the Danish National Space Centre. Indeed, these entities have been the means to developing research applications in both Hemispheres. In many jurisdictions, national aviation laboratory facilities cannot be seen to compete with the private sector airborne survey industry, and so valuable surveillance capacity may sit underutilized. C-CLEAR regularly conducts national-scale, multi–theme survey missions where all research stakeholders share the aviation costs. Other groups have endeavored to construct integrated systems by assembling off-the-shelf components and installing them in private light aircraft (Geophysical Institute, University of Alaska Fairbanks) or coordinating installations with air force or navy assets (Centro de Estudios Científicos, Chile).

Despite these challenges, the literature suggests that lidar-based surveys of glacier surface elevation change and other variables will assist differentiating interannual variability from long-term trends – a critical aspect of glaciological study in a water resources and sea level context.

Summary

This entry has presented a brief review of the principle of light detection and ranging, and a description of a variety of laser-based systems used in glaciological studies. A discussion of error considerations has been provided, and the capability of lidar was illustrated with numerous examples from the available literature. Basic survey planning considerations and some of the specific challenges of using lidar in the study of glaciers and ice sheets were discussed. A bibliography for further study and reference accompanies this text.

LITTLE ICE AGE

Rajesh Kumar
School of Engineering and Technology, Sharda University, Greater Noida, NCR, India

There is no agreed beginning year to the Little Ice Age when the world experienced relatively cooler temperatures compared to the present, but it is conventionally defined as a period extending from the sixteenth to the nineteenth centuries when there was expansion of mountain glaciers (http://www.meteo.psu.edu/~mann/shared/articles/littleiceage.pdf; Lamb, 1972; http://earthobservatory.nasa.gov/Glossary/?mode=alpha&seg=l&segend=n). During this period, glaciers in many parts of the world expanded and came down to the lower altitude. It is speculated that the amount of solar radiation emitted by the Sun was low at that time as a periodical phenomenon. Volcanic eruption is accounted for an unexpected blockage of sunlight, leading to worldwide cooling.

LOBE

Rajesh Kumar
School of Engineering and Technology, Sharda University, Greater Noida, NCR, India

A rounded projection of glacier is known as lobe. Ice lobes are dynamic features within large ice sheets that reflect glacier accumulation and ablation, ice temperature, bedrock topography, ice topography, marginal seas, and ice flow. The ice lobes are the more active parts of the uniform ice sheet. They represent parts that had bordered on each other in different directions or on more passive portions of the ice (Punkari, 1980). Marginal extension of ice stream along broad bedrock trough or valley may be hundreds of kilometers long often terminating in large ice lobes. With the increasing water pressure near the bed of ice lobe, the area of an ice lobe increases while its thickness decreases (Hughes, 1981). The ice is thickest near the central lines of lobe and thinnest near the marginal zone that gives rise to a fan-shaped directions of glacial flow (Reeh, 1982). At the ice margins, thrust moraines and hummocky stagnation topography are more common than single-crested, simple moraines if the ice lobes had repeated advances. Normally terminal moraines are formed at the farthest extent of ice lobe. In the boundary zones of the different ice lobes, there occur exceptionally large glaciofluvial forms and moraines.

MAPPING OF INTERNAL GLACIAL LAYERS

David A. Braaten
Department of Geography, Center for Remote Sensing of Ice Sheets, University of Kansas, Lawrence, KS

Synonyms

Isochronous layers

Definition

Internal glacial layer: A change in structure or composition of glacial ice that may be observed with remote sensing instrumentation, such as ice penetrating radar.

Introduction

Internal layers preserved within glacial ice are generally considered to be former deposition surfaces that became entombed in the ice, and therefore the age of a particular layer is equal or isochronous. Internal layers hold a wealth of information about glacier behavior and past climate, and may be detected and tracked with radio-echo sounding (RES) from both the surface and the air (Gogineni et al., 2007; Kanagaratnam et al., 2004). Internal glacial layers have been detected with RES on most polar glaciers, polar ice sheets, and high alpine glaciers, and these layers can often be mapped over great distances. RES detects internal layers, because a small portion of a transmitted electromagnetic radar pulse is reflected back from the layer and is detected by the radar receiver. A radar reflection from an internal layer is caused by a local change in the dielectric constant of the snow or ice, which can be due to an abrupt change in snow or ice density, acidity, or ice crystal fabric orientation (Hempel et al., 2000). If internal layers in glacial ice can be dated using ice core records or a depth-age model (Fahnestock et al., 2001), the layers can be used to understand the formation history of an ice mass, provide temporal information on snow accumulation, and provide input data for numerical ice sheet models, constraints for the model, and data for verification of the model results (Parrenin et al., 2006).

Near-surface internal layers

In the upper few hundred meters of glacial ice, abrupt vertical density changes are the primary cause of RES-detected internal layers. These density changes are related to seasonal changes in solar insolation, with the lower density layers forming during the summer, and high density layers forming during winter. These density contrasts remain intact until depths of several hundred meters (Fujita et al., 2002). Hence, near-surface internal layers can often be interpreted as annual layers, and along with a representative density profile, used to assess the temporal and spatial distribution of snow accumulation, which is a critical parameter in assessing ice sheet and glacier mass balance. By mapping internal layers with RES, an area average accumulation rate may be determined to compliment and reduce the uncertainty of a point measurement of accumulation rate from an ice core.

Deep layers

For RES-detected internal glacial layers at depths beyond a few hundred meters, the radar reflections generally result from acidity and/or ice crystal fabric changes, since the overburden has compressed the ice to a nearly homogeneous density at these depths. Annual layers are no longer detected, and the deep internal layers represent events that deposited acidic material on the glacial surface (e.g., from volcanic activity) or caused a realignment in the crystal

Vijay P. Singh, Pratap Singh & Umesh K. Haritashya (eds.), *Encyclopedia of Snow, Ice and Glaciers*, DOI 10.1007/978-90-481-2642-2,

fabric orientation. However, these deep internal glacial layers are isochronous, and reveal information about long-term climate patterns, long-term ice flow dynamics, and interactions of the glacial ice with the bed (Waddington et al., 2007; Eisen, 2008). The age of deep internal layers can be determined from the analysis of an ice core, and subsequently tracked over hundreds of kilometers (Siegert and Payne, 2004).

Summary

The ability to detect and track internal glacial layers at many different ice depths with RES has provided unique insights that have greatly benefited glaciologists and climate scientists. These internal layers are isochrones and their three-dimensional structure provides critical information on the flow history of glacial ice, changes in accumulation rates, and interactions with the underlying terrain. This information has provided critical inputs for numerical ice sheet models and serves to validate ice sheet model results (Waddington et al., 2007).

MARGINAL CHANNEL (LATERAL MELTWATER CHANNEL)

Amit Kumar
Department of Geology, Center of Advanced Study in Geology, Panjab University, Chandigarh, India

The marginal channels in the glacierized area are categorized as follows:

Ice marginal channel: It is a channel cut by flowing water along the ice margin. These channels are often left dry, or with remnant lakes, after the ice melts away. Parallel sets of ice marginal channels may form when the ice margin retreats down a slope.

Meltwater channel: It is a channel or a valley formed or followed by a glacial meltwater stream; according to their position, they are divided into ice-marginal (lateral) channels, subglacial channels, etc. Some lateral meltwater channels have only one side and form a step or terrace on the hillside. Others form meander-shaped gouges in the hillside, with both sides of the channel floor left hanging.

Lateral meltwater channels in general form along or just beneath and roughly parallel to margin of the ice. They occur in groups or single channels oriented subparallel to the contour of the land.

MARGINAL ICE ZONES

Rajesh Kumar
School of Engineering and Technology, Sharda University, Greater Noida, NCR, India

The region of solid ice cover near the edge of the sea ice pack where the ice breaks up and drifts away from or back to the ice cap under the action of waves or wind is known as the marginal ice zone (MIZ). It is an area of broken ice field between the interfacial region of frozen oceans and open oceans. The formation and dynamics of marginal ice zone is mainly governed by ocean wave interaction with the ice cover, wind and the strong temperature gradients in the atmosphere and ocean. Once formed, the broken ice scatters wave energy and protects the interior of the ice from further breaking (Squire et al., 1995). The wind blowing away from the ice pack can extend the marginal ice zone significantly while wind blowing towards the ice pack can squeeze the marginal ice zone to a relatively smaller width. These are very common in polar region and may extend hundreds of kilometers from the ice edge, and in some regions right to the coast.

MARINE GLACIERS

Rajesh Kumar
School of Engineering and Technology, Sharda University, Greater Noida, NCR, India

The glaciers, like floating slabs of ice that deform under their own weight and terminate in ocean or lakes, are termed "marine glaciers." They often end in an ice shelf. They are relatively small, independent streams of ice that travel from the higher altitudes to the sea level. Their fronts either ground and calve icebergs into the ocean, or push out into the water as a floating "tongue." In spite of being solid in appearance, glaciers are constantly flowing under the force of gravity. The average velocity of most of the glaciers are of the order of few metres per year but the marine glaciers (like Antarctic 'ice streams' and 'outlet glaciers') are capable of draining ice from the ice sheet interiors to the ocean with substantially larger velocity. Like other glaciers, marine glaciers are also under the retreating phase. Due to increase in the ocean temperature under global warming, the melting rate of marine glaciers will also increase, speeding the flow of outlet glaciers.

MARINE ICE SHEET

Rajesh Kumar
School of Engineering and Technology, Sharda University, Greater Noida, NCR, India

Marine ice sheets are continental ice masses resting on bedrock below sea level (Schoof, 2007). Large portions of its ice rest on the ocean floor well below sea level and its edges flow into floating ice shelves for miles out into the sea. The importance of the transition zone between grounded and floating ice in controlling the dynamics of marine ice sheets was pointed out in seventies by Weertman (1974). Dynamics of marine ice sheets are similar to those of land-based ice sheets except that they must couple with the surrounding floating ice shelves at the grounding line, where the ice reaches a critical flotation thickness. Marine ice sheets can lose mass not only through melting, but also through outflow of ice into the surrounding ice shelves. The stability of a marine ice sheet strongly depends on the basal slope and/or changes in the cross-sectional area. The transition from ice-sheet to ice-shelf flow takes place in case of rapidly sliding ice sheets.

Marine ice sheets are inherently unstable; whereby small changes in climate could trigger irreversible retreat of the grounding line (a location along the coast where the ice is no longer ground supported and begins to float) (Hughes, 1973; Thomas and Bentley, 1978; Weertman, 1974). During the last glacial period, which reached its peak about 20,000 years ago, large marine ice sheets existed in both the Northern and Southern Hemispheres. Due to the gradual warming that followed, they all disappeared by about 6,000 years ago, except for the West Antarctic Ice Sheet and some minor marine ice sheets of East Antarctica (e.g., that of the Lambert Glacier).

MECHANICAL WEATHERING

Rajesh Kumar
School of Engineering and Technology,
Sharda University, Greater Noida, NCR, India

Mechanical weathering is a special type weathering that works by physical means. It is related with the physical degeneration or breakdown of materials which are exposed to the natural environment. Under this process the larger rocks or minerals are gradually broken into smaller pieces. The important activities that cause the mechanical weathering are frost action, root action, water pressure, rain and wind. Mechanical weathering can be divided into following categories.

Exfoliation: The solar heating on the materials (rocks and minerals) can cause differences in temperature between the surface and the interior of materials. This differential temperature causes a loosening of the surface of the materials and break in sheets along the joints parallel to the earth surface. This process of weathering is known as exfoliation. This process is mostly occurring on the large rock masse brought on the surface as a result of tectonic activities.

Abrasion: It is the type of mechanical weathering which occurs under the action of wind, running water, waves and gravity. The frictional force of wind, running water and waves removes the upper layer of the rock and make them smaller. The rock fall under the gravitational pulls break the bigger rock into pieces.

Mechanical Weathering, Figure 1 Example of mechanical weathering in the Kumaon Himalaya, India (photograph by Rajesh Kumar).

Freeze and Thaw Weathering: It is the type of weathering which is common in places where the night temperature goes down below freezing point. Water that infuses into a rock fracture grows as crystals under the freezing temperature. The volume of frozen water is higher than the liquid water that exerts pressure on the rock and expands the cracks for the further attack and in due course of time it breaks the rock. Also the changing temperature in the day and night cause unequal expansion and contraction of rock materials (especially different minerals expands and contracts at different rates), which give rise to the development of cracks. Under this process, rocks are deformed into smaller sizes. Plant root growth also helps in expanding the cracks to further expand, making them more vulnerable to frost expansion and breaking of the rocks.

MEDIAN ELEVATION OF GLACIERS

D. P. Dobhal
Wadia Institute of Himalayan Geology, Dehradun, India

The median elevation is mean of total elevation extent of a glacier (arithmetic mean value of highest and lowest elevations of a glacier) and used value as elevation parameter in glacier inventory. In earlier studies it was often used for quick Equilibrium-line altitudes (ELA) estimation, but geometry and empirical evidence from modern glaciers suggests that this method overestimates the ELAs. In addition, in the modern glaciers median elevation of a glacier is found far away from the ELA as ablation area exceeds the accumulation area.

MEDITERRANEAN GLACIERS AND GLACIATION

Mediterranean. Lands surrounding the Mediterranean Sea
Glaciers. Dynamic body of ice
Glaciation. The action of glaciers in shaping the land surface

The Mediterranean region: physical characteristics

The Mediterranean Sea lies between 35°N and 45°N and is almost surrounded by mountains – the only exception being the southeastern shores in North Africa (and of course, the Straits of Gibraltar). The climate of the Mediterranean is distinct and is characterized by pronounced seasonality with hot and dry summers and cool and wet winters. This seasonal climate produces large snowfalls in many mountain areas, and in some places this snow lasts all year round, even sustaining glaciers today (Figure 1).

Modern glaciers in the Mediterranean mountains

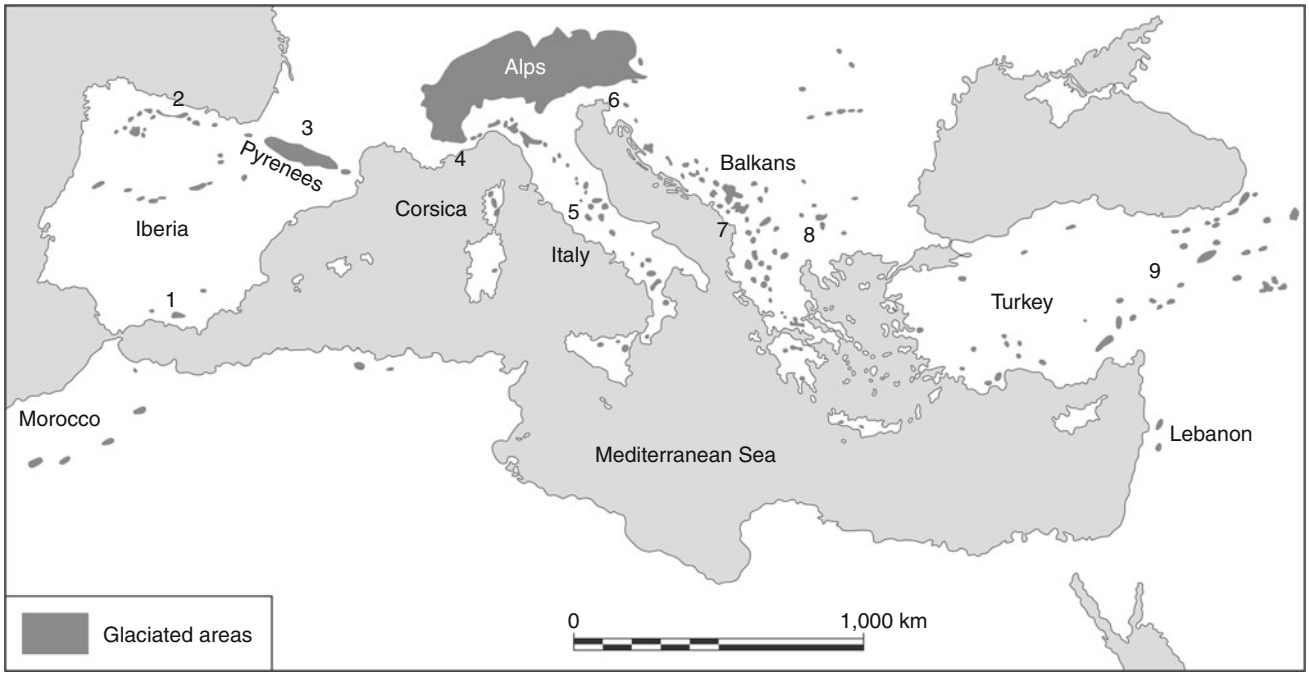
Small temperate glaciers, like those in the Mediterranean mountains, are extremely sensitive indicators of climate and their behavior provides important insight into climatic changes in this important climatic region. The modern-day glaciers are described below.

Iberia (Spain/France)

Until recently, the southernmost glacier in Europe existed in the Sierra Nevada, Spain (37°N, 3°E). Here, a glacier survived in the Corral Veleta cirque until it disappeared during the first decades of the twentieth century. Further north, in the Picos de Europa, four ice patches still survive. The only "true" remaining glaciers in Iberia are present in the Pyrenees where 21 glaciers were present at the beginning of the twentieth century covering a total area of 495 ha; of which less than 260 ha are on the Spanish side and 235 ha are on the French side (González Trueba et al., 2008). The highest peak in the Pyrenees, Pico de Aneto (3,404 m), supports the largest glaciers in these mountains. However, as with most other areas of the Pyrenees, glaciers retreated dramatically through the twentieth century and glaciers had shrunk by 530 ha between 1894 and 2001 (González Trueba et al., 2008).

Maritime Alps (France/Italy)

Fifteen small glaciers are present in the Maritime Alps on the border of France and Italy (Federici and



Mediterranean Glaciers and Glaciation, Figure 1 The extent of past Pleistocene glaciers in the Mediterranean mountains showing the locations of surviving (or recently extinct) modern-day glaciers and ice patches. **1**: Sierra Nevada, Spain – Corral Veleta glacier disappeared in twentieth century (González Trueba et al., 2008); **2**: Picos de Europa – 4 ice patches (González Trueba et al., 2008); **3**: Pyrenees – (21 glaciers González Trueba et al., 2008); **4**: Maritime Alps – 15 glaciers (Federici and Pappalardo, 1995); **5**: Italian Apennines – 1 glacier (D'Orefice et al., 2000); **6**: Julian Alps – 2 glaciers; **7**: Dinaric and Albanian Alps – 5 glaciers (Hughes, 2007; Hughes, 2009); **8**: Pirin Mountains, Bulgaria – 2 glacierets (Grunewald et al., 2006); **9**: Turkey – >40 glaciers (Kurter and Sungur, 1980; Kurter, 1991).

Pappalardo, 1995). These glaciers are the most southerly in the European Alps and some are situated less than 50 km from the Mediterranean Côte d'Azur. The rest of the European Alps are excluded here, despite draining into the Mediterranean Sea, since given the scale of these mountains they are best described as a separate geographical entity. Thirteen of the glaciers are found in the Argentera Massif, which contains the highest peaks of the Alpes Maritimes. The equilibrium line altitude (ELA) of the six largest Argentera glaciers is currently c. 2,800 m a.s.l. (Fisinger and Ribolini, 2001). In common with other parts of the Mediterranean, all of these glaciers have retreated during the last century and ELAs during the Little Ice Age were 100–150 m lower than in the late twentieth century (Federici and Pappalardo, 1995; Pappalardo, 1999).

Apennines (Italy)

A small glacier is present in a north-facing cirque below the highest peak of the Italian Apennines, Corno Grande (2,912 m). The glacier retreated through the twentieth century and between 1916 and 1990, and over this period the volume of the glacier is estimated to have been reduced by about 90% and the area by about 68% (Gellatly et al., 1994; D'Orefice et al., 2000). In recent years, the glaciers split into two portions and the remaining ice is rapidly shrinking (Pecci et al., 2008).

Julian Alps (Slovenia)

In Slovenia, two small glaciers exist below the peaks of Triglav (2,864 m a.s.l.) and Skuta (2,532 m a.s.l.). On Triglav, the Zeleni Sneg glacier is situated on the northern slopes between c. 2,550 and 2,400 m a.s.l. This glacier has undergone dramatic retreat throughout the second half of twentieth century. In 1995, the glacier covered an area of only 3.3 ha (Gabrovec, 1998). By 2003, the glacier area had reduced to only 0.7 ha. The Skuta glacier has also suffered from rapid retreat (Pavšek, 2004).

Dinaric and Albanian Alps (Montenegro/Albania)

In the Dinaric Alps of Montenegro, a small glacier exists at Debeli Namet in the Durmitor massif. This glacier survives in a north-facing hollow below the mountain of Sljëme (2,455 m) (Figure 2). In 2005, this glacier covered an area of c. 5.0 ha (Hughes, 2007). The glacier has suffered only minor retreat since the late nineteenth century and the glacier front in 2006 was only 25–50 m up-valley of moraines dated at c. 1878 and 1904 AD using lichenometry (Hughes, 2007). In northern Albania, several small glaciers also survive in the

Mediterranean Glaciers and Glaciation, Figure 2 The Debeli Namet glacier, Montenegro. (Photograph by Philip Hughes, September 2006.)

Prokletije Mountains (North Albanian Alps). At least four glaciers are present around the highest peak, Maja Jezerce (2,694 m), the largest covering an area of c. 5.4 ha (Milivojević et al., 2008; Hughes, 2009). The Montenegrin and Albanian glaciers survive at a very low altitudes for this latitude as a result of avalanching and windblown snow in addition to shading, with snow accumulation of more than 4,000 mm (water equivalent) required to balance summer melting (Hughes, 2008, 2009).

Pirin Mountains (Bulgaria)

In the Pirin Mountains of Bulgaria, Grunewald et al. (2006) noted two glacierets (mikrogletscher) and several perennial snow patches. The largest of these, the Sneschnika glacier, was found below the northern cliffs of Vihren (2,914 m) and covered an area of just 1 ha in 2005. This Bulgarian glacieret is currently the southernmost such feature in Europe.

Turkey

At least 40 glaciers are present in the mountains of Turkey and the largest Mediterranean glaciers occur in the mountains of eastern Turkey (Akçar and Schlüchter, 2005). In 1980, glaciers covered a total area of c. 22.9 km^2 (Kurter and Sungur, 1980), although almost everywhere glaciers are in retreat (Çiner, 2004). Mount Ararat, a dormant stratovolcano situated in the easternmost Taurus Mountains, is the highest peak in Turkey (5,137 m) and is covered by an ice cap of about 10 km^2. However, the recent state of this ice cap is unclear. Glaciers are also found on other Turkish volcanoes, including Mount Süphan (4,058 m) and Mount Erciyes (3,917 m). The southeastern Taurus contains the greatest concentration of modern glaciers in Turkey. These are also the most southerly glaciers in the Mediterranean basin and owe their existence to the high altitude of these mountains (>4,000 m) (Kurter, 1991). The largest occur on Mount Cilo (4,135 m) where the Uludoruk glacier is nearly 4 km long and covers an area of 8 km^2. In common with many other glaciers in Turkey, it has retreated throughout the twentieth century and the altitude of the glacier front rose approximately 400 m between 1937 and 1991 (Çiner, 2004). Smaller glaciers occur in the central Taurus, further to the west on the mountains of Aladag (3,756 m) and Bolkardag (3,524 m). The snowline in these areas is situated at c. 3,450 m and glacier survival in such marginal conditions is controlled by local climatological and physiographic conditions (Kurter, 1991). Further north, at least 12 small glaciers exist in the Pontic Mountains on mountains such as Kaçkar (3,932 m) and cover a total area of about 2.54 km^2 with ELAs between 3,100 and 3,400 m (Çiner, 2004).

Pleistocene glaciations in the Mediterranean mountains

Most of the Mediterranean mountains supported glaciers during the Pleistocene – from Morocco in the west to the Lebanon in the east (Hughes et al., 2006a). The largest ice caps formed over the Pyrenees and the Maritime Alps.

Mediterranean Glaciers and Glaciation, Figure 3 Pleistocene cirque moraines in the High Atlas Mountains, Morocco. (Photograph by Philip Hughes, January 2007.)

In the case of the latter, Pleistocene ice caps were contiguous with the main Alpine ice sheet that covered a total area of 126,000 km^2 during the last cold stage (Ehlers, 1996). Ice caps also formed over the mountains of northwest Iberia (Vieira, 2008; Cowton et al., 2009) and also over large areas of the Balkans (Hughes et al., 2006a) while large ice fields formed in northern Greece. The consequences of these glaciations are clearly seen in the Mediterranean mountains where glaciers have shaped the landscape to form cirques, U-shaped valleys, arêtes, roche moutonees, glacial lakes, and moraines (Figure 3).

In many areas, glacial deposits record glaciations during multiple Pleistocene cold stages. The oldest and most extensive glaciations occurred during the Middle Pleistocene. In northwest Spain, this has been shown using cosmogenic nuclide analyses (Fernandez Mosquera et al., 2000), while in Greece Middle Pleistocene glacial deposits have been recognized using Uranium-series dating (Hughes et al., 2006b). Elsewhere, in Turkey and Corsica, cosmogenic nuclide analyses suggest that the most extensive recorded glaciation occurred during the last cold stage of the Pleistocene. It appears that the timing of glacier advances was asynchronous across the Mediterranean and the extent of glaciations also varied between regions during different Pleistocene cold stages (Hughes and Woodward, 2008).

Summary

Glaciers exist today in the mountains of the Mediterranean. Some survive at very low altitudes (2,000–2,500 m) for this latitude as a result of high levels of winter precipitation and also avalanching and windblown snow. However, many Mediterranean glaciers have retreated significantly since the nineteenth century and many have vanished completely over the last 100 years. During the Pleistocene cold stages, glaciers were much larger and existed in mountains all over the Mediterranean region and glaciation has been a major contributor to landscape development in this region.

MELT RUNOFF MODELING

Pratap Singh
Tahal Consulting Engineers Ltd, New Delhi, India

Synonyms

Glacier melt runoff modeling; Snowmelt runoff modeling

Definition

The melt runoff is modeled using a watershed hydrological model which has an option of computing melt runoff. The model attempts to mathematically represent each component of the total melt process. The basic difference between the various models is the mathematical relationships which they use for each component. The simulation models are relatively recent innovations and offer a great potential as both a forecasting tool and a means to improve the understanding of snowmelt processes. Such a model can be used to provide hydrologic simulations of basin required for the planning, design, and operation of hydropower and water resources projects.

Introduction

Snow is an important part of the hydrologic cycle and considered as a dominant source of streamflow in many parts of the World. The geographical distribution of snow indicates a general increase in both snowfall and snow cover with an increase in latitude and altitude.

Accurate estimates of the volume of water stored in the basin in the form of snow in winter and its rate of release due to melting in summer are needed for many purposes, including streamflow and flood forecasting, reservoir operation, watershed management, water supply, and design of hydraulic structures. The planning of new multipurpose projects further emphasizes the need for reliable estimates from rain, snow, and glacier runoff. For purposes of melt runoff modeling, a thorough understanding of the relationships between meteorological variables and snow and glacier melt processes is needed for seasonal and short-term water yield forecasting.

The worldwide status of data collection, and climatic and physiographic characteristics are not uniform. In some countries, the network in the mountainous regions is dense or reasonably good providing adequate hydrometeorological data, whereas in many countries, such as Asian countries, it is very poor or sparse with very limited data. Therefore, development, selection, or application of models is not the same for each region. A number of hydrological models with snowmelt component have been developed worldwide.

Types of models

Snowmelt models are categorized on the basis of approach adopted for snow or ice melting computation. There are

two basic approaches generally adopted for the computation of snowmelt from a snowpack. The first approach is known as energy budget or the energy balance approach (see entry *Surface Energy Balance*) and the second is the temperature index or degree-day approach (see entry *Degree-Days*). Hydrological models either use an energy balance approach or a temperature index approach for melt computation. Thus snowmelt models are divided into two types of models, namely, index models and energy budget models. Broadly, energy balance models require information on radiant energy, sensible and latent heat, energy transferred through rainfall over snow and heat conduction from ground to the snowpack. Several meteorological parameters are to be monitored to obtain this information over the snowpack. An understanding of the basic energy transfer processes and their role in melting of snowpack helps in improving the performance of the operational snowmelt models.

Index models use one or more variables in an empirical expression to estimate snow cover energy exchange. Air temperature is the most commonly used index, but other variables, such as net radiation, wind speed, vapor pressure, and solar radiation, are also used. The studies have been made to assess the relative importance of meteorological variables in snowmelt and found that if only one meteorological variable is available for snowmelt prediction, average temperature is the best predictor. The degree-day method is more popular, because temperature represents reasonably the energy flux and at the same time it is relatively an easy parameter to measure, extrapolate, and probably to forecast. However, snowmelt prediction can be significantly improved by using vapor pressure, net radiation, and wind rather than the temperature variable alone.

Consideration of limited variables in an index model is preferred; otherwise it becomes difficult to correctly account for the interdependency between the variables when a large number of variables are considered. If data for a number of parameters are available for use, it is probably much more logical to use a theoretically based energy balance model to ensure that the variables are combined in a reasonable manner. Techniques need to be devised to account for the effect of factors like slope, aspect, elevation, and forest cover on various input parameters.

Energy budget models

The physics of melting of snow and ice and transformation of meltwater into runoff is well represented in such models. The melting of snow is an overall result of the different heat transfer processes in the snowpack. Sun is the ultimate source of energy that is responsible for the melting of the snowpack, but there is a complex interaction between the incoming solar radiation, earth's atmosphere, and the terrain surface. Hence, a number of intermediate steps in the process of energy transfer to the snow surface have to be considered to understand the process of snowmelt and also to make quantitative estimates of the melt.

Energy balance or heat budget of a snowpack governs the production of meltwater. This method involves accounting of the incoming energy, outgoing energy, and the change in energy storage for a snowpack for a given period of time. The net energy is then expressed as equivalent of snowmelt. The seasonal variability in the energy inputs available for melt, in general, increases toward the poles. The energy balance of the snowpack for any time interval can be expressed as

$$Q_m = Q_{nr} + Q_h + Q_e + Q_p + Q_g + Q_q \quad (1)$$

where Q_m, the energy available for melting of snowpack; Q_{nr}, the net radiation; Q_h, the sensible or convective heat gained from the air; Q_e, the latent heat of evaporation, condensation or sublimation; Q_g, the heat gained through conduction from underground; Q_p, the heat content of rainwater; and Q_q, the change of internal energy of the snowpack.

In the above energy balance equation, different components of energy are considered in the form of energy flux, which is defined as the amount of energy received on a horizontal snow surface of unit area over a unit time. The positive value of Q_m will result in the melting of snow.

The relative importance of the various heat transfer processes involved in the melting of a snowpack depends on time and local conditions. For example, radiation melting dominates in the weather conditions when wind is calm. Melting due to sensible heat flux dominates under warm weather conditions. When all the components of energy balance equation are known, the melt rate due to the energy flux can be expressed as

$$M = Q_m/[\rho_w L \beta] \quad (2)$$

where M is the depth of meltwater (m/day), L is the latent heat of fusion (333.5 kJ/kg), ρ_w is the density of water (1000 kg/m^3), and β is the thermal quality of snow. The thermal quality of snow depends on the amount of free water content (generally 3–5%) and temperature of the snowpack. For a snow that is thermally ripened for melting and contains about 3% of free water content, the value of β is 0.97.

Temperature index models

The specific type of data required for the energy budget method is rarely available for carrying out snowmelt studies. This is particularly true for the Himalayan basins where the network for data collection is very poor. The most generally available data are daily maximum and minimum temperatures, humidity measurements, and surface wind speed. That is why temperature indices are widely used in the snowmelt estimation, because it is generally considered to be the best index of heat transfer processes

associated with snowmelt. Air temperature expressed in degree-days is used in snowmelt computations as an index of the complex energy balance tending to snowmelt. This method is also known as the degree-day method. A degree-day, in a broad sense, is a unit expressing the amount of heat in terms of persistence of a temperature for 24 h period of 1°C departure from a reference temperature. The simplest and the most common expression relating daily snowmelt to the temperature index is

$$M = D_f(T_i - T_b) \quad (3)$$

where M, the melt produced in cm of water in a unit time; D_f, the degree-day factor (cm $°C^{-1}day^{-1}$); T_i, the index air temperature (°C); and T_b, the base temperature (usually 0°C).

Daily mean temperature is the most commonly used index temperature for snowmelt. There are several methods of dealing with the index temperature used in calculating the degree-day value. When using the maximum–minimum approach, the most common way is to use the temperature as it is recorded and calculate the average daily temperature. In many parts of the Western US mountainous areas, the drop in minimum temperature is so much that the daily mean temperature comes to below 0°C, thereby indicating no degree-days, whereas snowmelt conditions have prevailed during part of the day when air temperature was much above the freezing point. The inclusion of minimum temperature at an equal weight with the maximum temperature gives undue emphasis to this effect. On the other hand, the use of maximum temperature only excludes this effect entirely. Figure 1 shows a comparison of observed and computed daily runoff in the Gangotri Glacier basin (Indian Himalayas), which has snow and ice melt dominated runoff in the river.

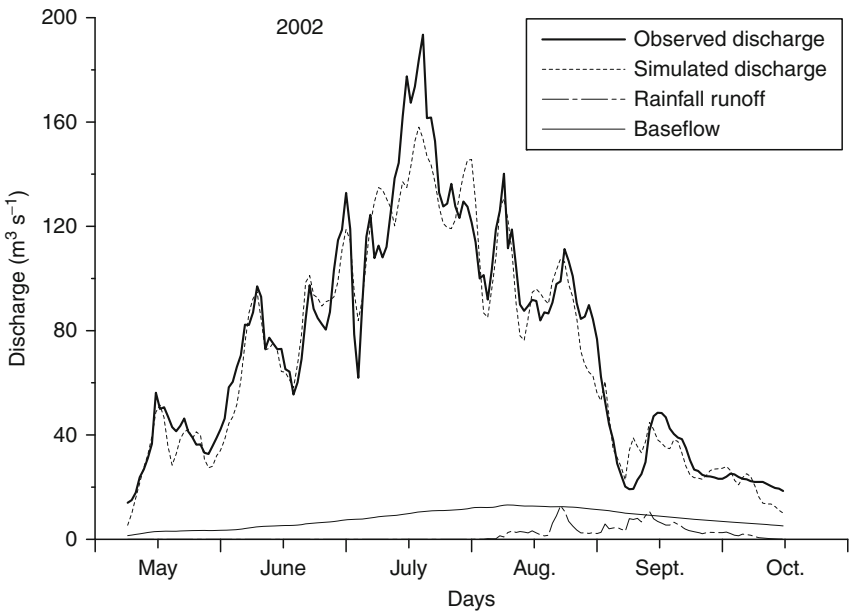
Application of melt runoff modeling

Efficient management of water resources, including water availability, flood forecasting, reservoir operation, and design of hydraulic and hydrologic structures, requires best estimates of available resources. Keeping in view the importance of water generated from snow and glaciers, the modeling of melt runoff becomes an important tool for various applications such as:

1. Forecasting of the volume of water to be released from snow and glaciers
2. Simulation/forecasting of streamflow, including floods caused by high-intensity rainfall, combination of rainfall and intense melting, and glacier–lake outburst flood (GLOF)
3. Better estimates of water availability and design flood for the planning and designing of hydropower projects on snow and glacier-fed rivers
4. Simulation of continuous supply of meltwater for ground water reservoirs and in turn the contribution of ground water as base flow during the lean season for operation of hydropower projects
5. Impact assessment of climate change on different hydrological variables

Some important snowmelt models

Several simulation models accounting for snow accumulation and melting processes have been developed



Melt Runoff Modeling, Figure 1 Comparison of observed and simulated discharge for Gangotri glacier basin in the Himalayan region using snowmelt model (SNOWMOD).

worldwide. Hydrologic simulation models that include snow are generally divided into three basic components, namely, snow cover, precipitation–runoff relationship, and runoff distribution and routing procedures. Most simulation models simulate the entire snow accumulation and melt season. Some of the models simulate only the snowmelt processes, whereas other models are used in conjunction with models of soil moisture accounting.

Snowmelt models that simulate runoff can be classified using a number of model characteristics. It begins with the division of the basin model into two major components, namely, a snowmelt model and a transformation model. The snowmelt model simulates the processes of snow accumulation and snowmelt, while the distribution and routing is accomplished by the transformation model which relates the snowmelt and rainfall-runoff volumes to discharge hydrographs. The most common transformation function is the unit hydrograph. For downstream channel reaches, the routing may be accomplished by a number of hydrologic routing techniques.

Singh and Singh (2001) have described snowmelt and ice melt modeling processes as well as concerned models in detail. Some of the important snowmelt runoff simulation models are listed below:

1. Snowmelt Model (SNOWMOD), India
2. Streamflow Synthesis and Reservoir Regulation (SSARR), USA
3. Snowmelt Runoff Model (SRM), Switzerland
4. University of British Columbia Watershed Model (UBC), Canada
5. Hydrologic Engineering Center (HEC-1) Model, USA
6. National Weather Service Snow Accumulation and Ablation Model, USA
7. HBV Model, Sweden

Summary

Modeling of melt runoff generated from snow and glaciers in a basin involves an understanding of snow accumulation, depletion, water percolation through snowpack, and routing of generated runoff up to the point of interest. In melt computation, mostly temperature index methods are used simply because of the availability of temperature data as compared to radiation data. Although there are a number of models available to simulate and forecast melt runoff, there is still much scope for improving modeling of melt runoff focusing on accurate estimation of spatial distribution of melt rate.

Surface Energy Balance

MELTING PROCESSES

Luke Copland
Department of Geography, University of Ottawa, Ottawa, ON, Canada

Definition

Melting refers to the change of state from solid to liquid, such as the change from ice to water. It occurs at 0°C for pure ice/snow at surface atmospheric pressures, although both changes in pressure and impurities (e.g., salt) can change the melting point. This review describes melting processes as they relate to ice and snow, with a focus on processes that contribute to both surface and basal melting on glaciers.

Surface melting

The main controls on surface melting of ice and snow are air temperature and solar radiation, although other factors such as surface albedo, rainfall, humidity, and wind can also be important (Hock, 2005). The importance of these factors has long been researched (e.g., Ångström, 1933), and is illustrated by discharge records from alpine glaciers, which show strong diurnal variability in the summer. Surface melting is usually the main way by which snow and ice bodies lose mass in temperate climates, although in cold climates (e.g., Antarctica) mass losses from iceberg calving and sublimation often dominate. In terms of surface melting, there are three main factors that control rates on ice and snow:

1. Net radiation
   The net radiation at the surface describes the difference between incoming and outgoing energy (Hock, 2005). Incoming energy is provided by:
   (a) Direct, diffuse, and reflected shortwave radiation that originates from the sun. On clear days, most shortwave radiation reaches the surface as direct sunshine, but on cloudy days diffuse radiation dominates due to the effectiveness of atmospheric water vapor, dust, and aerosols in scattering shortwave radiation (Paterson, 1994; Hock, 2005).
   (b) Longwave radiation emitted by objects such as clouds and surrounding mountain slopes after they have been heated, typically by incoming shortwave radiation.

   Outgoing energy occurs in the form of longwave radiation. Net melting occurs if there is less energy emitted than absorbed once the ice/snow has reached 0°C. Surface albedo is one of the most important factors in controlling how much shortwave radiation is absorbed by a surface and variations in albedo can produce dramatic differences in surface melt rates. For example, an old (firn) snow surface with an albedo of ~0.45 will melt approximately twice as fast as a new snow surface with an albedo of ~0.90 for the same

amount of incoming solar radiation (albedo values from Paterson, 1994, Table 4.1).

In a study of melt patterns on a glacier on Ellesmere Island, Canada, Arendt (1999) found that the absorbed shortwave radiation flux accounts for 96–99% of the energy available for melt. In a summary of 16 studies by Hock (2005), it was similarly found that net radiation provides the majority of energy for melt, averaging 65.1%.

2. Sensible heat
   Sensible heat refers to heat that is transferred between the atmosphere and an ice/snow surface, and is primarily supplied by warm air masses (Benn and Evans, 1998; Paterson, 1994). In general, it is less important than net radiation, with the review of Hock (2005) finding that it contributed an average of 26.4% of the total melt energy. However, the proportion of glacier melt that originates from sensible heat is very sensitive to wind, with the sensible flux sometimes dominating over net radiation on windy days (Holmgren, 1971). A rough ice surface also encourages wind turbulence and the transfer of sensible heat to the surface. Rain also produces a sensible heat flux, but is generally an insignificant factor for the annual surface energy balance of most glaciers (Hock, 2005). However, it can be locally important during heavy rain events on glaciers in temperate climates such as New Zealand, where Hay and Fitzharris (1988) found that it contributed 37% of the daily ablation during one prolonged event.
3. Latent heat
   Energy from latent heat is produced from a change in state, and can warm an ice/snow surface when there is condensation of water vapor (e.g., dew) or the freezing of rainwater. It can also significantly raise temperatures where there is refreezing of percolating meltwater within a snowpack. It can be locally important, but in general it is the least significant source of energy for surface melt, with the review by Hock (2005) indicating that it accounted for an average of 7.8% of total melt energy.

Seasonal characteristics and snowpack processes

In the spring, melting and runoff from snow and ice bodies typically occur several days to weeks after air temperatures reach 0°C as energy is initially expended on warming the snow and ice to the melting point. Once melt begins, surface runoff from the lower (ablation) area of glaciers typically occurs via supraglacial streams as ice is essentially impermeable. These streams can enter crevasses and moulins, which enable the movement of meltwater to the interior or base of glaciers through englacial and subglacial streams. Direct measurements of melt rates on alpine glaciers record typical surface losses of ~50–100 mm day^{-1} in summer. For example, Purdie and Fitzharris (1999) recorded average summer surface melt rates of 96 mm day^{-1} on bare ice over the terminus of the Tasman Glacier, New Zealand, with a variation between 30 and 175 mm day^{-1}. However, surface debris had a significant insulating effect, with melt rates averaging only ~7 mm day^{-1} where the debris was 1.1 m thick.

In snowpacks and snow-covered parts of glaciers (mainly their accumulation areas), meltwater will not directly runoff the surface but will instead percolate vertically and refreeze where there are internal cold layers and irregularities in the snowpack. This creates internal ice lenses that can lead to retardation and vertical and horizontal channeling of meltwater. The percolation and refreezing process warms the snow via the release of latent heat, and is typically the dominant method by which snow in the accumulation area of many glaciers is warmed. Indeed, it is common for polythermal glaciers in locations such as Svalbard to have high altitude accumulation zones, which are warmer (i.e., typically at 0°C) than their low altitude ablation zones due to this process (Björnsson et al., 1996).

On polythermal glaciers, the refreezing of surface meltwater within and at the base of a snowpack can produce significant quantities of superimposed ice. In this situation, the melting process does not result in a net loss of mass, but the redistribution of it within the existing snow/ice body. Superimposed ice typically occurs at the boundary between the accumulation and ablation zones, and has the net effect of moving the equilibrium line altitude to a lower level.

Basal melting

Significant melting can occur at the base of glaciers and ice sheets if energy is available from sources such as geothermal heat, frictional heat due to ice flow, and sensible heat from meltwater that originated from the surface. The relative importance of these heat sources varies between ice masses, with surface-derived meltwater likely dominating on temperate glaciers (due to the predominance of crevasses and moulins), and geothermal heat dominating in the center of the large ice sheets (where there is little basal motion and no surface meltwater). The inaccessibility of the glacier bed makes it difficult to directly measure the importance of these processes, although the recent discovery of a large number of subglacial lakes beneath the Antarctic Ice Sheet (Siegert et al., 2005) indicates that basal meltwater can persist for a long time once formed.

The influence of pressure on the melting point can be a significant factor for thick ice masses, depressing it at a rate of 0.072°C per million Pascal (MPa) (Benn and Evans, 1998). A 1 km thick glacier has a basal pressure of ~8.8 MPa, which means that the pressure melting point at the base of the ~4 km thick Antarctic Ice Sheet is approximately −2.5°C. The change in pressure melting point with depth means that a body of ice that is solid near

the surface can melt at its base without any change in temperature. In addition, if all ice is at the pressure melting point (e.g., in a temperate glacier) then local variations in pressure can be expected to cause local melting. This regelation process can result in melting on the upstream side of bedrock bumps where pressures are higher than average, and refreezing on the downstream side where pressures are reduced. This explains how water can be produced at the glacier bed without a change in temperature.

Summary

In summary, surface melt processes on ice and snow are strongly tied to climatic conditions, with net radiation typically providing the main source of energy for melt. Internal factors such as geothermal heat fluxes are more important for determining basal melt rates and processes, although climate conditions are also important where surface meltwater is able to reach the bed of a glacier via moulins or crevasses.

MELTWATER CHANNELS

Cliff Atkins
School of Geography, Environment, and Earth Sciences, Victoria University of Wellington, Wellington, New Zealand

Definition

Channels eroded by glacial meltwater into bedrock or sediment beneath or near the margins of glaciers and other ice masses.

Introduction

Meltwater channels encompass a wide variety of erosional channel features formed by flowing water sourced from melting glacier ice. They form either beneath the ice (subglacial), along the margins of the ice (ice marginal), or immediately in front of the ice (proglacial). Meltwater channels may be single, discrete channels or branching networks and range in size from small (meter scale) channels (e.g., Hambrey, 1994) to large-scale tunnel channels, hundreds of meters deep and kilometers wide (e.g., Jorgensen and Sandersen, 2006). However, most references to meltwater channels refer to channels that range from meters to tens of meters width and depth and range from tens of meters to kilometers in length.

Meltwater channels are one of the most obvious features of past and present glacial environments and provide a complex but powerful means of delineating past ice limits, glaciological conditions, and deglaciation trends for glaciers and ice sheets. The majority of studies regarding meltwater channels have focused on the Pleistocene ice sheets of the Northern Hemisphere. For example, the recognition of different channel types, combined with mapping of channel distribution have allowed detailed meltwater flow patterns and deglaciation histories to be constructed for the Pleistocene British Ice Sheet (e.g., Glasser and Sambrook Smith, 1999; Evans et al., 2005; Greenwood et al., 2007), Fennoscandian Ice Sheet (e.g., Kleman et al., 1997), and Laurentide Ice Sheet (e.g., Dyke, 1993). However, meltwater channels have been described from many other regions and from various intervals of earth history. For example, Lewis et al. (2006) described meltwater channels formed by subglacial drainage from beneath the East Antarctic Ice Sheet during the Miocene and Williams (2005) reported channels thought to have formed by subglacial meltwater 1.8 billion years ago in what is now the arid northwest of Australia.

Temperature, glacier thermal regime, and meltwater

The amount of meltwater generated in a glacial system varies according to the regional climate and associated thermal regime of glaciers (Eyles, 2006). The thermal

regime controls how the water can move in, under, and around the glacier and therefore influences the types of channels that are formed.

Temperate glaciers, sometimes called "wet-" or "warm"-based glaciers are those that have ice at melting point throughout and generate large amounts of meltwater. The water can move on the surface (supraglacial), within (englacial), or at the bottom of the glacier (subglacial). Where the meltwater reaches the base of the glacier, subglacial channels form. Meltwater draining along the flanks of the glacier may produce marginal channels and water draining away from the glacier margin form proglacial meltwater channels. Subglacial and proglacial meltwater channels are a particularly common feature of past and present temperate glacial environments.

For subpolar (polythermal) and polar (cold-based) glaciers, the margins of the glacier are frozen to the substrate. Subglacial channels do not form because supraglacial meltwater is prevented from moving downward to the bed. Instead, it is deflected and concentrated along the margins of the glacier, producing distinctive lateral meltwater channels. Despite the generally low volume of meltwater, lateral channel formation often constitutes the dominant geomorphic process occurring along cold-based margins (O'Cofaigh et al., 1999; Atkins and Dickinson, 2007) and may be the only evidence left by predominantly or fully cold-based glaciers and ice caps (Benn and Evans, 1998).

Subglacial meltwater channels

Subglacial channels are most commonly associated with temperate glaciers and form where meltwater under pressure erodes into the substrate beneath a glacier. Where the substrate is bedrock, they are often referred to as Nye Channels (N-channels) following the work of Nye (1973). The channels represent subglacial drainage systems and occur both as single channels and networks of channels typically aligned with the glacier flow, although they sometimes wind around subglacial topography (Benn and Evans, 1998). These channels often have abrupt terminations and sometimes show undulating long profiles indicating that meltwater was under pressure allowing it to flow "uphill." These channels reflect the hydraulic conditions beneath the glacier, and have therefore been widely used to reconstruct glacier surface slopes and subglacial drainage histories (e.g., Benn and Evans, 1998).

A variety of small-scale (cm–m) erosional features known as "P-forms" or "S-forms" such as muschelbruche, sichelwannen, flutes, furrows, and potholes are also widely considered to be the result of scour by pressurized subglacial meltwater flow (e.g., Shaw, 1994; Benn and Evans, 1998). However, despite some of these features reaching several meters in length (Hambrey, 1994), they are not usually classified as meltwater channels.

Large subglacial channels are referred to as tunnel channels or tunnel valleys and have been described in many areas that have formerly been covered with ice sheets. They are typically elongated, sinuous troughs that may form anastomosing networks and can be up to hundreds of meters deep and several kilometers wide (Beaney, 2002). They form in both bedrock and sediment substrates and are thought to form by subglacial drainage under high hydrostatic pressure or from catastrophic meltwater flows (Jorgensen and Sandersen, 2006). An example of these is the impressive network of channels known as the Labyrinth in front of the Upper Wright Glacier at the margin of the East Antarctic Ice Sheet in the Antarctic Dry Valleys (Denton and Sugden, 2005; Lewis et al., 2006).

Lateral meltwater channels

Lateral meltwater channels are incised into bedrock or sediment along the margins of glaciers. They are particularly common along the flanks of cold-based and polythermal glaciers where meltwater is concentrated in ice marginal streams (Skidmore and Sharp, 1999). However, they can also form along the margins of temperate glaciers in some situations and care is required when using the presence of lateral meltwater channels as an indication of glacier thermal regime (Syverson and Mickelson, 2009). Lateral meltwater channels can occur in contact with ice or lie between an ice-cored lateral moraine and valley side or in some cases, actually erode into the glacier ice rather than the permafrozen ground, forming submarginal channels (Hambrey, 1994; Benn and Evans, 1998). Lateral meltwater channels are typically short (tens to hundreds of meters) and shallow (<20 m) and often occur oblique to topographic contour lines (Hattestrand and Stroeven, 2002). Where topography is suitable, sets of nested lateral channels are formed (e.g., O'Cofaigh et al., 1999) and these have been used to delineate the retreat of cold-based or polythermal ice sheet margins, sometimes with successive closely spaced channels providing very fine temporal resolution (Dyke, 1993). Nested lateral meltwater channels along the margins of fully cold-based glaciers in hyperarid regions, such as the Dry Valleys of Antarctica are often the most obvious and persistent geomorphological signature of cold-based glacier activity. In this setting, the glacier may be able to advance and retreat over older channels and relict surfaces without necessarily destroying them, resulting in a potentially complex record of glacial events and channel formation (Atkins and Dickinson, 2007).

Proglacial meltwater channels

Proglacial meltwater channels are not in direct contact with the ice and typically drain downslope away from the glacier margin. These are most common in front of temperate glaciers where the volume of meltwater is generally high but variable on diurnal and seasonal timescales (Benn and Evans, 1998). Therefore, proglacial channels are subject to widely fluctuating flows, including catastrophic outburst floods known as jökulhlaups, which can cause rapid and dramatic channel changes and deposit large blocks of ice downstream from the glacier.

The meltwater in proglacial channels usually contains a high volume of sediment and although the channels may occupy and accentuate Nye channels exposed by glacial retreat, they typically grade into a network of shallow, sediment-floored channels separated by gravel bars that collectively make up an outwash plain or sandar (Benn and Evans, 1998). The channels tend to shift rapidly and share many processes and features of braided fluvial channels.

Meltwater channels on Mars?

There is a growing body of literature describing a wide variety of gully and channel features on the surface of Mars. Several studies have compared the channels to meltwater channels in the Canadian Arctic (e.g., Lee and Rice, 1999) and Antarctica (e.g., Marchant and Head, 2007). The similarity in channel characteristics has led to the interpretation of the Martian channels as subglacial, ice marginal, and proglacial channels formed by meltwater sourced from ground ice and glaciers. Ongoing study of these channels is likely to provide further insight into the glacial history of Mars.

Summary

Channels eroded by glacial meltwater vary widely in shape and size. The characteristics of the channels depend on the availability of meltwater, thermal regime of the glacier, and also the substrate conditions. They constitute one of the most obvious and persistent features of glacial landscapes and are useful for interpreting past glacial conditions. Ongoing research into meltwater channels includes new descriptions of modern meltwater channels (e.g., Atkins and Dickinson, 2007; Syverson and Mickleson, 2009) and paleo meltwater channels (e.g., Evans et al., 2005), combined with refinement of diagnostic geomorphological criteria used to classify and interpret meltwater channel origin (Greenwood et al., 2007). This continues to improve the use of meltwater channels in reconstructing past glacial events on earth and beyond.

MELTWATER CONDUIT

D. P. Dobhal
Wadia Institute of Himalayan Geology, Dehradun, Uttarakhand, India

Once the snow or ice is melted it can take several pathways over the ice bed in the form of supraglacial, englacial, and subglacial channels. Water carrying channel flows through narrow, tubular chute and cylindrical hollows and that connects to glacier beds or margins is called meltwater conduit.

MELTWATER EROSION

Landscapes that experience glaciations undergo considerable modification as a result of the erosion caused by the moving masses of ice. The direct glacial erosion is accomplished by three processes, namely, abrasion, crushing, and plucking. Another important, but indirect erosion

Meltwater Erosion, Figure 1 Erosion by Gangotri glacier meltwater, observed few kilometers down to snout.

Meltwater Erosion, Figure 2 Bed erosion visible at the cave type terminus of a glacier in Suru Basin, India.

process is meltwater erosion. The production of water through melting of ice that undergoes erosional process like loosening, dissolving, and removing action on debris or rock material in a glacial environment is called as meltwater erosion. Glacial meltwater is a very effective agent of mechanical erosion as well as chemical erosion because of the high water pressure that flows through tunnels in the ice and emerges at the end as a meltwater stream. The meltwater inside the glacier may be under hundreds of feet of ice and is under great pressure. The release of this water under high pressure mixed with the sediment carves rock on the way like a saw and enhances the rate of erosion.

If there are large amounts of meltwater under the glacier, it lubricates the ice and may allow the glacier to slide more rapidly down its bedrock valley hence enhancing the erosion of the bedrock. In addition, the meltwater streams that flow along the base of glacier has strong erosive potential and erode rocks in the same way as surface streams. Water at the base of a glacier is squeezed by the enormous weight of ice above (hydrostatic pressure) and causes meltwater stream to flow much faster. This combined effect makes meltwater stream a stronger erosive agent than surface rivers (Figures 1 and 2).

The broader relevance of meltwater erosion in glaciology can be used in estimating the depth of ice sheets, dating glaciers and ice sheets, as well as in tracking their seasonal movements.

MELTWATER PRESSURE

Rajesh Kumar
School of Engineering and Technology, Sharda University, Greater Noida, NCR, India

Meltwater flows through tunnels in the ice and may emerge at the end as a meltwater stream. Beneath the glacier, the water may be under hundreds of feet of ice and is under great pressure. If it can escape, the water pressure plus the sediment in the water can carve rock like a saw. If there are large amounts of meltwater under the glacier, it lubricates the ice and may allow the glacier to slide more rapidly down its bedrock valley. However the surface meltwater streams will be influenced by overall relief of the glacial surface. The sliding eventually halts when the moving glacier opens up spaces in its bed that can accommodate some of the excess water, helping to relieve the water pressure. In addition, high rates of water flow eventually enlarge the conduits and control the outburst flood of meltwater by decreasing the water pressure.

Meltwater pressure influences the glacier hydrology and impacts sediment yields in two ways. First, high water pressure beneath the glacier enhances the rate that the ice can slide over its bed and more rapid sliding results in faster bedrock erosion rates. Second, the ability of water flowing through the glacier system to transport sediment is dictated by water pressure that governs the rate of water flowing through the system. In general, subglacial conduits have high capacity and competence to transport sediment due to their large water pressure and relatively rapid water speeds (Riihimaki et al., 2005).

In some temperate glaciers, the seasonal changes in the amount of meltwater influence the meltwater pressure in the hydrologic system. The conduits tend to form or enlarge near the terminus in the spring, and extend further upglacier as the melt season proceeds. With the onset of winter, the melt rates slow down and conduits collapse. Seasonal changes in the transport of sediment out of the glacier system are strongly controlled by the evolution of this subglacial drainage and the meltwater pressure in the drainage system (http://serc.carleton.edu/vignettes/collection/25438.html).

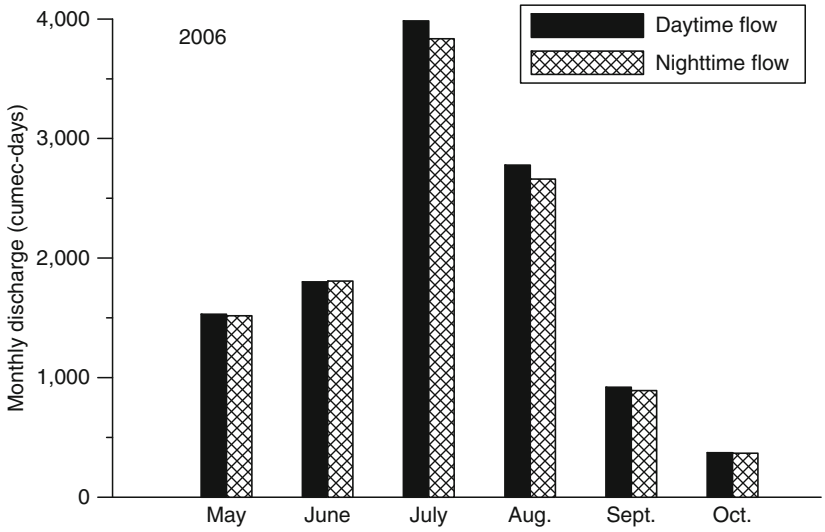
MELTWATER STORAGE

Pratap Singh
Tahal Consulting Engineers Ltd,
New Delhi, India

Definition

The meltwater storage is defined as storage of the part of meltwater generated during the day time over the glacier surface. This happens when the upper surface of glacier is covered by snow/firn. Thermal characteristics of the available snowpack control the passage of water through snowpack. At times, like in the beginning of melt season, meltwater passing through the snowpack is frozen within the snowpack as the lower part of snowpack has sub-zero temperatures. Meltwater is not stored in the exposed ice surface of glacier because ice is impermeable to water.

Snow and glaciers exhibit meltwater storage characteristics. During the summer period, in the glacier fed streams only a portion of the meltwater produced each day emerges as runoff from the snout of the glacier on the same day. The remaining meltwater is stored within the glacier. Thus a considerable contribution to streamflow is received from the meltwater stored in the glacier. Even at diurnal cycle, the runoff also contains a part of this stored meltwater. Evidently, the streamflow of a glacier fed stream is controlled by storage characteristics of the glacier and determined by delayed response of the basin. The size of the glacier, extent of snow cover, depth of snow over the glacier, and drainage network of the glacier are important factors that control the



Meltwater Storage, Figure 1 Monthly distribution of daytime and nighttime observed discharge near the snout of Gangotri Glacier (Indian Himalayas) for summer 2006.

flow rate and volume of the water emerging as runoff. The discharge time response is also a function of the ablation and accumulation area ratio. Runoff dominated by meltwater from the accumulation area has a longer time of concentration as compared to the meltwater generated in the ablation area. The runoff generated from the melting of snow and glaciers plays a vital role in the runoff generated in the rivers. In some case, like the Himalayas, contribution from snow and glaciers makes the rivers perennial and ensures the continuous availability of streamflow. The presence of snow and glaciers act as natural frozen reservoirs in the basin and provide flows in a regulated manner for the operation of hydropower and water resources schemes. In case of polar regions, where extent and depth of snow and ice cover is very large, meltwater storage characteristics are very strong.

The meltwater storage characteristics of snow and glacier fed river can be demonstrated by analyzing hourly data of streamflow. Daily (24 h) streamflow records are sub-divided into daytime flow (0900–2000 h) and nighttime flow (2100–0800 h). Monthly daytime and nighttime discharges for summer months for Gangotri Glacier (Indian Himalayas) are shown in Figure 1. The magnitude of the streamflow during daytime and nighttime indicates that the volume of the nighttime flow is comparable with the daytime flow. As such, very little or no melting takes place on the glacier surface during the night period, but still a high amount of discharge is observed in the stream during the nighttime. It shows that meltwater produced during the daytime is partly stored in the glacier and released later, while such trends in the rain fed rivers do not exist.

This analysis suggests that meltwater storage characteristics of the glacier are much stronger in the early part of the melt season and reduces as the melt season develops. Trends of variations in the ratio of daytime flow to nighttime flow with melt season can be explained on the basis of availability of snow cover on the glacier body and progressive development of the drainage network in the glacier. The greater extent of snow cover in the early part of the melt season along with a poorly developed drainage network amounts to a more delayed response of the meltwater from the basin to the outlet, resulting in reduced difference between daytime and nighttime streamflows. Reduction in the extent of snow cover area and progressive development of a drainage network with melt season also attribute to a faster response of meltwater in mid- or late-melt season, which also increases the difference in the daytime and nighttime flows. Singh et al. (2004, 2005) have provided useful information by carrying out detailed studies of meltwater storage behavior of glaciers. They have suggested that such behavior of glaciers play an important role in runoff delaying characteristics of the glaciers.

MICROORGANISMS ASSOCIATED WITH GLACIERS

Vanya I. Miteva
Department of Biochemistry and Molecular Biology, The Pennsylvania State University, University Park, PA, USA

Definition

Microorganisms. Microscopic forms of life (bacteria, archaea, fungi, small protists, viruses) which are ubiquitous in the environment, found virtually everywhere on Earth, and play important roles in natural processes and biogeochemical cycles.

Introduction

Permanently frozen environments such as the polar *Ice Sheets* (qv) and the nonpolar high-altitude *Glaciers* (qv) on all continents are characterized by extremely hostile conditions for living organisms. However, they contain an enormous microbial reservoir (9.61×10^{25} bacterial cells in the Antarctic and Greenland ice sheets according to Priscu and Christner (2004)) and provide a unique low-temperature habitat that preserves diverse microbial life chronologically for hundreds of thousands of years. Therefore, similarly to the historic trace gas records used to reconstruct past climates, microbial populations entrapped in glaciers may yield valuable information about the biological history on Earth and potentially augment paleoclimatic data. Furthermore, glacier ice is considered the best analogue of possible extraterrestrial life. Glacial microorganisms also provide ideal models for studying the mechanisms of cold adaptation and survival. These exciting possibilities spurred a significant recent interest in microbiological studies of glaciers.

Microbial origin, chronological deposition, and variable distribution

Microbial cells associated with dust particles, aerosol droplets, pollen grains, plant debris, insects, etc., are carried by atmospheric circulations from geographically close and distant places, deposited with snow on the ice surface, and gradually compressed and embedded in the deeper ice layers. Major sources of microbial cells are terrestrial dust, marine surface aerosols, and volcanic ashes with varying dominance at different periods and in different glaciers. Isotopic and mineralogical measurements have provided excellent in-depth geochemical records used to estimate the dust and aerosol geographic origins, for example, eastern Asian deserts are the main source of dust (microbes) deposited over Greenland, while dust in Antarctic ice originates mostly from Patagonia.

Microbial cells have been found on the glacier surface, in deeper ice reaching 3–4 km at the poles and in subglacial terrestrial and liquid water environments. Their number varies with depths, glacier altitudes, and among glaciers, ranging from less than 100 to 10^6–10^7 cells/mL. The pioneering work of Abyzov (1993) in Antarctica showed that these quantitative fluctuations are directly proportional to the dust load and aerosol content in annual snow precipitation and depend on the climate conditions with higher cell numbers deposited during colder climates. Similar correlations were reported in Tibetan and Greenland ice (Xiang et al., 2005; Yao et al., 2006; Zhang et al., 2007; Miteva et al., 2009). Local and global environmental factors also shape the composition of the microbial populations and determine the variable distribution of distinct microbial types within ice.

Glacial ice as a microbial habitat: microbial survival and metabolic activity

Despite reports of microorganisms having been observed and isolated from glaciers since the beginning of the twentieth century, many considered this extreme environment devoid of life or a mere repository of dormant cells. It was only recently that glacier ice was viewed as a habitat for living, and possibly metabolizing, microbial cells. Price (2000, 2009) suggested three habitats within the polycrystalline ice: (1) the liquid veins at the triple junctions of ice crystals that can provide water, energy, and carbon in sufficient quantities to maintain a small population (10–100 cells/cm^3) for up to 400,000 years; (2) the thin liquid layer coating the mineral grains, and (3) the interior of individual ice crystals, where cells can metabolize by redox reactions with ions from the grains or dissolved gases diffusing through the ice lattice. This hypothesis was supported experimentally by microscopic observations of cells partitioned in veins (Mader et al., 2006) and demonstrations of microbial activity at subfreezing temperatures down to −39°C (reviewed in Miteva, 2008). The spatial limitations and other specific factors within ice may restrict microbial activity to survival or basic maintenance to repair molecular damage with increased metabolic potential under suitable conditions, for example, near the glacier surface or in basal ice. The *Cryoconite* (qv) holes, which cover up to 10% of the glacial surface are known as "hot spots" of microbial activity and geochemical cycling by bacteria, algae, and viruses (Hodson et al., 2008; Anesio et al., 2009). The deep subglacial habitats have drawn strong attention recently due to their ecological variability (frozen terrestrial sediment, melt waters, or lakes), significant microbial content and potentially diverse microbial processes (Christner et al., 2008). Certainly, *Lake Vostok* (qv) and the accretion ice above it has been and still is the focal point of numerous studies (Christner et al., 2001; Priscu et al., 2007; D'Elia et al., 2008).

Although the conditions within glaciers are considered extreme for most living organisms due to subfreezing temperatures ranging from −56°C to −10°C, high hydrostatic pressure, low nutrient and water availability, darkness, etc., these special habitats are also superior for long-term

microbial survival and ancient DNA preservation (Willerslev and Cooper, 2005). Earth glaciers provide an excellent model system to study cold adaptation and to refine strategies for searching for life on icy extraterrestrial bodies.

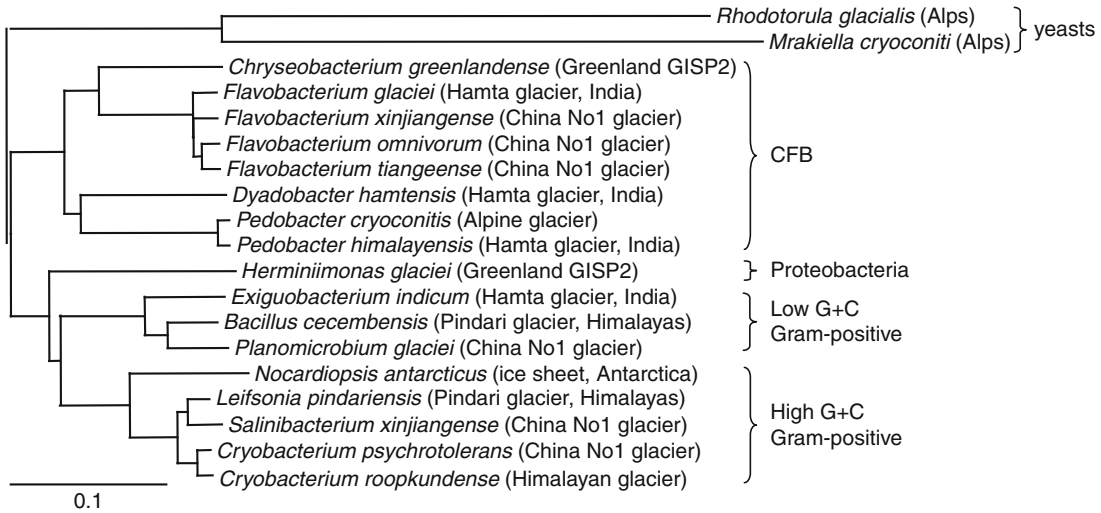
Detection of microorganisms in glaciers

Modern microbiological studies of glaciers use a variety of methods and instrumentation to reveal the microbial abundance, diversity, and activity in relationship to climate history and to advance our understanding of the mechanisms of survival at the lowest temperature limits of life. These investigations are performed on specifically drilled shorter (up to 100 m) *Ice Cores* (qv) or on previously drilled deep polar ice cores (3–4 km) stored in special facilities such as the US National Ice Core Laboratory (http://nicl.usgs.gov). The detection of glacier microorganisms is methodologically challenging for several reasons: (1) Decontamination of each sample is needed to eliminate any accidental microbial contamination during ice core retrieval and storage and to validate the authenticity of the detected and cultivated microorganisms as truly indigenous to the corresponding sample. Existing procedures (rinsing with disinfectants, physical removal of the outer surface, aseptic sub-coring) are efficient but not yet standardized among laboratories. (2) The limited volume of ice core samples, often with extremely low cell numbers, significantly hampers obtaining sufficient quantity and quality DNA for molecular analyses. Novel methods for whole genome amplification are then required to increase DNA yields; (3) Cultivation of individual organisms from environmental samples and glacier ice in particular is especially difficult because of the well-established phenomenon of nonculturability. Over 99% of the otherwise viable environmental microorganisms cannot be cultivated on conventional laboratory media due to temporal dormancy, cell damage, or unknown growth requirements. Nontraditional cultivation strategies have proven promising for recovery of novel organisms. Another related problem is the assessment of the viability status of nonculturable microbial cells, which often depends on the method used.

Recent methodological advances have significantly improved the detection of individual cells and microbial populations in glaciers and the determination of their abundance, viability, metabolic activity, and diversity. Approaches can be divided in three groups: (a) direct observations using modern high-resolution microscopic, spectroscopic, and flow cytometric techniques that are often combined with selective staining or molecular and isotopic biomarkers; (b) culture-independent methods based on analyses of nucleic acids extracted directly from melted ice; and (c) cultivation of complex enrichments or individual organisms on laboratory media with the addition of labeled substrates in some cases.

Microbial diversity associated with glaciers

Microbial diversity defines the variability of all types of microorganisms. Based on genetic, morphological, and physiological characteristics, microorganisms are classified hierarchically in taxonomic groups with the species as the lowest systematic unit. The accepted phylogenetic classification system, commonly used to determine microbial diversity, reflects genetic similarity and evolutionary relatedness based on sequence analyses of universal genes for ribosomal RNA. The relationships are expressed as branched diagrams referred to as trees (Figure 1). New microbial sequences obtained by polymerase chain reaction (PCR) are identified through comparisons with sequence databases (http://www.ncbi.nlm.nih.gov)



Microorganisms Associated with Glaciers, Figure 1 Phylogenetic tree of validly named novel glacial isolates designated with genus and species name (*italics*) and origin (*in parenthesis*). Clusters show major phylogenetic groups.

representing the three major domains of life: Bacteria, Archaea, and Eukarya.

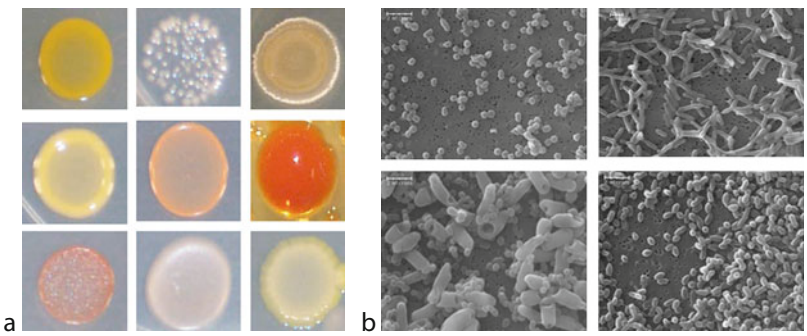
The recently intensified microbiological studies of glaciers have revealed microbial populations with widely diverse morphological, physiological, and phylogenetic representation. Some general findings from studies of polar and nonpolar glaciers are:

- Smaller microbial cells are more likely to occupy the thin liquid veins within glacial ice.
- Diversity results obtained by culture-independent and cultivation methods are complementary rather than overlapping, which helps create a better picture of the microbial populations.
- Glacial microorganisms represent all major bacterial phylogenetic groups: Proteobacteria, high and Low G + C Gram-positives, and CFB (Cytophaga-Flavobacteria-Bacteroides). Bacteria possess enormous structural, genetic, and physiological diversity indicating significant metabolic potential and nutrient versatility. Examples of such features differentiating bacterial groups and species include formation of spores, oxygen tolerance, use of simple inorganic or complex organic nutrients, etc. In addition to bacteria, many cold-adapted eukaryotic microorganisms (fungi, yeasts) are often detected in glacial environments (Abyzov, 1993; Ma et al., 2005, Butinar et al., 2007). Interestingly, the plant and bacterial viruses found in glaciers (Castello et al., 2005) were suggested to control microbial population size. Very few Archaea have been detected up to date mostly due to methodological issues.
- The relative distribution of these groups at different ice depths or in geographically distant glaciers has shown specific patterns that may be related to deposition climate characteristics or origin. At the same time, the consistent finding of several common genera and species in different glaciers has triggered the question whether these organisms are cosmopolitan or specific only for particular habitats. At present, the worldwide distribution of related glacial microorganisms has been explained by similar strategies for cold adaptation and survival. Further bipolar and among glacier comparisons of diversity and novel methodologies are needed to solve this problem.

Recovery of microbial isolates from glaciers

Obtaining isolates is important for describing new species, complete genomes sequencing, and identifying physiological properties of the organisms, which cannot be found by sequence analysis alone. Recently the recovery of isolates from glaciers has been fairly successful. The application of innovative cultivation strategies, mostly by mimicking the specific glacier environment, has increased the number of culturable organisms and resulted in obtaining hundreds of individual microorganisms. A common observation is the very long period of initial growth (colony formation), which is explained with the need for repair of cell injuries or transition of cellular structure and metabolism from dormant, nonculturable state that may have lasted for thousands of years. Many isolates originated from ancient ice core samples such as 120,000-year-old Greenland ice (Miteva and Brenchley, 2005), 420,000-year-old Vostok accretion ice, and 750,000-year-old ice from the Guliya ice cap in Tibet (Christner et al., 2001, 2003). This suggests that microbial cells have adapted and remained alive at extremely stressful conditions. Common physiological and cellular features related to cold adaptation include colony pigmentation (Figure 2), formation of exopolymeric substances as cryoprotectants, ability to grow at low temperatures with low nutrients, specific membrane structure, and synthesis of cold-shock proteins and cold-active enzymes. Numerous studies have suggested unique molecular mechanisms of cold adaptation and their potential for biotechnological applications (reviewed in Margesin et al., 2008).

At present, about 10,000 microbial species isolated from all environments have been officially named and described whereas their estimated number in nature ranges from 3 to 100 million (for updates see http://www.bacterio.cict.fr). Similarly, the number of novel validly described species from glaciers is still very limited



Microorganisms Associated with Glaciers, Figure 2 Examples of pigmented colonies of glacial isolates (**a**) and scanning electron microscopy of microbial cells of different sizes and shapes (**b**).

although phylogenetic analyses of isolates have detected many novel organisms (Figure 1). Each of these organisms has been subjected to a set of required morphological, physiological, biochemical, and genetic analyses in order to be validated as a new species that is sufficiently different from closest relatives. Further efforts in this direction will fill this gap and provide new model organisms for genomic and functional studies.

Summary

Recent important findings from microbiological studies of glaciers include: (a) an estimated significant microbial content in polar and nonpolar ice, (b) detection of viable and diverse microbial populations in ancient ice, (c) evidence for microbial activity at subfreezing temperatures, and (d) correlations between microbial composition and deposition climates. Employing advanced technologies and interdisciplinary approaches will allow the analyses of genomic and cellular components of individual cells and the exploration of the composition and functioning of complex microbial populations in their natural environment enhancing our understanding of the diversity and ecological role of microorganisms dwelling in one of the harshest environments on Earth.

climatic-system fluctuations, is an essential variable for quantifying impacts of climate change. Reliable monitoring of glacier systems requires long-term measurements of mass balances, changes in volume, area, or length with time. Such data are valuable indices of long-term climate change. Worldwide glacier surveys were initiated in 1894 at the 6th International Geological Congress in Zurich, Switzerland. Since then the World Glacier Monitoring Service (WGMS) and its predecessor organizations have monitored dimensions and magnitudes of glaciers around the world. In cooperation with the US National Snow and Ice Data Center (NSIDC) in Boulder and the Global Land Ice Measurements from Space (GLIMS) initiative, the WGMS is in charge of the Global Terrestrial Network for Glaciers (GTN-G) within the Global Climate/Terrestrial Observing System (GCOS/GTOS).

Today, WGMS collects standardized observations on glacier fluctuations obtained by direct glaciological and geodetic methods around the globe (WGMS, 2008; Zemp et al., 2009), with 30 glaciers that have continuous in situ measurements going back to 1976 and earlier based on ablation stakes and snow pits (Zemp et al., 2009). Data collection is done annually through the collaboration network of national investigators. Preliminary data are published on the WGMS website (www.wgms.ch) and every 2 years in the "Glacier Mass Balance Bulletins," as well as every 5 years, in full detail, in "Fluctuations of Glaciers." All data are available digitally on request and free of charge. However, the mass-balance observations are unequally distributed around the globe, with about 90% of the mass-balance series coming from the Northern Hemisphere and about 40% from Europe (Table 1).

Besides the monitoring of glacier fluctuations, the early warning of potential hazards related to, e.g., rapid melting or outbursts of moraine-dammed glacier lakes (GLOFS) is an important task. Mountainous regions are prone to such hazards and therefore flood warning systems, that monitor the water level of the glacier lakes, are installed, and engineering approaches to lower the lake level have been operating in order to mitigate the risk. An interesting example for an early warning system is the Tsho Rolpa glacier lake in Nepal. It is one of the best monitored lakes in the Himalayas, and it is expected that the intensive monitoring and engineering works reduces the risk of GLOF by about 20% (Rana et al., 2000).

Monsoonal records: Indices monsoonal strength from different records such as ice cores, lake sediments, loess sediments, stalagmite, and tree rings.

The monsoon is a seasonal reversal of wind patterns and precipitation on Earth. The primary cause of monsoon is the much greater annual variation of temperature over large land areas compared with neighboring ocean surfaces, causing an excess of pressure over the continents in winter and a deficit in summer (Glickman, 2000). The monsoon regions include North America, South America, Sub-Saharan Africa, Australia, East Asia, and South Asia. In particular, the monsoons are strongest on the southern and eastern sides of Asia, affecting 60% of the Earth's population via the availability of water.

The formation of the Asia Monsoon has been linked to the uplift of the Tibetan Plateau after the collision of India and Asia around 50 million years ago (Ye and Wu, 1998; An et al., 2001). Now the monsoonal strength varies significantly under the influence of global climate change. For example, the variation in the strength of the South Asia monsoon has been suggested to be linked to the variation of soil moisture (Douville, 2002), Eurasian snow cover (Wu and Qian, 2003), ElNino-Southern Oscillation (ENSO) (Davis et al., 2005), and tropical sea surface temperatures (Cole et al., 2000). However, the relatively short period of most instrumental climate records restricts the study of South Asian monsoon variability over longer time periods. The Himalayas mark the boundary between the South Asia monsoon and continental climate of central Asia. The glaciers located at very high elevation (usually more than 5,500 m) receive most of the moisture from Indian subcontinent and thus records summer monsoon rainfall. Therefore, the ice cores drilled from the Himalayas and the Tibetan Plateau are special interest for the information they contain to depict the variation of the monsoonal strength in the past with the help of proxy data (such as snow accumulation and oxygen isotopic ratios, $\delta^{18}O$).

According to a study carried out at Dasuopu, central Himalayas with elevation over 7,000 m, the seasonal variations of $\delta^{18}O$ values and major ion concentrations indicate the summer monsoon and dust signals in the firn core (Kang et al., 2000). Annual variations in the $\delta^{18}O$ values are controlled by the amount effect, with more negative $\delta^{18}O$ representing summer monsoon precipitation from tropical regions (Kang et al., 2000). Meanwhile, the variability of snow accumulation (monsoon precipitation) could be deduced from an ice core also drilled at Dasuopu, which covers the last 295-year record. The record shows the monsoon in central Himalayas had weakened in eighteenth century and strengthened throughout much of nineteenth and early twentieth century, and then weakening again from early 1920s to the present (Duan et al., 2004).

At Mt. Qomolangma (Everest), the summit of the world, similar works on ice cores were also conducted (Kaspari et al., 2007, 2008). Annual-layer thickness data, spanning AD 1534–2001, from an ice core from East Rongbuk Col yield an age-depth profile. The profile shows that the mean accumulation rate has changed every 50–100 years. The mean annual accumulation rate decreased from ~0.8 m ice equivalent in the 1500s to ~0.3 m in the mid-1800s. From ~1880 to ~1970 the rate increased. However, it has decreased since ~1970. Comparison with six other records from the Himalaya and the Tibetan Plateau shows that the changes in accumulation in East Rongbuk Col are broadly consistent with a regional pattern over much of the Tibetan Plateau. However, the record from Dasuopu, 125 km northwest of Qomolangma and 700 m higher than East Rongbuk Col, shows a maximum in accumulation during the 1800s, a time during which the East Rongbuk Col and the Tibetan Plateau ice core and tree-ring records show a minimum. This difference may be due to altitudinal or seasonal differences in monsoon versus westerly moisture sources or complex mountain meteorology (Kaspari et al., 2008).

Summary

Generally, ice cores from the mid-latitudes provide an extended record of the monsoon variability in a densely inhabited part of the globe where instrumental records are short and other proxy records sparse, despite more work still needed in the future.

Synonyms

The term "moraine" was previously used both to describe glacigenic sediments (diamict, till) and glacial landforms. The current use of the term should be restricted to descriptions of glacial landforms, i.e., moraines.

Definition

"Moraine" is a genetic term for a landform or landscape formed by deposition and/or deformation in a glacial environment. Most commonly "moraine" is used to describe ridge-shaped glacial landforms, i.e., moraine ridges, although the term also covers landforms of large spatial extent, such as subglacial till plains (ground moraines) and hummocky moraines formed by melt-out of large areas of stagnant, debris-covered glacier ice. The interior of moraines consists of unconsolidated sediments, deposited or deformed by glaciers.

Introduction

The term "moraine" covers an extremely wide range of glacial landforms, both in modern and past glacial environments. Spatially, moraines span from small (~1-m wide and ~1-m high) annual moraine ridges (Krüger, 1995; Matthews et al., 1995; Krüger et al., 2010a) to vast till plains or ground moraine, covering thousands of kilometers, e.g., in North America and Canada (Dyke and Prest, 1987; Stokes and Clark, 2002; Ross et al., 2009). Moraines form in almost all glacial environments; end moraines and other ice-marginal moraines form at the margins of glaciers, ground moraines or till plains form in subglacial environments, and hummocky moraines form in dead-ice environments. In addition, a number of other less-abundant moraines form in such environments or a combination of them. This broad category comprises, but is not restricted to, ribbed moraines, rim ridges, controlled moraines, and morainal banks (e.g., Lagerbäck, 1988; Hättestrand and Kleman, 1999; Mollard, 2000; Dunlop and Clark, 2006; Todd et al., 2007; Lindén et al., 2008; Evans, 2009).

Moraines in past glaciated areas are important features for palaeoenvironmental reconstructions. End moraines or terminal moraines indicate the extent of former glaciers and ice sheets. In alpine landscapes, lateral moraines additionally aid in deciphering past ice thickness. The distribution of ground moraine or till plains indicate deposition by warm-based glaciers and are thus an important key to understanding past glacier dynamics. Similarly, hummocky moraines suggest deposition from stagnant, debris-covered ice in dead-ice environments.

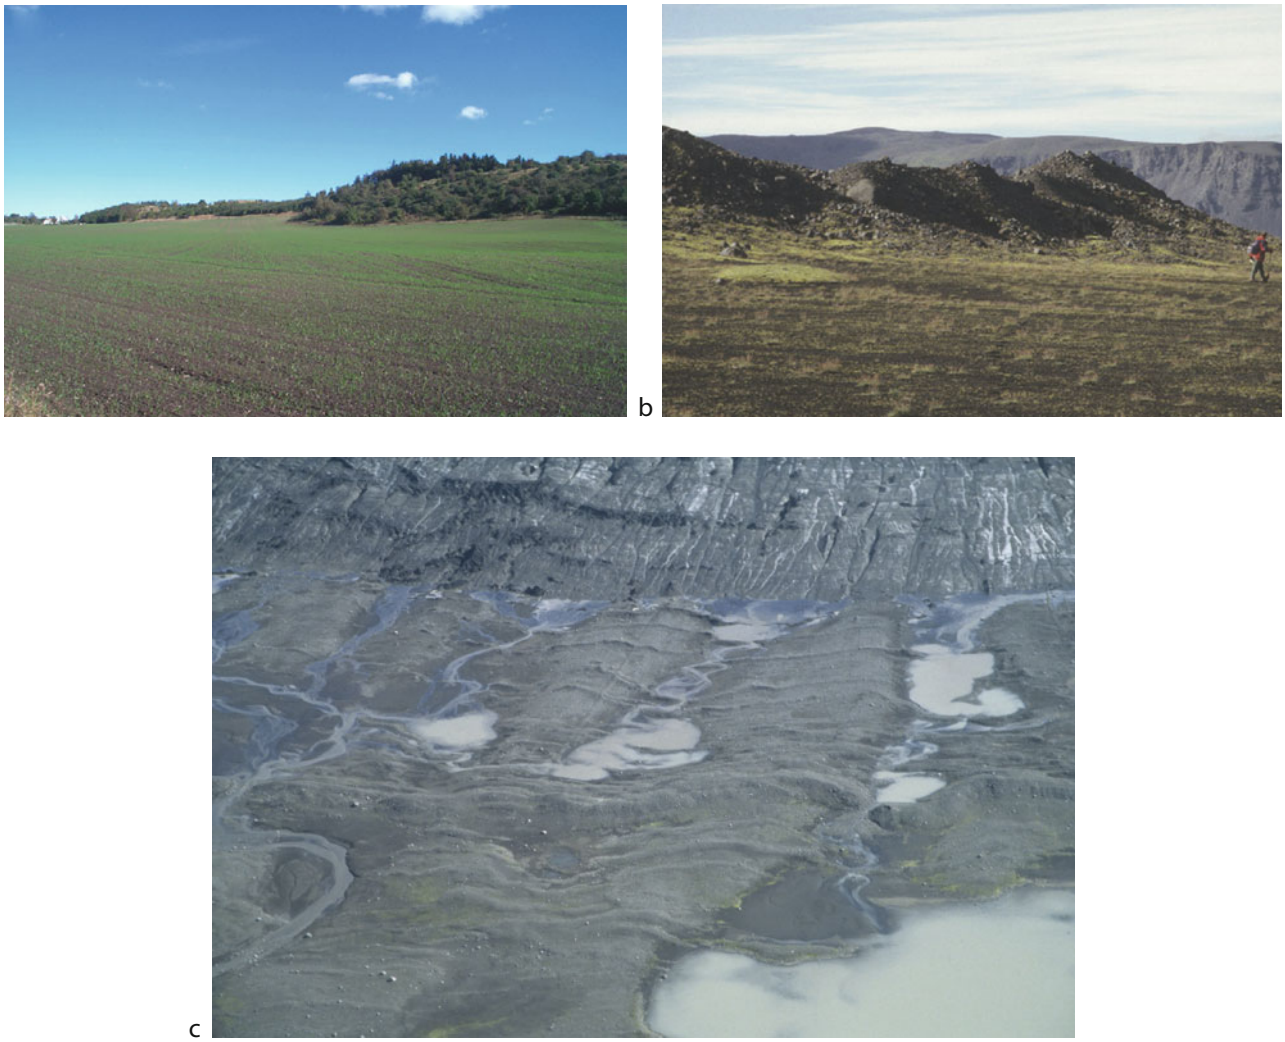
Moraines consist of unconsolidated sediments, directly deposited by glaciers or deformed and accumulated by glaciers. Marginal moraines may contain sediment dumped, squeezed, pushed, or thrusted by a glacier (Price, 1970; Boulton et al., 1999; Krüger et al., 2002; Bennett, 2001; Benediktsson et al., 2008, 2009, 2010). This implies that such moraines are either built up of glacial sediments or of preexisting sediments deformed by a glacier. Thus, the interior of many moraines are of non-glacial material such as seen in many prominent push moraines in modern and past glacial environments (Aber and Ber, 2007; Benediktsson et al., 2008, 2010). The spectacular push moraine in front of Holmströmbreen, Svalbard, for instance, consists mainly of glaciotectonically deformed fine-grained marine and tidal sediments (Boulton et al., 1999).

Ground moraines (till plains) are formed subglacially by actively flowing ice (Stewart et al., 1988; Evans and Twigg, 2002; Kjær et al., 2008; Schomacker et al., 2010). They therefore consist of subglacial sediments, typically basal till. Basal till is a diamict sediment with diagnostic subglacial characteristics: strong clast fabric, striated clasts, stoss-lee-shaped clasts, and often with subglacial surface landforms such as drumlins, flutes, and other glacial lineations (e.g., Krüger, 1979; Piotrowski et al., 2004; Evans et al., 2006). Hummocky moraines, on the other hand, form in dead-ice environments and contain more chaotic sediments. Often, they are composed of resedimented diamicts and sorted meltwater-deposited sediments (e.g., Boulton, 1972; Ham and Attig, 1996; Schomacker, 2008).

This paper briefly reviews the most important moraine types, with respect to geomorphology, sedimentology, genesis, and palaeoenvironmental significance. Focus is directed both toward moraines recently formed or currently forming in modern glacial environments and toward Pleistocene moraines.

Ice-marginally formed moraines

Ice-marginally formed moraines are ridges mirroring the ice-marginal shape and position at the time of formation (Figure 1). Ice-marginal moraines range from minor single-crested ridges, around 1 m or less in height and width, to large multi-crested ridge complexes up to ca. 10-km width and ca. 200-m height (e.g., Benn and Evans, 1998; Bakker, 2004; Aber and Ber, 2007). The material in marginal moraine ridges might either be of glacial origin with direct deposition at the ice margin (dumping) or consist of non-glacial or preexisting glacial material as seen when older sediments are pushed and thrusted by marginal glaciotectonism. Minor moraine ridges may also form by squeezing-out of sediment at the margin due to the ice load and the pressure gradient directed toward the margin (Price, 1970; Benn and Evans, 1998). Ice-marginal moraines are known from the margins of modern and past glaciers, from ice sheets to cirque glaciers, at temperate, polythermal, and cold-based glaciers, and during retreat, advance, surge, and stationary phases. The morphology and sedimentary architecture of such ridges reflects the depositional environment and glacier dynamics. The nongenetic terms "ice-marginal moraine," "end moraine," and "terminal moraine" all refer to marginal moraine



Moraine, Figure 1 **(a)** Late Weichselian end-moraine ridge, Bjergsted, Denmark. Krüger, August 1997.) **(c)** A series of annual moraine ridges deposited during the retreat of the Sléttjökull glacier, South Iceland, August 2001.

ridges, although "terminal moraine" is used to describe a moraine ridge marking the maximum extent of a glacier advance both in Pleistocene and modern settings.

Push moraines form when an advancing glacier transfers stress to sediments in its forefield. When the applied stress exceeds the shear strength of the forefield sediments, they deform into a push moraine (Figure 2). This deformation can either be ductile, brittle, or a combination of both, and each process leaves characteristic structures in push moraines. Ductile deformation produces folds and brittle deformation produces (thrust) faults. The surface morphology of push moraines depend on the style and magnitude of deformation during formation and of the nature of the deformed material. Typically, folding forms smooth ridges with washboard morphology, whereas thrust faulting forms series of imbricated slabs with steeper slopes (e.g., Benediktsson et al., 2010). However, multi-crested push moraines might appear with washboard morphology in both cases. Degradation of the surface makes it hard to determine the style of deformation, only based on the geomorphology. Internal sedimentary structures are better preserved and often provide an excellent view of the deformations either directly from geological sections or from geophysical investigations (e.g., Boulton et al., 1999; Bennett, 2001; Jakobsen and Overgaard, 2002; Aber and Ber, 2007; Benediktsson et al., 2010).

A certain type of annual push moraines might form when receding or stationary glaciers re-advance shortly during winter and spring (Figure 1c; Boulton, 1986; Krüger, 1993). At the peak of these winter re-advances, a small frozen-on slab of the forefield is pushed up at the margin (Krüger, 1993, 1995; Krüger et al., 2010a). As seen in Figure 1c, series of annual moraines form during multi-year periods of glacier retreat. These landforms are, however, too small to be preserved and have not been described from Pleistocene glacial landscapes.

Moraine, Figure 2 Oblique aerial view from 1936 of the prominent push moraine in front of the Holmströmbreen glacier, central Spitsbergen, Svalbard. Ice flow was from left toward right. (Aerial photograph number S36 1382, © Norwegian Polar Institute. Published with permission.)

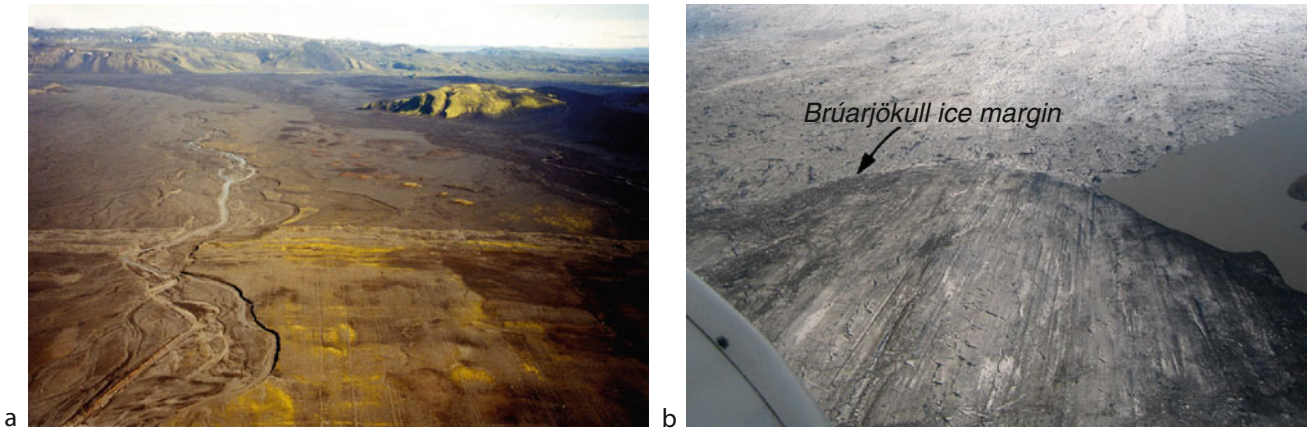
Ice-marginal dump moraines are ridges consisting of en- and supraglacial material that melts out and flows down a stationary ice margin (Figure 1b; Boulton and Eyles, 1979; Krüger et al., 2002). Frontal dump moraines might continue as lateral moraines along the sides of valley glaciers. Most commonly, they consist of diamict with coarse-grained, passively transported material, although parts of the debris might have experienced a subglacial transport prior to dumping at the ice margin (Boulton and Eyles, 1979; Benn and Ballantyne, 1994). The size of dump moraines depends on the duration of the glacier standstill and the debris flux to the margin (Benn and Evans, 1998; Spedding and Evans, 2002). In alpine environments and at debris-covered glaciers, the debris flux is high, and frontal dump moraines might reach considerable heights. The spectacular ice-marginal dump moraine in front of Kvíarjökull, Iceland, for instance, is more than 100-m high (Spedding and Evans, 2002; Iturrizaga, 2008). This moraine ridge might, however, be the result of more than one glacier advance and stillstands at the same position.

Subglacially formed moraines

Ground moraine

Ground moraines, or basal till plains, are low-relief glacial landscapes commonly with a surface of ice-flow parallel subglacial landforms such as drumlins, flutes, or mega-scale lineations (Figure 3). They are well known both from past glaciated areas and modern glacier forefields. In North America, vast areas of ground moraine formed by the Laurentide Ice Sheet dominates the landscape for hundreds of kilometers, e.g., in the Great Lakes region and Ontario (Boyce and Eyles, 2001; Jennings, 2006). On a smaller spatial scale (1–10 km), many till plains are being exposed during the current retreat of the broad lowland glacier lobes of the Icelandic ice caps (Evans and Twigg, 2002; Kjær et al., 2003, 2008; Schomacker et al., 2010) and at many other glaciers (e.g., Eklund and Hart, 1996; Larsen et al., 2006).

As the synonymous genetic term "basal till plain" indicates, ground moraines consist of basal till. Basal till is a diamict deposited by a glacier sole that slides over and/or deforms its substratum, and sediment accumulates from pressure-melt-out from the glacier sole, lodgement, and deformation of the bed (e.g., Boulton and Hindmarsh, 1987; Benn and Evans, 1996; Piotrowski et al., 2004; Nelson et al., 2005; Evans et al., 2006). Thus, basal till displays many features characteristic for deposition in a subglacial environment such as strong clast fabrics, striated and bullet-shaped clasts, and shear structures (Krüger, 1979; Kjær et al., 2003; Larsen and Piotrowski, 2003). Because ground moraines are deglaciated by a frontal retreat, very little or no supraglacial debris overlies the basal till.



Moraine, Figure 3 **(a)** Fluted ground moraine in the forefield of the Sléttjökull glacier, South Iceland. The Mælifellssandur outwash plain is seen in the background, distal to the end-moraine ridges, August 2001. **(b)** Fluted ground moraine appearing during the retreat of the Brúarjökull glacier, East Iceland, September 2008.

Although ground moraines generally have a low relief, they might display a prominent subglacially streamlined surface of flutes, drumlins, or mega-scale glacial lineations. Flutes are elongate ice-flow parallel ridges with a length much longer than the width (Figure 3). They rarely exceed 1 m in height or width, whereas the length might exceed 2 km (Gordon et al., 1992; Evans and Twigg, 2002; Kjær et al., 2008). Flutes are small-scale landforms, and their preservation potential is low. They therefore occur mainly in modern glacier forefields, whereas drumlins and mega-scale lineations are better preserved and well known from Pleistocene glacial landscapes.

The large basal till plains in North America host many spectacular drumlin fields, e.g., in New York State with ca. 10,000 individual landforms (Menzies, 1979; Briner, 2007). Drumlins are subglacially streamlined, ice-flow parallel hills with a steep, blunt stoss side and a gentle, tapering lee side (Menzies, 1979; Menzies and Rose, 1987; Jørgensen and Piotrowski, 2003). Mega-scale glacial lineations (MSGLs) also belong to the group of subglacial landforms that might cover the surface of ground moraines. MSGLs are much larger than flutes and drumlins; in length they might extend up to 100 km and in width up to 200–1,300 m (Clark and Stokes, 2003). They are indicative of fast ice flow, i.e., ice streams. In terrestrial settings, MSGLs are well described from the paleo-ice streams of the Laurentide Ice Sheet in North America (e.g., Stokes and Clark, 2001, 2002; de Angelis and Kleman, 2007).

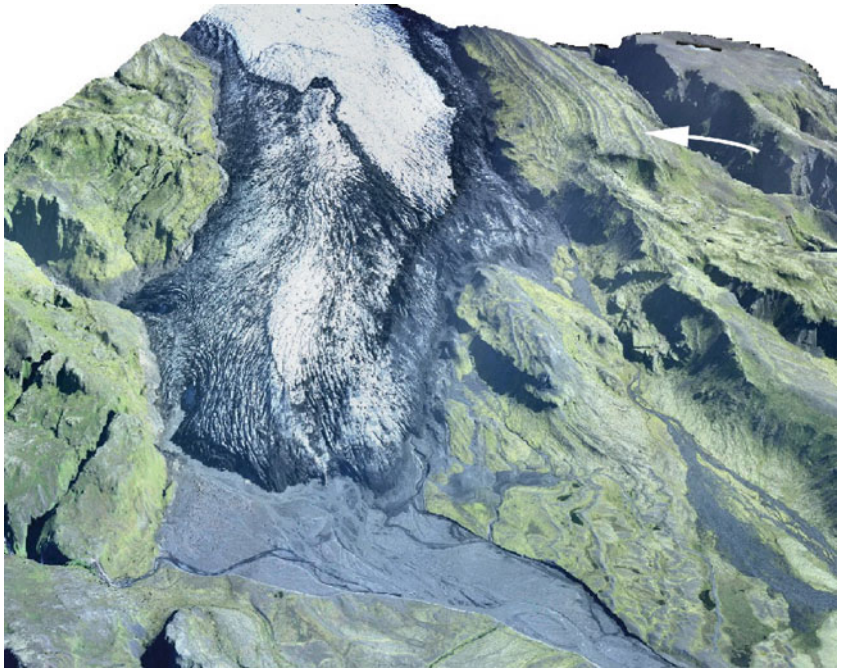
Supraglacially formed moraines

Lateral moraine

Lateral moraines are ridges of supraglacially deposited debris located along the sides of valley and cirque glaciers (Figure 4a; Boulton and Eyles, 1979; Spedding and Evans, 2002). Where debris accumulation is high, they can reach heights of more than 100 m (e.g., Iturrizaga, 2008). In modern glacial environments, lateral moraines might be ice cored. Typically, the material in lateral moraines is angular and coarse-grained supraglacial debris, originating from the valley sides, although they might also contain debris that has experienced sub- and englacial transport before deposition in the lateral moraine (Benn and Ballantyne, 1994). Lateral moraines form only below the equilibrium line altitude (ELA), where debris accumulates due to net ablation. The maximum elevation of lateral moraines is therefore an important indicator of the ELA, both in modern and ancient glacial environments (Nesje, 1992). Because lateral moraines occur on unstable valley sides, they generally have a low preservation potential. However, some Pleistocene lateral moraines exist, in particular, where valley glaciers have expanded out of their confining valleys (Clark et al., 2003; Easterbrook et al., 2003).

Medial moraine

Medial moraines are ice-flow parallel debris ridges on the surface of glaciers (Figure 4c). They are very striking features in the supraglacial environment, giving an impressive visualization of the ice-flow dynamics. Similar to the lateral moraines, they only occur below the ELA. Medial moraines can extend for tens of kilometers but usually only consist of a thin layer of supraglacial debris. Medial moraines are the surface expression of englacial debris septa, sometimes extending to the glacier bed (Hambrey et al., 1999). The debris might therefore contain a component of en- and subglacially transported material, although coarse-grained, angular supraglacial material is most common. “Ablation-dominant medial moraines” occur in the ablation area by the melt-out of debris entrained further upglacier (Eyles and Rogerson, 1978). “Ice-stream interaction medial moraines,” such as shown in Figure 4c, occur downglacier of the confluence of two



a

The medial moraines originate where individual ice flow units merge downstream of the Esjufjöll nunataks, September 2009.

individual ice-flow units. Such medial moraines are often the continuation of two merged lateral moraines from each flow unit. When supraglacial rock avalanches are transported downglacier, they might get stretched out and appear as "avalanche-type medial moraines" on glacier surfaces.

A certain type of medial moraines, looped medial moraines, appears on surge-type glaciers. When a main trunk glacier surges, it advances so rapidly that medial moraines from tributary glaciers are detached or extended into a loop or a drop-shaped supraglacial feature. Looped medial moraines on a glacier are easily identified and strongly suggest that the main glacier has surged (Meier and Post, 1969).

Medial moraines from Pleistocene glaciations are not common due to the low preservation potential and the small volumes of sediment in such landforms. Prominent Pleistocene medial and lateral moraines have been described from the eastern Sierra Nevada, California, USA (Easterbrook et al., 2003).

Hummocky moraine

Hummocky moraine (also known as dead-ice moraine or moraine mounds) is a chaotically appearing glacial landscape consisting of many individual hummocks, with no preferred orientation or organization of landforms, size, spacing, or slope. Controlled moraines and rim ridges (circular moraine ridges) are described separately below. Depressions, usually referred to as sinkholes or dead-ice hollows, are abundant in such landscapes. Hummocky moraines occur both in lowlands glaciated in the Pleistocene and in the forefields of past and present valley glaciers. Other landforms characteristic of deposition in dead-ice environments, such as ice-walled-lake plains, kames, and flat-topped eskers, commonly occur in association with hummocky moraines (Clayton et al., 2008; Krüger et al., 2010b). Individual hummocks may range from a few meters in diameter (e.g., Spedding and Evans, 2002) to several hundreds of meters (e.g., Johnson and Clayton, 2003). The relief and hummock height often varies significantly both within the same hummocky moraine and between different localities. Hummocks just a few meters in height are known from, e.g., Kvíarjökull, Iceland (Figure 4b), whereas hummocks up to 60 m originating from the last Laurentide Ice Sheet have been described from North America (Ham and Attig, 1996).

The sediments within hummocky moraines are normally dominated by diamicts (Benn, 1992; Kjær and Krüger, 2001; Lukas, 2005; Schomacker and Kjær, 2007, 2008). Diamicts in hummocky moraines are often heterogeneous and associated with sediment gravity-flow deposits and meltwater-deposited sediments (e.g., Kjær and Krüger, 2001; Lukas, 2005).

Most depositional models for hummocky moraines suggest that they form in dead-ice environments by melt-out and resedimentation of debris from stagnant glacier ice. Thus, the hummocky topography originates from the resedimentation of an unevenly distributed supraglacial debris cover and topographical inversion cycles during dead-ice melting. The models are often supported by the observations from modern glacial environments, where the genesis of hummocky moraines has been monitored (e.g., Boulton, 1972; Clayton and Moran, 1974; Hambrey et al., 1999; Schomacker and Kjær, 2007, 2008). For instance, Krüger and coworkers closely followed the dead-ice melting and hummocky moraine development at Kötlujökull, Iceland over a 30-year period and were able to link the sedimentary processes to the products left in the geological record (Krüger and Kjær, 2000; Kjær and Krüger, 2001; Krüger et al., 2010b). Alternative models for hummocky moraines have suggested formation by sinking of stagnant ice into a soft subglacial bed (Boone and Eyles, 2001) or even by erosion by subglacial meltwater (Munro and Shaw, 1997). These models are, however, mainly of local interest and should not be viewed as general explanations for the genesis of hummocky moraines.

Controlled moraine

Controlled moraines also form in dead-ice environments and are characterized by inherited linear ridges, originating from debris-rich thrust planes in the parent dead ice (Boulton, 1972; Bennett et al., 1998; Evans, 2009). Supraglacial linear outcrops of debris-filled thrusts are often seen in early stages of melt-out of ice-cored moraines (Schomacker and Kjær, 2008; Krüger et al., 2010b). Although such thrusts are very exposed to resedimentation in the dead-ice environment, the occurrence of controlled moraines in Pleistocene landscapes and recently deglaciated forefields indicates that the debris-rich thrusts can survive as ridges after deicing (Bennett et al., 1998; Lukas, 2005; Evans, 2009). Based primarily on studies of modern glaciers in Svalbard, it has been suggested that controlled moraines form at polythermal glacier snouts, where marginal debris entrainment and thrusting is particularly likely to occur (e.g., Bennett et al., 1996; Hambrey et al., 1999; Evans, 2009).

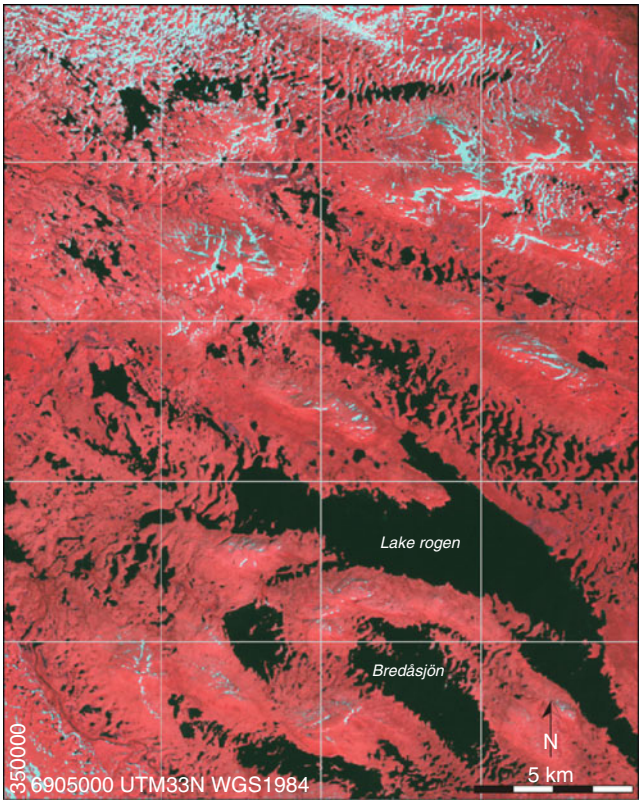
Polygenetic moraines and other important moraine types

Ribbed moraine

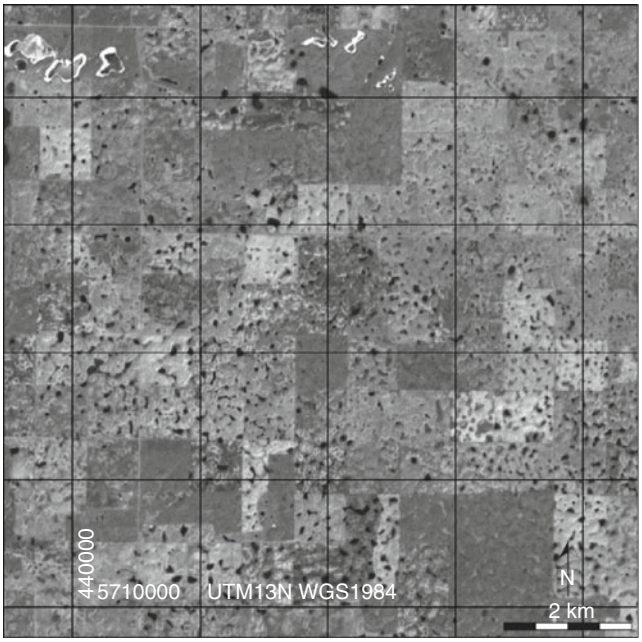
Ribbed moraines are ice-flow transverse ridges, occurring in fields with ridges arranged in a subparallel pattern (e.g., Hättestrand and Kleman, 1999; Lindén and Möller, 2005; Dunlop and Clark, 2006; Möller, 2006; Todd et al., 2007; Lindén et al., 2008). The ridges are usually curved and some types have "horns" pointing downice. They might reach heights of 10–30 m and widths of 150–300 m. Ribbed moraines are located in the core areas of former ice sheets (Dunlop and Clark, 2006). This broad category of moraines spans over ridges formed in many different glacial environments, and there is no single unifying model of formation for "ribbed moraine," rather they represent a group of moraine ridges with morphological similarities.

De Geer moraines are transverse moraines found below the highest shoreline, e.g., in areas glaciated by the Scandinavian Ice Sheet and the Laurentide Ice Sheet (Lindén and Möller, 2005; Todd et al., 2007). Based on the detailed sedimentological and morphological studies of De Geer moraines in North Sweden, Lindén and Möller (2005) suggested that the De Geer moraines formed submarginally in a glacioaquatic environment at the grounding line of the retreating ice sheet. Moraine ridges built up due to subglacial sediment advection in a deforming bed and deposition of sediment gravity flow material at their distal side.

"Rogen moraines" are probably the most striking type of ribbed moraine (Figure 5). Many highly differing models of formation have been suggested, some involving reshaping of earlier glacial landforms, subglacial extensional fracturing of sediments, or shearing and stacking of basal debris-rich ice (e.g., Hättestrand and Kleman, 1999; Dunlop and Clark, 2006; Finlayson and Bradwell, 2008).



Moraine, Figure 5 Ribbed moraine landscape in the Lake Rogen area, western Sweden. This is the type locality of "Rogen moraines." Individual moraine ridges are up to ca. 1,000-m long, ca. 50–200-m wide, and ca. 20-m high. The ribbed moraine ridges appear in a pattern transverse to the local ice-flow direction of the Scandinavian Ice Sheet during the Weichselian glaciation. The "horns" usually point in a downglacier direction. False-color Landsat ETM7+ imagery recorded May 19, 2002. Coordinates are in meters, UTM WGS 1984.



Moraine, Figure 6 Circular moraine ridges ca. 30 km East of Kenaston, Saskatchewan, Canada. The ring forms are up to ca. 200 m across and are located in a low-relief glacial landscape formed by the Laurentide Ice Sheet during the Wisconsinan glaciation. Landsat 7ETM+ imagery recorded May 24, 2001. Coordinates are in meters, UTM WGS 1984.

Most studies have focused on the geomorphology of Rogen moraines, and only recently sufficiently detailed sedimentological investigations have added to the understanding of these landforms (Möller, 2006). Based on studies in central Sweden, Möller (2006) suggested that Rogen moraines form in a two-stage manner. According to his model, preexisting transverse moraine ridges deposited in dead-ice environments survived below cold-based ice until the Preboreal deglaciation, where the ice sheet turned warm-based and became more dynamic. It is in this final phase that the "horns" formed and the precursor transverse landforms were re-moulded into Rogen moraines.

Rim ridges or circular-shaped moraines

Rim ridges are ring-shaped moraines, with an outer ridge surrounding a central depression (Figure 6; Mollard, 2000; Johnson and Clayton, 2003). They have mainly been described from the Great Plains of North America, although ring-shaped moraines and ice-walled lake plains also occur in Scandinavia (e.g., Lagerbäck, 1988; Lidmar-Bergström et al., 1991). Rim ridges usually occur in clusters of hundreds or thousands of low-relief landforms, each one sized up to 200 m in diameter (Johnson and Clayton, 2003). Most conceptual models suggest that they form by a topographical inversion in the last melt-out phase of individual buried ice blocks in dead-ice environments (Clayton and Moran, 1974; Ham and Attig, 1996; Johnson and Clayton, 2003). Despite their organized appearance in clusters, they might therefore be considered as a type of hummocky moraine.

Conclusions

The geomorphology, sedimentology, and genesis of most moraines described here are generally well understood. However, the variety between moraines in the same area and between the same types of moraines in different areas is immense. This also explains why moraines of similar type are often termed with local names. In particular, studies of processes in modern glacial environments have provided important depositional models for ancient moraines. Although this approach has been very valuable, there are still many research questions to be answered. One of the largest challenges is the lack of suitable modern analogs. For instance, the vast areas and large sediment volumes

of the hummocky moraines and ground moraines in North America are hard to understand from the studies on modern glaciers, which are orders-of-magnitude smaller than the Pleistocene ice sheets. Because most modern ice sheets terminate in marine environments or in alpine terrain, it is still very challenging to understand the deposits and palaeodynamics of past ice sheets terminating in lowlands and resting on soft sediment beds.

Definition

Moulins are narrow, tubular shafts that allow surface meltwater to enter a glacier (Figure 1).

In order to form, a moulin requires crevasses, enough availability of melt water, and relatively flat area. It normally forms at the tip of a crevasse, when it starts accumulating supraglacial meltwater. When a new moulin is formed upstream, it restricts water movement downstream and ultimately abandons the old moulin. It is a big part of the glacier system and can be found in almost all type of glaciers. In many ways moulins are one of the most complex yet stunning features to view. They can be several meters wide and can go all the way to the bed of the glacier, linking supraglacial system of the glacier with the subglacial system. Although most moulins stop somewhere in between and link the supraglacial system with the englacial system. Moulins can be used to inject a fluorescent dye which is one of the widely used methods to study glacial drainage networks and channel systems. Moulins also lower supraglacial and englacial debris to the glacier bed and plays a major role in sediment entrainment and transport. In the last two decades, our understanding about moulins has been widely enhanced by major research initiatives that have drawn conclusions about their importance in the distribution of water within a glacier, glacier's ability to store water, glacier velocity, and pressurizing the subglacial system. Efforts are underway to use moulins as a pathway to study the linkage between glacial water flow from the ice sheets to the sea.

MOUNT EVEREST

Rijan B. Kayastha
Himalayan Cryosphere, Climate and Disaster Research Center (HiCCDRC), Kathmandu University, Dhulikhel, Kavre, Kathmandu, Nepal

Synonyms

Chomolungma (in Tibetan); Sagarmatha (in Nepali); Zhumulangma Feng (in Chinese)

Definition

Mount Everest is the highest mountain on Earth. The height of its summit is 8848 m above mean sea level and its coordinates are 27°59′17″N, 86°55′31E″. It is located on the border between Sagarmatha Zone, Nepal and Tibet, China. It is a part of the Mahalangur Himal in the

Himalaya Range in Asia. Since there was no local Nepali name of this highest mountain of the world, it was officially named Mount Everest by the Royal Geographical Society after the Surveyor General of India, George Everest, in 1865. In the early 1960s, the Nepalese Government gave its official name as Sagarmatha (सगरमाथा *meaning Head of the Sky*). It lies in the Sagarmatha National Park which was declared as the World Heritage Site by UNESCO in 1981. The first successful ascent of the Everest was made by the New Zealander Edmund Hillary and Tenzing Norgay from Nepal on May 29, 1953, via South Col Route. Since then, many climbers have reached the summit. By the end of the 2008 climbing season, there had been 4,109 ascents to the summit by 2,700 individuals. Appa Sherpa, on May 22, 2010, climbed the Everest for the 20th time breaking his own record for the highest number of successful summits.

Mount Everest, Figure 1 Mount Everest.

Mount Everest, Figure 2 Khumbu Icefall.

Geologists have subdivided the rocks comprising Mount Everest into three units called formations: the Qomolungma Formation, the North Col Formation, and the Rongbuk Formation (Yin and Kuo, 1978; Sakai et al., 2005). The Qomolungma Formation is from its summit to the top of the Yellow Band, about 8600 m above sea level. It consists of grayish to dark gray or white, parallel laminated and bedded limestone interlayered with subordinate beds of recrystallized dolomite with argillaceous laminae and siltstone. The North Col Formation consists of the bulk of the Mount Everest, between 7000 and 8600 m, of which the Yellow Band forms its upper part between 8200 and 8600 m. The Yellow Band consists of intercalated beds of diopsite-epidote-bearing marble, which weathers a distinctive yellowish brown, and muscovite-biotite phyllite and semischist. The lower part of the North Col Formation exposed between 7000 and 8200 m consists of interlayered and deformed schist, phyllite, and minor marble. The Rongbuk Formation below 7000 m consists of sillminite-K-feldspar grad schist and gneiss intruded by numerous sills and dikes of leucogranite.

The Khumbu Glacier and Rongbuk Glacier are on the southern and northern slopes of Mount Everest. The Khumbu Glacier is located on the Khumbu region and flows down from the Khumbu Icefall on the southern slopes of the Everest. The ablation area of the Khumbu Glacier ranges in elevation from 5400 m immediately below the icefall to 4900 m at the terminus. Within this ablation area, the ice thickness varies from about 20 m near the terminus to 450 m near the icefall (Gades et al., 2000). The Rongbuk Glacier is located in the Himalaya of southern Tibet. It is formed by two large tributary glaciers, the East and West Rongbuk Glaciers. It flows north and forms the Rongbuk Valley north of the Mount Everest.

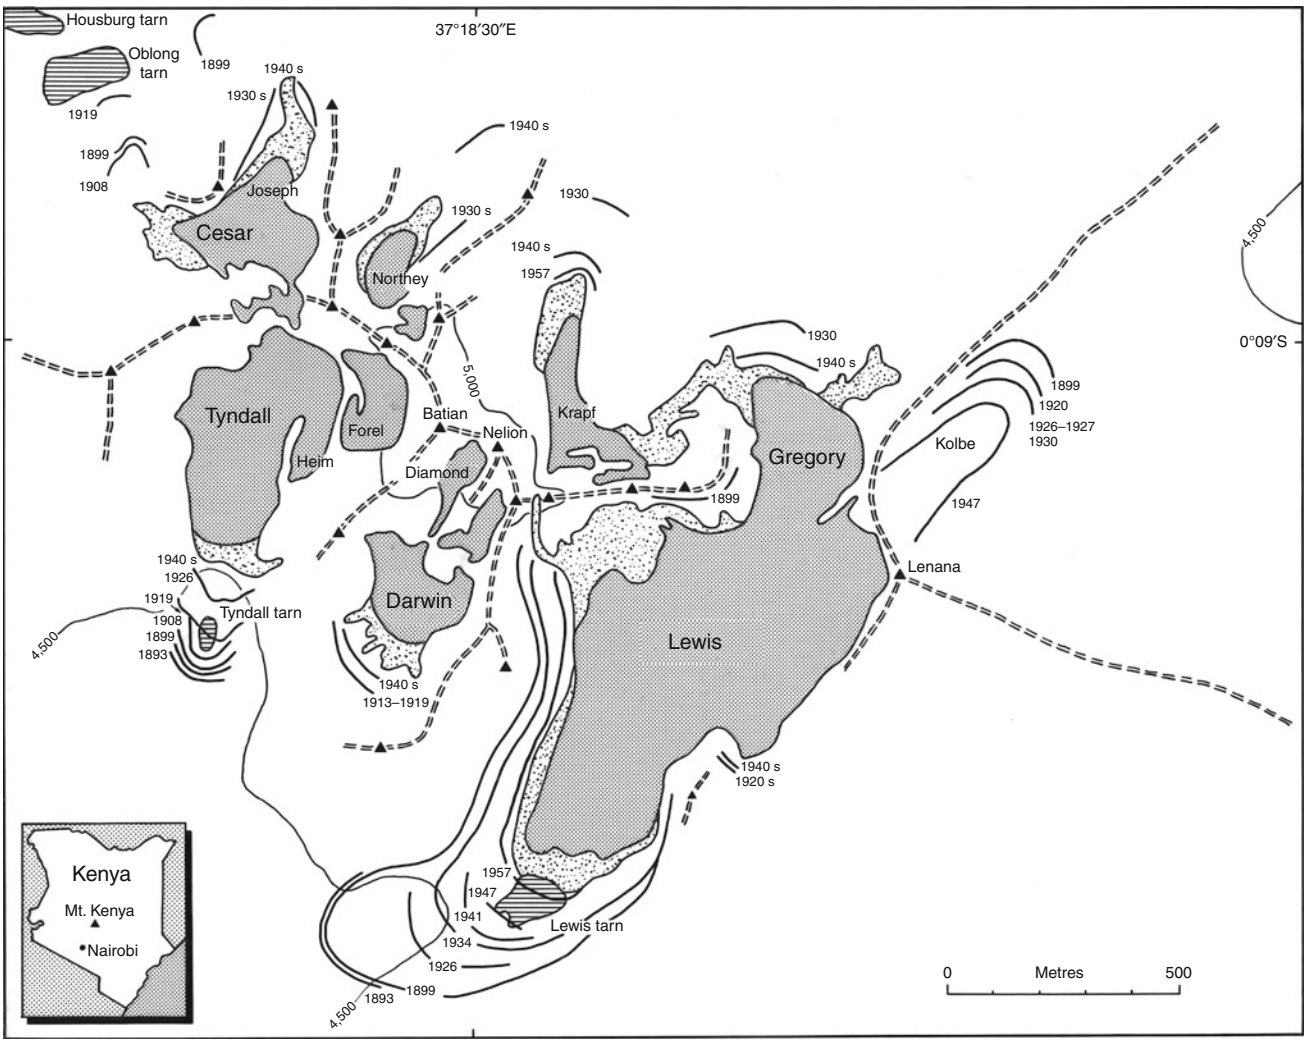
MOUNT KENYA

William C. Mahaney
Quaternary Surveys, Thornhill, ON, Canada

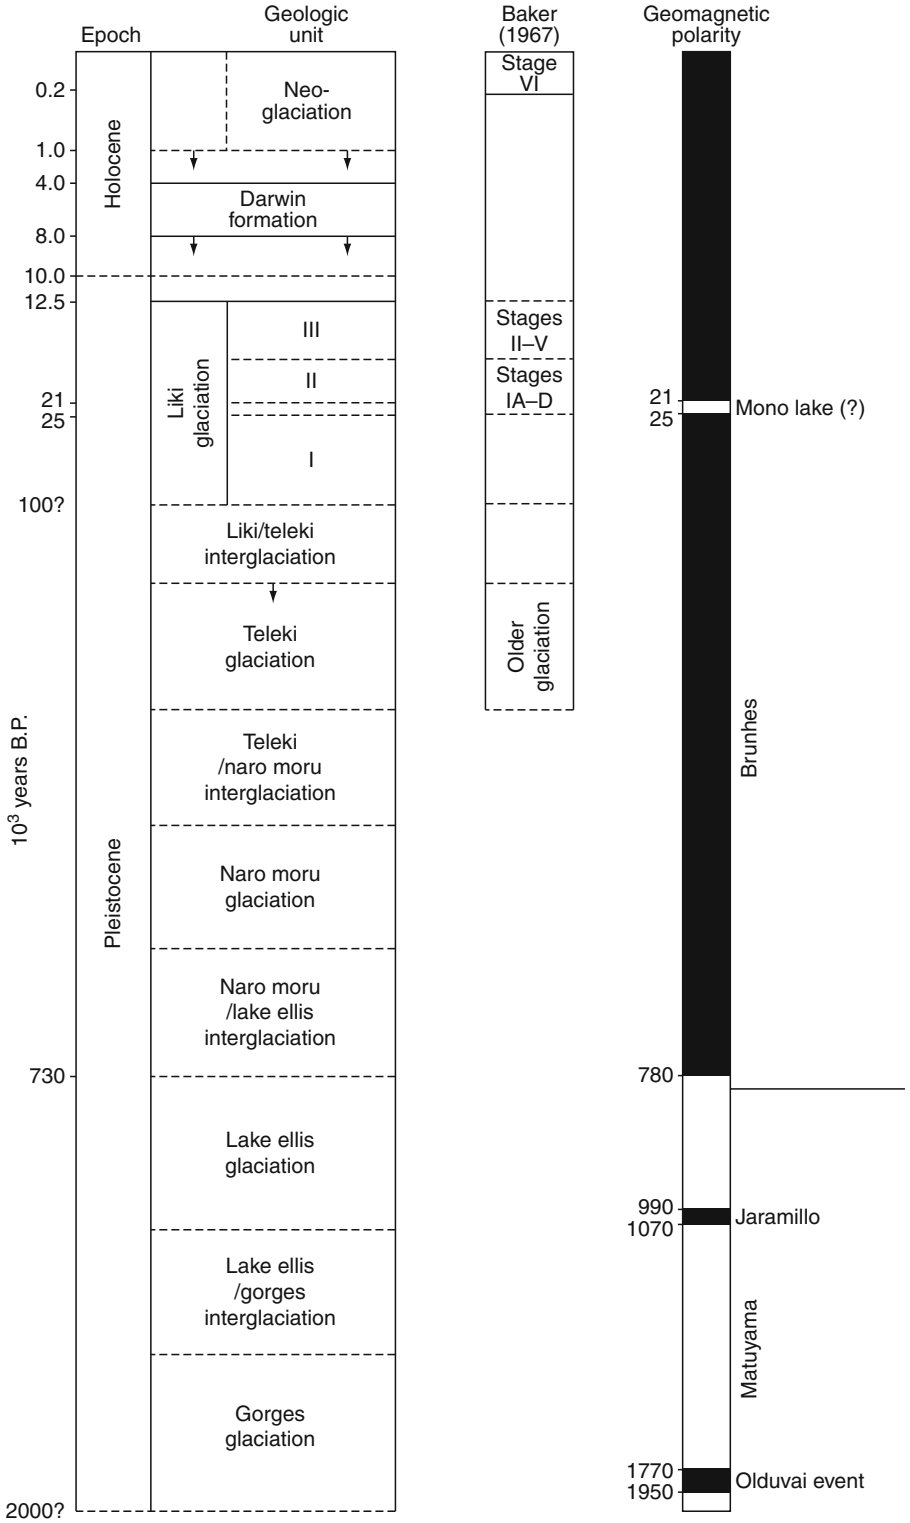
Definition and introduction

Mount Kenya, one of the principal high mountains of East Africa, rises to 5,199 m a.s.l. As a recorder of Quaternary glacial events, the massif contains documented tills reaching beyond the Olduvai subchron, nearly to the Plio-Pleistocene boundary. Surfaced with the oldest documented tills in the tropical mountains it is one of the most studied mountains in the tropics. Mount Kenya stands alone, not only as a major mountain, exceeded in altitude only by Kilimanjaro, which is much younger; but much higher than its nearest rivals in Kenya – Elgon and the Aberdares – and closer in elevation to the Virungas and the Ruwenzori in Central Africa. Mount Kenya has undergone six glaciations since the crystallization of the main volcanic plug 2.64 Ma (Everden and Curtis, 1965), and contains a wealth of interglacial paleosols that have provided important information on paleoenvironments between glaciations.

For just over a century, Mount Kenya has attracted the attention of glacial geologists keen to refine the chronology of episodic glaciation and climatic change (Gregory, 1894; Baker, 1967; Hastenrath, 1984; and Mahaney, 1990), which are the underpinnings of ecological change, dispersal of remnant flora and fauna



Mount Kenya, Figure 1 Central Peaks of Mount Kenya. Moraine ages are based on historical documentation to 1960 and ice limits (ca. 2009) are much reduced owing to global warming.



Mount Kenya, Figure 2 Chronology of Mount Kenya showing geological climatic units. Ages of glacial and interglacial deposits are based on radiocarbon dates (Liki Glaciation and younger) and paleomagnetic polarity. The Last Glacial Maximum (LGM) and Late Glacial stages of Baker (1967) are inclusive in Liki stades II and III, respectively.

(Coe, 1967; Harmsen, 1989), and genesis of soils and paleosols. After Gregory, Mackinder (1900) offered new insights into the biogeography of the mountain, but unfortunately lost most of his specimens on the way home. After several years of scientific inactivity, Eric Nilsson, in 1927 and 1932, mapped moraines in Gorges Valley near the Nithi Waterfall (Liki moraines of Mahaney, 1990); his observations (Nilsson, 1931) of an "early till," below the 3,200 m contour in the Nithi Catchment on the eastern flank, were followed up by Mahaney (1990) who carried out detailed investigations starting in 1983.

Nilsson's observations are particularly important because he was the first to describe the moraine sequence around Harris Tarn, on the northeastern flank of the mountain (Figure 1), into which the Kolbe Glacier descended in the first few decades of the twentieth century. The Kolbe Glacier has since melted away and will soon be followed by many of the other small glaciers on the mountain (Mahaney, 1990).

Moreover, Nilsson was the first to surmise that since the moraine sequence on Mount Kenya correlated closely with Mount Kilimanjaro, Mount Elgon, and the Ruwenzori Mountains, it was quite likely that all resulted from the same climatic change. Nilsson's maps of the eastern flank of the mountain are among the most accurate ever made on any of the East African summits.

At about the same time (1934), Carl Troll and K. Wien began glaciological investigations on Mount Kenya which resulted in a photogrammetric survey and flow measurements (Troll and Wien, 1949). Just after WWII, P.C. Spink (1945, 1949) began monitoring glacier recession, a series of observations that have continued on and off (Hastenrath, 1984) up to the present day. In 1947, F.E. Zeuner (1949) studied soil-frost structures and loess on the mountain, focusing attention on needle-ice development, a peculiar process involving diurnal freezing in the tropical mountains. Mahaney (1990) showed not only that loess is present in the surface of almost all soils on Mount Kenya, but that it is represented by quartz-rich horizons in the epipedons (surface horizons) of interglacial paleosols. The tills are represented principally by ferromagnesian minerals.

During the IGY, a number of reconnaissance studies in glaciology and glacial geology were undertaken in various catchments on the mountain, all briefly documented by Baker (1967) who also published the first detailed bedrock map of the mountain.

Mount Kenya is part of the Central Plateau of East Africa, an area of intense tectonic activity that has waxed and waned since the Early Miocene (Mahaney, 1990). Following fractures as old as Cretaceous, a system of rift valleys formed in the Late Tertiary with enormous lakes; major faulting led to down dropping of several rift valleys while others remained several hundred meters above sea level. Immense lava flows, including Mt. Kenya and Mt. Kilimanjaro, erupted through and were aligned with deep fractures in the crust, all dating from the Pliocene and Pleistocene. Not all mountain massifs are volcanic, as some formed as erosional remnants (Cherangani Hills, north of Mt. Kenya) and others from regional faulting of metasedimentary rocks (Mount Elgon on the Uganda–Kenya border, a prime example).

A full discussion of the climate on Mount Kenya is given by Mahaney (1990). While not known with precision, the MAT at 3,000 m a.s.l. is estimated at close to 10°C; at 4,000 m a.s.l., +3°C, which conforms to a lapse rate of 6.5°C/km (International Standard Atmosphere). Data on precipitation collected during the IGY show the wettest drainages to be on the west and south, all fed by thunderstorms. The eastern flank of the mountain is dry above 3,000 m altitude, whereas, below the 3,000-m contour, the climate becomes wet with precipitation well over 1 m/year; and during the monsoon (April–July), the lower reaches are exceedingly humid. The northern slopes are often under anticyclonic activity and very dry. In effect, this climatic distribution led to the development of the largest modern glaciers on the western flank (Figure 1) where they would be least starved of moisture. The ancient Pleistocene climatic regime was quite different, with the largest glaciers on the eastern side of the mountain, in Gorges and Hobley valleys. Presumably, during each glaciation, there may have been an upward shift in the monsoon which fed moisture in much greater quantity onto the upper eastern slopes, giving rise to a partial ice cap that covered Point Lenana (4,985 m a.s.l.; Mahaney, 1990).

Moraine positions, outlined on the Mount Kenya map shown in Mahaney (1990; Plates 1–5), are based on geologic mapping and stratigraphic data compiled into the chronology shown in Figure 2.

MOUNTAIN GEOMORPHOLOGY

David R. Butler
Mountain GeoDynamics Research Group, Department of Geography, Texas State University-San Marcos, San Marcos, TX, USA

Definition

Mountain. Although no universally accepted definition of *mountain* exists, it is generally accepted that a mountain is a large landform that rises abruptly from the surrounding level and attains a high elevation, typically in the form of a peak that is separated from the surrounding lower elevations and adjacent peaks.
Geomorphology. The study of landforms and the processes by which they are created.

Introduction

Mountains have long been a central focus in the discipline of Geomorphology (Harbor, 2004; Kennedy, 2006), and "their steep surface gradients, and rapid spatial and temporal changes in biophysical variables that control geomorphic processes" (Harbor, 2004, p. xix) offer a diverse landscape for geomorphologists. The study of mountain geomorphology has been the focus of several edited books (Slaymaker, 1972; Butler et al., 2003; Bishop and Shroder, 2004; Owens and Slaymaker, 2004), but no recent text has focused specifically on mountain geomorphology. Price (1986) surveyed the range of geomorphic processes that occur in mountain environments, but his work was not specific to mountain geomorphology.

Geomorphic processes in mountains

The high energy of alpine environments produces a suite of geomorphic processes that result in often unique landforms, many of which are associated with the presence of snow, ice, and/or glaciers. Glacial and periglacial conditions, past and current, typify most high mountain environments, and hazardous mass movements such as snow avalanches and a range of landslides are widespread (Giardino et al., 1987; Benn and Evans, 1997; Kalvoda and Rosenfeld, 1998). Quaternary glaciations sculpted many mountain ranges, leaving behind signature landforms such as U-shaped valleys. Smaller mountain glaciers reformed during the Little Ice Age, imparting their own legacy on the landscape. Active and relict rock glaciers (Giardino et al., 1987) are also found in mountain landscapes around the world, and geocryological processes associated with the presence of permafrost and/or seasonal ground ice are also widespread (Price, 1986). Twentieth- and twenty-first-century climate change associated with global warming has caused drastic recession, and in many cases disappearance, of alpine glaciers. Climate change has also affected geocryological processes and landforms in alpine regions, allowing tree seedling establishment and upward advance of upper tree line into alpine tundra (Butler et al., 2009).

Summary

Mountain geomorphology is a subfield of geomorphology focused on the geomorphic processes currently and recently operating in mountain environments. Mountains provide sensitive natural laboratories for the study of geomorphic processes, and mountain geomorphologists are actively involved in studies of climate change in the twenty-first century.

NATURAL HAZARDS ASSOCIATED WITH GLACIERS AND PERMAFROST

Andreas Kääb
Department of Geosciences, University of Oslo, Oslo, Norway

Introduction and definitions

Glacier and permafrost hazards are related to *glacial*, *paraglacial*, and *periglacial phenomena and processes*. Though usually defined more narrowly, we subsume here in the context of hazards any perennial land surface ice body as *glacier*. The glacial, paraglacial, and periglacial environment is defined, respectively, as the zone of glaciers or their action, the non-glacial zone directly conditioned by glaciation or deglaciation, and the non-glacial zone in cold regions with frost action being the predominant geomorphic process. Often, the periglacial zone is characterized by *permafrost* (lithospheric material with negative temperatures throughout 2 or more years). Glacier and permafrost hazards are, thus, connected to glaciers and their present or past actions, and to year-round negative ground temperatures and related processes. Hazards associated to glaciers and permafrost are best treated together in an integrative way, because the environments they origin from are often in direct contact and the relevant processes interact.

Disasters associated to the glacial, paraglacial, and periglacial environment can cause thousands of casualties in one event. Related damages or mitigation costs are on the order of several hundred million EUR as a long-term annual average global sum (Kääb et al., 2005b). Glacier and permafrost-related problems and threats include glacier- and permafrost-related floods, stable and unstable glacier length changes as well as glacier fluctuations, glacier- and permafrost-related mass movements, permafrost thaw settlement and frost heave, and threats from glacier-clad volcanoes. Often, combinations of these (and other) processes lead to the most severe glacier- and permafrost-related catastrophes. While the above direct glacier and permafrost threats are very palpable, so too are indirect threats, such as changes in dry-season river flows, adverse effects on land use, and related socioeconomic consequences.

In this contribution, the following terms are used (JTC1, 2004): *threat* is a "natural phenomenon that could lead to damage, described in terms of its geometry, mechanical and other characteristics. The threat can be an existing one (such as a creeping slope) or a potential one (such as a rockfall)." *Susceptibility* is the spatial distribution of threats (sometimes referred to as hazard disposition). *Hazard* is the "probability that a particular threat occurs within a given period of time." Threat therefore describes the process and magnitude of a dangerous event, susceptibility includes its spatial distribution, and hazard its temporal frequency. *Vulnerability* is the "degree of loss to a given element, or to a set of elements within the area affected by a hazard," or to a "set of conditions and processes resulting from physical, social, economic, and environmental factors." *Risk* is a "measure of the probability and severity of an adverse effect to life, health, property, or the environment."

In this contribution we do not treat natural threats associated with temporary land ice (seasonal ice or shorter), river, lake and sea ice, and snow (e.g., avalanches, snow melt floods).

Glacier-related floods

Generally, glacier floods represent the glacial threat with the highest potential for disaster and damages. Glacier floods occur in most glacierized mountains of the world and are triggered by the outburst of water reservoirs in, on, underneath, and at the margins of glaciers

Vijay P. Singh, Pratap Singh & Umesh K. Haritashya (eds.), *Encyclopedia of Snow, Ice and Glaciers*, DOI 10.1007/978-90-481-2642-2,

(Figures 1, 2, and 3). Most reservoir types develop slowly and can be identified at the surface, a precondition that favors the application of remote sensing techniques for monitoring glacial and periglacial lakes (Kääb et al., 2005a; Quincey et al., 2005; Kääb, 2008). Floods from ice-dammed lakes and proglacial moraine-dammed lakes, in particular, represent a recurring and severe danger. Different outburst mechanisms are involved in glacier floods.

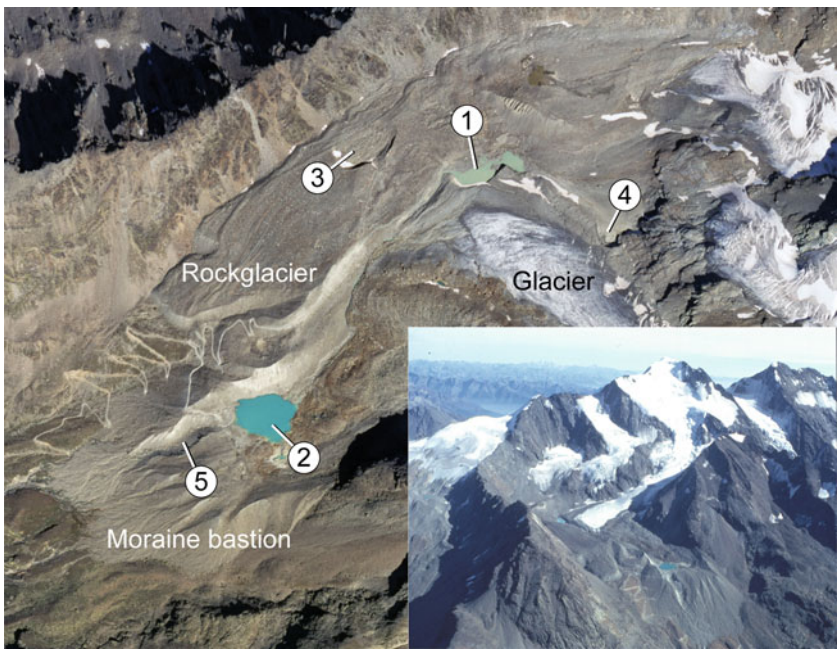
Breaching of moraine dams

Retrogressive erosion at the outer slope of a moraine dam or collapse of parts of a moraine dam may lead to a progressively enlarging breach through which large parts or the entire moraine lake may empty (Figure 1; Haeberli, 1983; Costa and Schuster, 1988; Clague and Evans, 1994; Clague and Evans, 2000; Richardson and Reynolds, 2000; Haeberli and Burn, 2002). Trigger for such processes are usually enhanced runoff into the glacial lake (e.g., heavy snow and ice melt), impact waves (e.g., from ice, rock or snow avalanches), temporary damming/jamming at the lake outlet (e.g., lake ice jams, snow drift), or progressive groundwater flow and erosion in the moraine (piping). A moraine lake outburst may stop before the entire lake has emptied when large blocks, which are large enough to not be washed away by the flood, are eroded out of the moraine and deposited at the breach bottom so that the breach is not further incised and stabilizes. As a consequence, typical maximum breach cross-section areas can be found for some regions, depending on the lake volumes and the composition of the moraine materials.

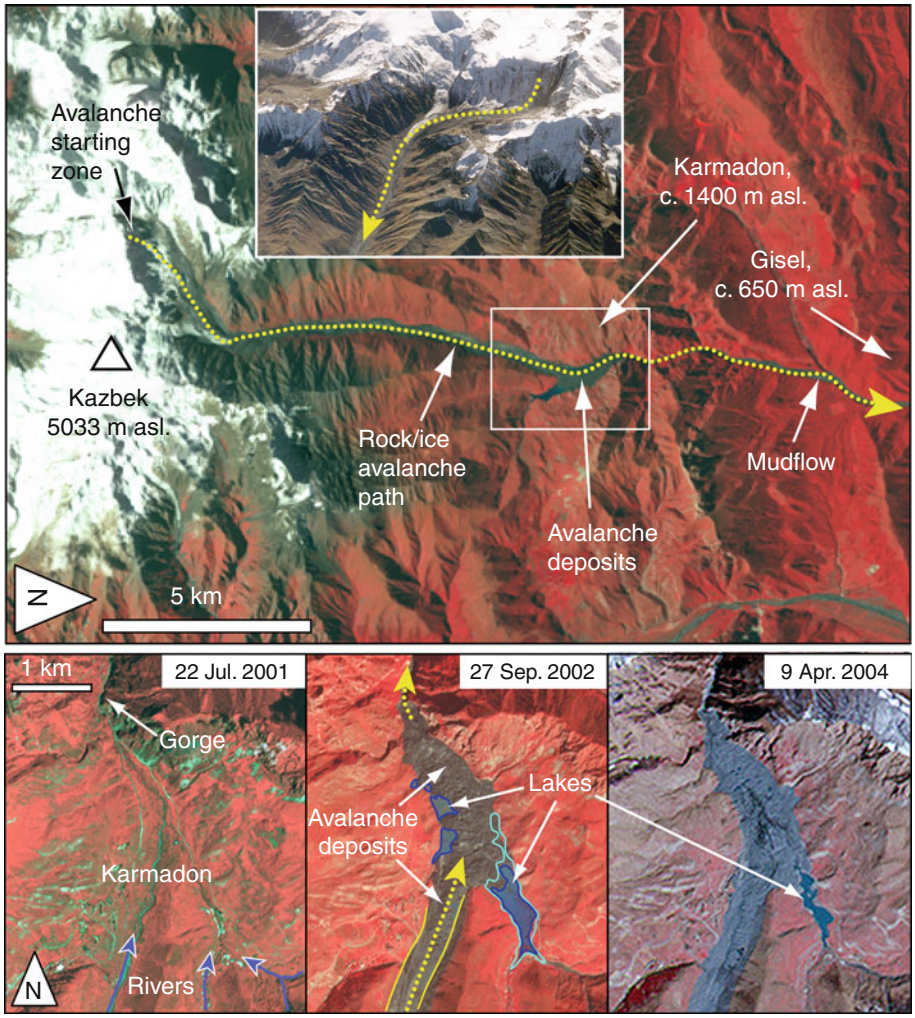
In cold conditions, ground thermal conditions in moraines are often important to the stability of moraine-dammed lakes. Permafrost or near-permafrost conditions cause the long-term preservation of dead-ice bodies, which leave behind cavities when they melt (Haeberli, 1992a; Haeberli et al., 2001; Kääb, 2008). Occurrence of such cavities may drastically reduce the stability of a moraine dam.

Failure or overtopping of ice dams

Natural ice dams may fail mechanically, hydraulically, or be overtopped. For permanent ice dams, the disasters often repeat because the ice dam may recover after an outburst. Related outbursts stem from ice-marginal lakes, supraglacial lakes, and from temporary ice dams formed by ice avalanche deposits or glacier surges (Figure 2). A sudden mechanical breach of an ice dam causes the highest peak discharges of glacier floods (Clague and Mathews, 1973; Clarke, 1982; Walder and Costa, 1996; Tweed and Russel, 1999; Ng et al., 2007). It happens in particular when the ice dam is composed by insufficiently coherent ice



Natural Hazards Associated with Glaciers and Permafrost, Figure 1 Gruben area, Saas valley, Valais, Swiss Alps (latitude 46.172°, longitude 7.976°). Ice-dammed lake (*1*), moraine lake (*2*), former thermokarst lake (*3*), former ice-dammed lake (*4*), and moraine breach (*5*). In 1968 and 1970 the ice-dammed lake *1* burst out, presumably triggered by extraordinary water influx from the ice-dammed lake *4*. The resulting flood reached the moraine lake *2*, causing dam overtopping, erosion of the moraine dam (breach *5*), and debris flow. Mitigation measures taken after these events performed well until the mid-1990s when a newly developed thermokarst lake (*3*) had to be emptied artificially, the ice-dammed lake *1* lowered, and the outflow of the moraine lake *2* toward the breach *5* stabilized (Haeberli et al., 2001; airphoto of 1999: swisstopo).



Natural Hazards Associated with Glaciers and Permafrost, Figure 2 Kolka/Karmadon area, North Ossetia, Russian Caucasus (latitude 42.84°, longitude 44.52°). On September 20, 2002, the break-off of the entire Kolka glacier, presumably triggered by repeat rock avalanches from the rock wall to its south (International Space Station image shortly after the event in the upper middle inset), caused a huge ice/rock avalanche that reached and partially destroyed the village of Karmadon 18 km downstream (overview on ASTER satellite image in upper panel; ASTER image details of Karmadon area of different times before and after the event in lower panels). A mud flow resulted immediately from the impact of the avalanche deposits at Karmadon and travelled another 15 km to the village of Gisel. The blue arrows in the lower *left* panel indicate the rivers that were dammed by the ice avalanche and formed lakes that changed size over time (*light blue* and *blue outlines* in *middle lower* panel). The *yellow dotted line* indicates the avalanche and mud flow path (Kääb et al., 2003).

fragments or highly crevassed ice, such as ice avalanche deposits or glacier ice under surge conditions.

Hydraulic failure of an ice dam happens through the (partial) floatation of the ice mass and leads to the progressive development of sub- and intraglacial channels due to the heat capacity and advection of the water bursting out (Clague and Mathews, 1973; Nye, 1976; Spring and Hutter, 1981; Clarke, 2003; Ng and Bjornsson, 2003; Roberts, 2005).

Overtopping of an ice dam happens when the level of the water reservoir rises, but the ice dam is stable enough not to burst and its density large enough to prevent floatation (e.g., through debris content or cover). Also, supraglacial permafrost conditions, that is, when the ice dam is frozen to its bed, may prevent from ice-dam floatation. The speed and magnitude of ice incision, and with that the discharge of a lake outburst through overtopping, depends much on the length and slope of the outburst channel over ice, and if supra- and intraglacial debris stabilize the channel bottom after a while.

Breaching of thermokarst and supraglacial lakes

Thermokarst and supraglacial lakes can develop on ice-rich permafrost or glacier ice, in particular stagnant ice (Figure 1; Benn et al., 2000; Reynolds, 2000; Kääb and Haeberli, 2001). Thermal convection leads to progressive

Natural Hazards Associated with Glaciers and Permafrost, Figure 3 Belvedere Glacier, Monte Rosa, Italian Alps (latitude 45.953°, longitude 7.911°). Connected to a surge-type acceleration that started in 2001, a large temporary lake developed on *top* of the Belevedere glacier posing a severe outburst threat to the villages downvalley, in particular Macugnaga. An outburst of the moraine lake to the right caused already severe damage in 1979 (Kääb et al., 2004).

lake growth. Outburst causes are similar to breaching of moraine and ice dams, and, in addition, progressive melt of the ice or permafrost dam. The development of such lakes is often slow, that is, over several years and can thus well be monitored. Permafrost thermokarst lakes are particularly common in Arctic low lands and breach regularly (Hinkel et al., 2007). But they may also develop in mountainous terrain (Figure 1; Kääb and Haeberli, 2001).

Glacier outbursts

For some cases, catastrophic water discharge from the en- or subglacial drainage systems is reported (Haeberli, 1983; Walder and Driedger, 1994, 1995; Bjornsson, 1998, 2003). Causes may be geothermal or volcanic activity, temporary en- or subglacial water storage and sudden release, or catastrophic water release connected to surge termination.

Displacement waves

Displacement waves impact on people, natural and artificial lake dams, and other installations (Tinti et al., 1999). Those displacement waves have been the trigger for a number of lake outburst events. They originate from the impact of snow-, ice-, rock-avalanches, landslides, debris flows, etc. into the lake, or from break-off and floatation of icebergs. Once such displacement waves create a tsunami they can run up the lake shores and create damage. If the waves overrun moraine or ice dams they may cause erosion at the airside slopes and eventually retrogressive dam breaching (see above sections) (Walder et al., 2003). Artificial dams are usually not designed to withstand forces from wave overtopping and might be damaged or even break.

Glacier length and volume changes

Advancing and retreating glaciers can pose a direct threat to infrastructures. From a global point of view, the prediction of glacier length variations is complicated by the fact that glaciers can vary in a continuous (stable) or unstable way (i.e., glacier surges).

Glacier surges

Glacier surges are a temporary instability of large glacier parts with ice velocity increased by an order of magnitude (or more) (Raymond, 1987; Harrison and Post, 2003). Usually, glacier surges are accompanied by drastic glacier advance. Surging glaciers are able to rapidly destroy installations or induce other threats, such as icefalls or falling rocks from supraglacial debris, for example, if they advance into steeper terrain (Haeberli et al., 2002; Kääb et al., 2004). They can temporarily dam lakes, which, when these dams fail, produce some of the largest known outburst floods (Bruce et al., 1987). Due to the crevassing and low cohesion of ice sections and ice debris within a surging glacier, there is a high probability that such temporary dams fail through sudden mechanical burst leading to particularly high flood peak discharges. Often, glacier surges are accompanied by enhanced englacial water storage, which is possibly released at the surge end in a catastrophic way (Figure 3).

Stable glacier advance and retreat

Advancing glaciers may inundate land, override installations (e.g., hydropower installations), dam rivers and form lakes, cause ice break-offs when the glacier advances over a cliff, etc. (Tufnell, 1984; Grove, 1987; Mayo, 1988; Yamada and Sharma, 1993). Glacier retreat forms usually no direct threat but is able to trigger a number of secondary threats such as various slope instabilities and ice avalanches (see below). Causes for such stable glacier length changes are changes in mass balance and/or in ice dynamics.

Changes in glacier runoff and seasonality

Glacier mass loss leads to reduction of water resources as stored in glaciers and to changes in dry-season river flows. The short-term perspective is increasing discharge due to enhanced melt; the long-term perspective is decreasing discharge when the glaciers in a basin become substantially smaller or disappear. These processes have consequences for drinking water supply, irrigation, hydropower production, industrial water use, fishery, water quality, etc. Arid and semiarid regions like parts of the Andes or Central Asia are particularly vulnerable to reduction of dry-season river flows (Wagnon et al., 1999; Francou and Coudrain, 2005).

Glacial and paraglacial mass movements

Compared to the distances covered by glacier floods, ice and rock avalanches often affect much smaller areas. Corresponding disasters are generally restricted to densely populated high-mountain regions. However, in combination with other processes, ice and rock avalanches have the potential for far-reaching disasters. In zones with high seismic activity and geothermal heat flow, the probability of major ice break-offs is greatly increased, as was demonstrated dramatically by one of the most destructive glacier catastrophes, the Huascarán disaster in 1970, with a loss of over 18,000 lives. Also, the extraordinary September 20, 2002, rock/ice avalanche at Kolka/Karmadon (Caucasus), a combination of rock and ice destabilization killing over 100 people, drastically underlines the devastating potential of ice/rock avalanches (Figure 2). A widespread hazard in high mountains is related to accumulations of loose sediments on steep slopes, which represent potential sources of debris flows. Such debris accumulations can occur in the form of moraines, moraine dams, or steep valley flanks uncovered by retreating glaciers.

Ice fall and ice avalanches

Steep glaciers (or glacier parts) are a common source of ice break-offs and subsequent ice avalanches (Alean, 1985; Margreth and Funk, 1999; Pralong and Funk, 2006). Ice break-offs are a usual form of ablation for steep glaciers, in particular at high elevations where melt ablation is not sufficient to keep a glacier in balance. In general, a discrimination between glaciers in cliff and ramp situations is useful. The break-off volumes from glaciers that flow from a flat part over a steep cliff are usually restricted to individual ice lamellas. Glaciers that lie on a steep ramp exist in such situations usually only because their entire bed or at least their frontal parts are frozen to the rock (i.e., permafrost conditions). For such ramp-type glaciers the break-off volumes can be larger or even include the entire glacier. The thermal conditions of the glacier front are crucial for the stability of ramp-type glaciers. Changes of these conditions, for instance through atmospheric warming, can therefore drastically alter stability conditions.

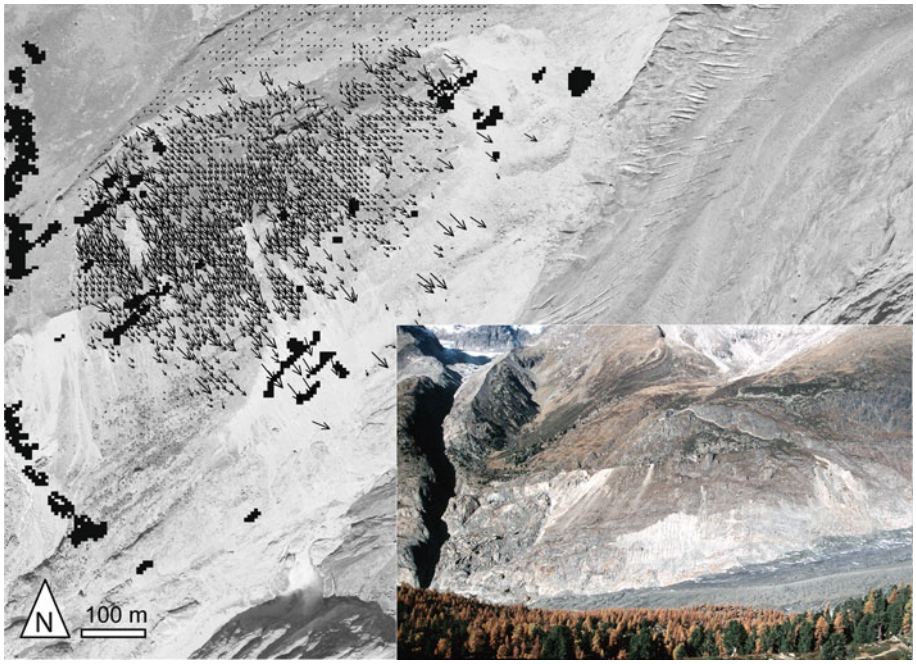
In rare cases also the detachment of complete flat glaciers seems possible (See for instance the 2002 Kolka/Karmadon event; Haeberli et al., 2005; Figure 2). Ice avalanches are particularly dangerous in winter with reduced basal friction, extended runout, and mass gain from snow. Glacier parts can also fail due to a failure of the underlying rock (e.g., the 1970 Huascaran event). Ice avalanches can be triggered by earthquakes. Ice avalanches itself can trigger lake outbursts, dam rivers, or transform into mud/debris flows.

Rock fall and rock avalanches

Glacier retreat uncovers and debuttresses rock flanks. The related change in thermal, hydrologic, hydraulic, and mechanic conditions can lead to rock fall and rock avalanches (fast mass movement) (Plafker and Erikson, 1978; Evans and Clague, 1988; Haeberli et al., 1997; Barla et al., 2000; Deline, 2001; Giani et al., 2001; Huggel et al., 2008). Rock avalanches can carry parts of overlaying glaciers. Rock avalanches can be of increased magnitude in glacial environments. The runout of such avalanches is extended on glaciers due the reduced friction on ice compared to other surface types. In addition, the rock mass may be combined with ice that was additionally released during the break-off (detachment of glacier parts overlying the failing rock mass), or entrained on the avalanche path (e.g., rip-off of crevasses). Such entrainment increases the volume of the avalanche and leads to partial liquefaction of the included ice through impact and friction energy (Evans and Clague, 1988; van der Woerd et al., 2004; Haeberli et al., 2005). Through processes not yet fully understood the slope angle of such combined rock-ice can be surprisingly low (Figure 2). Rock avalanches can be triggered by earthquakes.

Landslides and rock slides

Among other causes, glacier retreat or slope undercutting by floods uncovers and debuttresses rock and debris flanks. The related change in hydrologic, hydraulic, and mechanic conditions can lead to mass movements (slow mass movement) (Figure 4; Ballantyne, 2002; Holm et al., 2004; Kääb, 2005). These can create secondary hazards such as river dams, potentially causing outbursts and floods when these dams fail.



Natural Hazards Associated with Glaciers and Permafrost, Figure 4 Tongue of Aletsch Glacier, Swiss Alps (latitude 46.403°, longitude 8.027°). Glacier retreat and thickness loss of up to 300 m since the Little Ice Age caused debutressing and subsequent destabilization (rock sliding) of parts of the valley flanks. The main panel shows photogrammetrically derived surface displacements on the order of 10 cm a^{-1} superimposed on an aerial orthophoto. The inset is a view on the instable valley flank from the opposite side of the glacier (Kääb, 2005; airphoto of 2006: swisstopo).

Debris flows

Glacier retreat leaves behind unprotected and unconsolidated moraine material that is particularly prone to enhanced erosion and debris flows (Zimmermann and Haeberli, 1992; Rickenmann and Zimmermann, 1993; Chiarle et al., 2007). Furthermore, glacier and permafrost floods are often accompanied by debris flows when erodible material is available in steep parts of the flood path.

Interaction between volcanic activity and glaciers

Interactions between volcanic activity and glaciers are potentially among the most devastating disasters with glacier involvement (Brugmann and Post, 1981; Pierson et al., 1990; Thouret, 1990; Aguilera et al., 2004; Julio Miranda et al., 2005; Julio-Miranda et al., 2008). Enhanced geothermal activity, geometric and mechanic changes, deposition of hot eruptive materials, or albedo change by volcanic ash can lead to drastic melt of ice or ice break-off on ice-clad volcanoes and to volcanic landslides or lahars. Ash layers thicker than some millimeters or centimeters insulate the underlying ice.

Permafrost-related problems and hazards

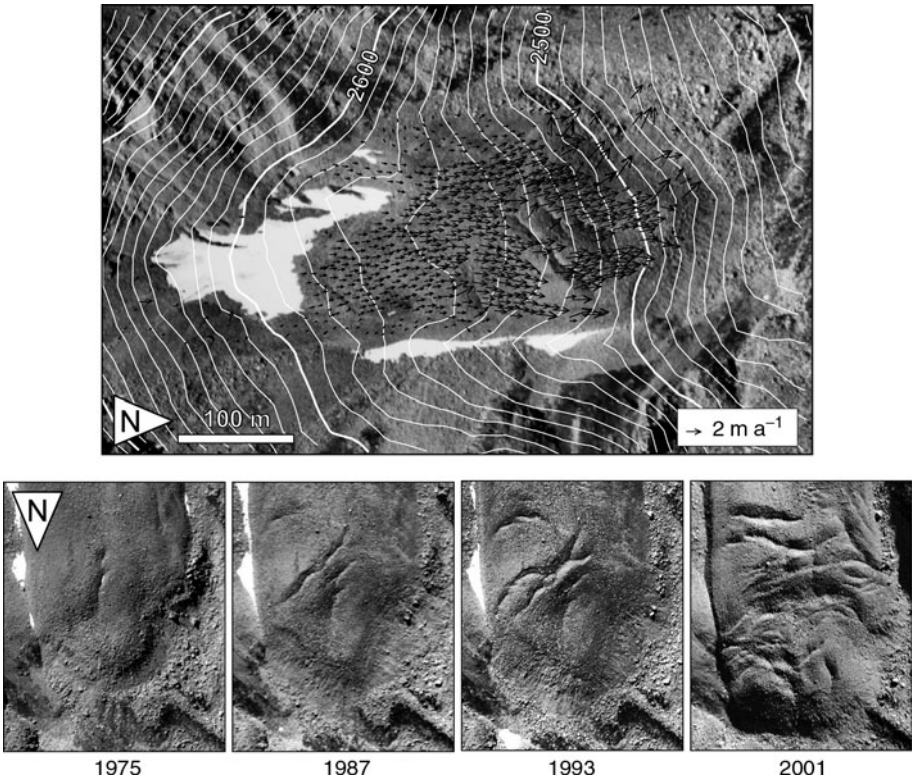
Permafrost influences the stability and hydrology of debris and rock slopes. While the trigger mechanisms of frequently unexpected debris flows and rock avalanches from permafrost zones often remain unclear (melting dead ice, permafrost-hydrology interactions, etc.) and are therefore difficult to predict in individual cases, the respective hazard potential seems to be connected to the presence of permafrost and its changes. Changes in the thermal regime of cold rock walls and related effects on rock stability are still poorly understood processes but are of increasing concern in view of some recent catastrophes.

Adverse effects of permafrost creep

Permafrost creep, exemplified by the creep of rockglaciers, may have adverse effects such as inundation of land, destabilization of construction, and rockfall from the rockglacier front. Permafrost creep can transport debris into locations from which debris flows or landslides originate (Figure 5; Burger et al., 1999; Kääb and Reichmuth, 2005; Kääb et al., 2007).

Thaw settlement and frost heave

Changes in ground ice content from ice-lense accumulation or thermokarst processes may result in changes in permafrost surface geometry. Such changes can affect constructions or trigger the development of thermokarst lakes (Nelson et al., 2001, 2002). Thaw and frost heave processes may also be caused by constructions, for instance, when they change the local snow cover regime or through basement heating.



Natural Hazards Associated with Glaciers and Permafrost, Figure 5 Destabilizing rockglacier, Turtmann valley, Swiss Alps (latitude 46.202°, longitude 7.723°). *Upper* panel: photogrammetrically derived surface velocities on the rockglacier. *Lower* panel: series of airphotos showing the decay of the rockglacier tongue causing rock fall and landslide hazards (Kääb et al., 2007; airphotos: swisstopo and university of Bonn; processing I. Roer).

Debris flows from permafrost

Permafrost thaw changes the mechanical and hydrological conditions in frozen material. While frozen debris can reach very steep slope angles through the strong cohesion by its ice content, thawing debris has to adjust to much lower friction angles. In addition, the water content of such thawing ice-containing materials is comparably high. As a consequence the hazard from periglacial debris flows may increase (Haeberli, 1992b, a; Zimmermann and Haeberli, 1992; Kneisel et al., 2007). Temporary runoff concentration and ground saturation is, thereby, often involved as trigger.

Destabilization of frozen debris slopes

In rare cases entire sections of rockglaciers or frozen debris slopes might destabilize (Figure 5; Kääb et al., 2007). Reasons for such processes are largely unknown (dynamics, ground warming?). Such destabilization can lead to rock fall, debris flows, inundation of land, and destruction of infrastructure.

Rockfall and rock avalanches from frozen rock faces

The thermal regime and ground ice in frozen rock faces have complex thermal, mechanical, hydraulic, and hydrological effects on rock stability (Figure 2; Haeberli et al., 1997; Wegmann et al., 1998; Fischer et al., 2006; Noetzli et al., 2006).

Runoff concentration at the permafrost table

There are cases reported where runoff concentration at the permafrost table has triggered debris flows and other mass movements.

Active layer detachments, thaw slumps, and permafrost-related landslides

In areas of continuous permafrost or large patches of discontinuous permafrost even small disturbances or changes in the active layer, for instance by river bank erosion, may trigger, often progressive, active layer detachments, thaw slumps, or landslides (Burn, 2000; Lantuit and Pollard, 2005; Lewkowicz and Harris, 2005a, b; Lyle and Hutchinson, 2006; Wei et al., 2006).

Erosion of frozen river banks, lake shores, and sea coasts

Frozen river banks, lake shores, and sea costs are vulnerable to thermally driven and mechanical erosion. Thereby both atmospheric heat and heat advection from the water may lead to fast and large-scale erosion and retreat of the

coast line that endangers coastal settlements and installations (Johnson et al., 2003; Mars and Houseknecht, 2007).

Hazard interactions and integral assessment

The glacier- and permafrost-related processes listed above represent relevant hazard potentials on an individual basis. However, combinations and interactions between these or other hazard types are of similar or even greater importance. In fact, many of the largest known glacier catastrophes are characterized by threat combinations and/or process chains. The assessment of glacier and permafrost hazards requires, therefore, systematic and integrative approaches. Concentration on just one obvious threatening process may easily lead to misjudgment of a situation and its full consequences.

Climate change, human activities, and related shifts of hazard zones

Mountain and polar regions are particularly sensitive to climate change. Changes in glaciers, snow and permafrost, and corresponding impacts on natural threats are among the most directly visible signals of global warming and may seriously affect human activities (Haeberli and Beniston, 1998; Haeberli and Burn, 2002; Kääb et al., 2005b). For example, in the Himalayas in Nepal and Bhutan, glacier lake outburst floods occurred at a frequency of roughly one flood per decade in the 1950s; this rate has since increased to one flood every 3 years in the 1990s and it is anticipated that event frequency could further increase (Richardson and Reynolds, 2000). It is predicted that both the number and size of glacial lakes will increase as climate changes and atmospheric warming causes through negative glacier mass balances most glaciers worldwide to retreat and possibly leave behind glacier lakes.

Coupled with increasing rural development and investments in infrastructure, particularly in hydropower, the vulnerability of mountain communities to outburst floods is growing rapidly. Furthermore, for those rivers fed largely by ice melt, reduction in glacier volumes will have a particularly strong impact on dry-season river flows, and on the provision of downstream water for hydropower, irrigation, and potable water supplies. In some regions, most noticeably in Pakistan, climate change will increase environmental, economic, and social vulnerability for tens of millions of people. While catastrophic floods (too much water too quickly) are a very palpable hazard, so too are "soft" threats, such as reduced glacier water during the dry season. Consequently, threats in high mountains must be considered in relation to water resource management and cannot be seen in isolation. As an example, in Peru, hazards associated with high altitude glacial lakes are being mitigated, using methods that control the lake water volume and ensure safe water reservoirs.

Marked changes in glacier extent due to climate change may be accompanied by both the formation and disappearance of ice- and moraine-dammed lakes, and steep hanging glaciers may become less stable. On the other hand, steep glacier tongues with their present-day potential for large ice avalanches could disappear. Revegetation of deglaciated terrain is slow and leaves morainic deposits unprotected against erosion over extensive time periods of several decades and more. On steep slopes, freshly exposed or thawing non-consolidated sediments can become unstable, resulting in debris flows and landslides of varying magnitudes. Once one event has occurred in a particular valley, the remaining slopes may become destabilized even further. In places of pronounced glacier retreat, changes in stress distribution and surface conditions of rock walls in deeply cut glacier troughs could induce large mass instabilities. The general tendency is thus toward a shifting of hazard zones with considerable changes in the processes involved and a widespread decrease in the stability of slopes. Special measures are needed to ensure the structural stability and durability of installations for tourism, transportation, and telecommunication in permafrost areas. Similarly, detailed hazard assessments must be undertaken routinely and regularly to avoid damage to hydropower installations due to the impact of glacier-derived floods, which can cost many tens of millions of Euros. With the evolvement of environmental conditions in high-mountain and polar regions beyond the range of historical variability, hazard assessments become increasingly difficult because estimates of hazard potential based on empirical data from the past (historical documents, statistics, geomorphological evidence) will not be directly applicable under new conditions.

Hazard assessment

Historical data on glacier and permafrost hazards can be used to test spatial models based on new earth-observation and geo-informatics techniques. Such modern methodologies provide powerful tools to assist hazard assessments in complex mountain or polar systems, which are experiencing increasing change and divergence from equilibrium conditions.

The assessment of glacier and permafrost hazards requires systematic and integrative approaches. Presently, the most successful strategy is based on the combination of remote sensing, modelling with geographical information systems (GIS), geophysical soundings, and other local field surveys. These methods are best structured in a downscaling approach from area-wide first-order assessments for systematically detecting hazard potentials (i.e., the domain of space-borne remote sensing and GIS techniques) to detailed ground-based or air-borne local investigations in high-risk areas (i.e., the domain of geophysics, surveying, and air-borne and close-range remote sensing).

The application of earth-observation techniques is particularly important for a number of reasons:

- Typically, related threat source areas are situated in remote regions, often difficult to access physically for topographic, political, and/or security reasons.

- The remote location of most threat sources, the potential process interactions and chain reactions, and the far reach of some of the threats require remote sensing sensors capable to cover large areas at once.
- Climate change induces disturbance in glacier and permafrost equilibrium and can shift hazard zones beyond historical knowledge. In addition, human settlements and activities increasingly extend toward endangered zones in many regions. As a result, historical data alone are not sufficient any more for hazard assessments and have to be combined with new observation and modelling approaches (see above).
- Due to the current rapid change of high-mountain environments, hazard assessments shall be undertaken routinely and regularly, combined with continuous monitoring. Remote sensing is particularly suited for both regular and rapid observation.

Air- and space-borne optical and microwave data can be applied to automatically classify glaciers, lakes, debris, and other terrain types relevant to glacier and permafrost hazards (Kääb et al., 2005a; Quincey et al., 2005; Kääb, 2008). Furthermore, some of this data can be used to derive digital terrain models (DTM), an invaluable prerequisite for analyzing hazard potential in high mountains and for related GIS-modelling. Even ice flow and terrain displacements can be measured with high accuracy from repeated remote sensing data. With these methods, the terrain cover, geometry, and dynamics of an area can be fully investigated without direct access. This can be especially beneficial in areas where the potential sources of glacial hazards lie in geopolitically unstable regions (e.g., Kashmir, Afghanistan) but where the principal impact zones lie significantly downstream. Remote sensing can also be of great use in assessing glacial hazards across international borders where glaciers in an inaccessible part of a country extend their impact into a neighboring country (e.g., China into Bhutan, India, and Nepal).

A further step toward an integrative hazard assessment consists in the application of GIS and other numerical models for simulating processes that are too complex or undetectable by remote monitoring. Glacier lake outburst floods, ice avalanches, or debris flows can be modelled with a GIS. Also, permafrost distribution, approximate ground-, firn-, and ice-temperatures, or various other terrain parameters that have an impact on natural hazards can be computed. Especially the fusion of remote sensing results with numerical process models provides a promising base for the assessment of hazard potentials.

A more detailed analysis of the hazard sources detected by remote sensing often involves ground-based methods. Geophysical investigations, employing electrical resistivity tomography and ground penetrating radar, in particular, have been used to develop three-dimensional maps of geological structures and have provided information on instability zones such as buried ice bodies within moraine dams, which could lead to breaches in the dam if the ice were to melt. Furthermore, the use of geophysical methods can provide information about the prevalent physical processes behind glacial and periglacial hazards and can lead to a better understanding of the behavior of natural dams and their potential to fail. Terrestrial surveying, using laser ranging or global positioning systems (GPS), is needed for accurate mapping and detection of terrain dynamics with high spatial and temporal resolution.

While many glacial and periglacial hazards may develop into major potential threats, if left unchecked, there are many examples in the Alps, in Nepal, Bhutan, and especially Peru, where lakes with high hazard potential have been remediated very successfully. The remote monitoring of changes in glacial lakes is crucial in order to help prioritize which lakes should be remediated first and when it would be most expedient.

Mitigation

Once a threatening situation is recognized and assessed, it might be necessary to undertake mitigation measures. Such measures can be *active* or *passive*, and *temporary* or *permanent.*

Typical *temporary passive* mitigation measures are to control and limit access to the endangered area, closing down infrastructure that brings people to critical areas, or to temporarily evacuate population living or staying in such areas. Typical *permanent passive* measures are land planning and hazard zoning that lead to, for instance, a permanent prohibition of building construction or access. The application and success of such passive measures depends a lot on specific regional socioeconomic factors, such as the civil protection, political, police, and legal system, culture, religion, economic dependencies, etc., that have to be taken into account when developing such measures.

Passive measures can be much less described in general terms but are rather very specific to the process and threat type. In general measures can be undertaken at the threat source and in the runout zone.

Ice fall and avalanches. In case of ice fall and avalanches, explosives might be used at the steep glacier for controlled triggering of impending events. In the runout zones deflection or retention dams can prevent an avalanche reaching critical zones. In case a potential ice avalanche would reach a river it might be useful to situate the river within the critical zone in a tunnel or tube in order to prevent the ice debris to dam up the river and cause a flood threat. In case a potential ice avalanche would reach an artificial or natural lake, where displacement waves could overtop the dam and cause an outburst, it might be necessary to temporarily or permanently increase the freeboard by lowering the lake level or heighten the dam, or to secure the dam in order to prevent erosion in case of dam overtopping (see below for lakes).

Glacial and periglacial lakes. The major goal at dangerous temporary or permanent glacial and periglacial lakes is to lower the lake level and reduce the lake volume.

This can be achieved by pumping or siphons. These measures are effective only for a limited time and are thus mainly used as rapid response or in order to prepare construction of more permanent measures. Such more permanent measures can be open channels and spillways, or tubes and tunnels either through the lake dam itself or through the surrounding bedrock or debris. Additionally, and possibly in combination with the above measures, parts of the lake can be filled up by debris and thus its volume reduced. Glacial and periglacial environments are very prone to, sometimes fast, changes such as lake changes or dam settlement. It is therefore crucial to integratively monitor the site, regularly control the functioning of the constructions, and possibly adapt the measures to environmental changes (Haeberli et al., 2001).

Lake outbursts in a glacial and periglacial environment often lead to debris flows due to the large amounts of erodible material available. Active permanent measures in the runout zone of a potential lake outburst can be deflection or retention dams. Channel constructions may prevent or reduce the bed erosion and debris uptake by the flood, or the flooding and inundation of surrounding terrain. Sediment traps can separate parts of the water and debris content of the debris flow. Reduction of the water content of a debris flows is an established measure to bring it to a stop.

Glacier advance. Few possibilities exist to mitigate threats related to a glacier advance. Endangered installations might be moved or changed, for instance converted from surface to subsurface type. The latter measures are, for example, applied in case of water intakes for hydropower purposes. In case a glacier advance increases the ice avalanche disposition or creates a dangerous lake, the above-listed measures can be necessary.

Periglacial debris flows. Few possibilities exist to remediate potential starting zones of periglacial debris flows, possibly influencing the ground thermal or hydrological regime. In the runout zone measures as listed above for debris flows from glacial lake outbursts are applied.

Rock fall/rock avalanches. Steel nets on parts of a rock face can prevent rock falls to break off. Explosives can be used to trigger rock avalanches of limited volume in a controlled way. The adverse effects of rock avalanches or combined ice-rock avalanches of limited size can be reduced by deflection or retention dams, and steel nets or barriers.

Summary and outlook

Threats related to glacier and permafrost are usually characterized by the involvement of surface or subsurface ice. As such they are highly sensitive to climatic changes and other changes in boundary conditions. Environmental changes can thus rapidly change hazard conditions. Furthermore, glacier and permafrost disasters are often characterized by complex and sometimes far-reaching process combinations and chain reactions. These can be particularly difficult to assess. These special challenges for the detection and management of glacier and permafrost threats require systematic and frequent observation and modelling work.

The expertise about handling of glacier and permafrost threats is worldwide highly scattered, among others due to the temporally and spatially highly scattered occurrence of the related disasters. An improved common understanding of such threats among involved scientists, civil protection agencies, and engineers should thus be a major aim of coordinated activities – on local, national, and international levels. Particularly little developed is the account for socioeconomic and cultural aspects of glacier and permafrost threats and their management.

NEGATIVE TEMPERATURE GRADIENT (IN ICE)

Rajesh Kumar
Remote Sensing Division, Birla Institute of Technology, Extension Center Jaipur, Jaipur, Rajasthan, India

When the temperature at the top layer of ice is lower than the temperature at the bottom layer, it creates a negative temperature gradient. The temperature gradient is a function of the depth of the snow and ice, and the temperature at the top and bottom of the snow and ice. The relationship of the variations of temperature with depth in snow and ice can be expressed as:

$$dT/dZ = (T_s - T_b)/Z$$

where T = temperature, T_s = surface temperature, T_b = bottom temperature, and Z = depth of the ice.

The ice is a good insulator to heat. The atmospheric cooling easily reduces the surface temperature of ice but it does not affect so easily the vertically downward profile of ice due to very less conductivity. Hence the upper surface has low temperature than bottom and creates negative temperature gradient. The rise in the temperature of the ice generally shows an exponential rate of increase with depth in glacier.

NEOGLACIATION

Rajesh Kumar
Remote Sensing Division, Birla Institute of Technology, Extension Centre Jaipur, Jaipur, Rajasthan, India

The neoglaciation is the Earth's climatic phase characterized by rebirth and/or growth of glaciers associated with a readvance of ice sheets between the postglacial phase and the present. It basically describes the cooling trend in the Earth's climate during the Holocene period. It has no well marked beginning but a period of general expansion of glaciers variously defined approximately as spanning from 3,000 to 2,000 years ago or covering the last 4,000–5,000 years.

The neoglaciation period was the return of cool moist condition from the warming of Holocene period. The cooling was accompanied by increased precipitation and moisture which helped in the renovation of the glaciers that had not existed since the last ice age.

Neoglaciation is also said to have started with the fluctuations of ice field in response to the climatic oscillations of the little ice age cycle. The most severe part of the neoglacial period seems to have been at its end, in the Little Ice Age. The neoglacial period is ending in present times and appears to be partially due to natural cycles and partially to man-made global warming.

NETWORK OF STAKES

Pratap Singh
Tahal Consulting Engineers Ltd, New Dehli, India

Snow stakes are used to determine the depth of snow accumulation in a basin. They are fixed at a representative site which can be easily inspected and read from a distance. Stakes represent a point value of snow depth. Snow stakes are used where a large accumulation of snow occurs. Stakes are painted white to minimize undue melting of snow in their immediate surroundings. Larger snow stakes, called aerial snow depth marker, are used for monitoring of snow depth using a low flying aircraft.

The variability of water equivalent and other associated parameters is established through a snow surveying network where stakes are installed. The network of stakes is designed in such a way that reliable index of water stored as snow over the entire basin is represented by the data obtained through the stakes. An appropriate network of stakes is also required for the mass balance studies of glaciers. For this purpose, stakes are installed over the glacier surface and read to know accumulation or depletion of snow over the glacier.

NEW ZEALAND GLACIERS

Wendy Lawson
Department of Geography, University of Canterbury, Christchurch, New Zealand

Definition

The *glaciers of New Zealand* are the valley and alpine glaciers of the mountain ranges of the tectonically active Southern Hemisphere mid-latitude island nation of New Zealand.

Overview

There are more than 3,000 glaciers in New Zealand – *Aotearoa*. Most of the glaciers are clustered in the Southern Alps of the South Island, in the latitudinal range of 42°–46° south, within a 100 km radius of *Aoraki* Mt Cook (3,754 m asl, Figure 1). In the North Island, there are a handful of rapidly retreating glaciers on the slopes of the active volcano Mt Ruapehu in the central volcanic plateau. A late twentieth

New Zealand Glaciers, Figure 1 The locations of glaciers of New Zealand (from McSaveney, 2009).

century glacier inventory reported that the 3,144 glaciers covered approximately 1,160 km^2, with a total ice volume of 53km^3 at that time (Chinn, 1989).

New Zealand's mid-latitude position and island topography is such that the glaciers are temperate, and the climate regime ultra maritime, characterized by high precipitation and very steep precipitation gradients. Annual precipitation exceeds 12 m in the wettest parts of the Southern Alps (Griffiths and McSaveney, 1983), and there is a strong west-east gradient of precipitation across the main divide, which in places is located within 35 km of the western coastline.

The best known, frequently visited, and most widely studied glaciers in New Zealand – the Franz Josef Glacier, the Fox Glacier, and the Tasman Glacier – share a basin boundary along the main divide of the Southern Alps, with the Franz and the Fox lying to the west of the main divide, and the Tasman to the east. The Tasman Glacier is the longest glacier in New Zealand, at 29 km in length, and its debris-covered tongue is rapidly retreating inside substantial late-glacial moraines. A rapidly enlarging lake that is currently more than 4 km long has formed in the last 20 or so years.

Mass balance of New Zealand's glaciers

Direct measurement of mass balance in New Zealand has been limited to short periods of study at individual glaciers. The most comprehensive direct record of mass balance to date is from the Ivory Glacier (43.13°S, 170.92°E), and was obtained between 1969 and 1975 when the Ivory was selected as New Zealand's glaciated representative basin for the International Hydrological Decade. Over those 6 years of measurement, the Ivory Glacier experienced dramatic retreat, lake formation at the terminus, and a cumulative negative mass balance of nearly 15 m w.e. (Anderton and Chinn, 1978).

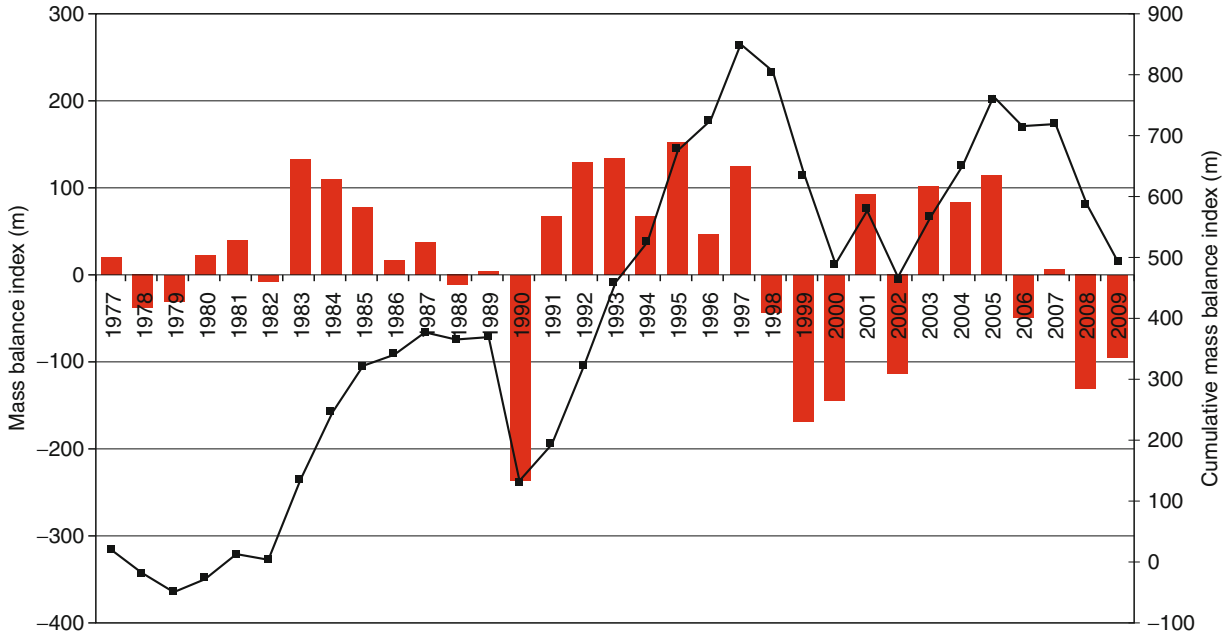
Most mass balance information in New Zealand is derived indirectly, based on an annual oblique aerial survey. This method yields proxy information on annual mass balance, in the form of an elevation difference between the annual end-of-summer snowline for a series of 50 index glaciers, and an assumed equilibrium line altitude (ELA_o) for each glacier (Chinn et al., 2005a). The method is affected by a series of uncertainties, not least of which is the assumptions necessary to determine ELA_o. Nevertheless, the value of the data has been recognized by the World Glacier Monitoring Service (WGMS, 2008).

For 21 of the last 33 years (1977–2009), the average mass balance for the 50 index glaciers inferred from this indirect method has been positive (Figure 2). The recent positive mass balances, like those of Scandinavia's coastal glaciers, are a result of precipitation delivered by increased westerly airflow associated with a change in the Interdecadal Pacific Oscillation (Chinn et al., 2005b). The predominantly positive mass balance state of New Zealand's in the last few decades follows a period of significant loss since the middle of the nineteenth century: between 1850 and 1977, for example, New Zealand glaciers lost 49% of their surface area (Hoelzle et al., 2007).

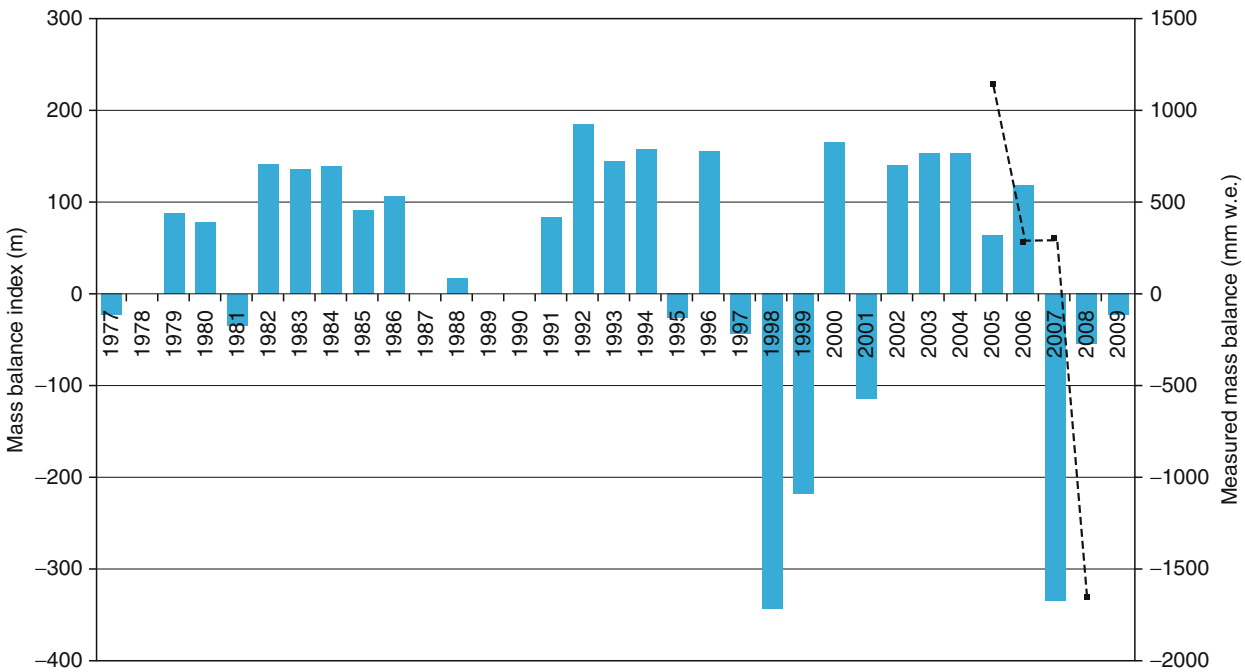
At the Brewster Glacier (44.05°S, 169.44°E), where mass balance has been measured directly since 2004, the results of direct measurements coincide in direction with the results of indirect analysis (Figure 3). In balance year 2005/2006, the Brewster Glacier was one of only 7 of the 104 WGMS glaciers that experienced positive balance (WGMS, 2008, 2009). A spatially distributed surface energy–balance model suggests that the temperature sensitivity of mass balance at the Brewster is −2.0 m w.e. $a^{-1}\,°C^{-1}$, one of the highest sensitivities reported globally (Anderson et al., 2010).

Franz Josef glacier Ka Roimata O Hine Hukatere

The Franz Josef Glacier is the best known of New Zealand's glaciers to scientists and tourists alike, with 100s of tourist walking on the glacier each day during the summer months. The Franz Josef Glacier is 11 km long, 35 km^2 in area, and ranges in elevation from 2,900 m asl to a few hundred meters asl (Figure 4). Annual rates of ablation at the terminus can reach 20 m w.e., and annual accumulation lies in the range 4–8 m w.e. in the upper



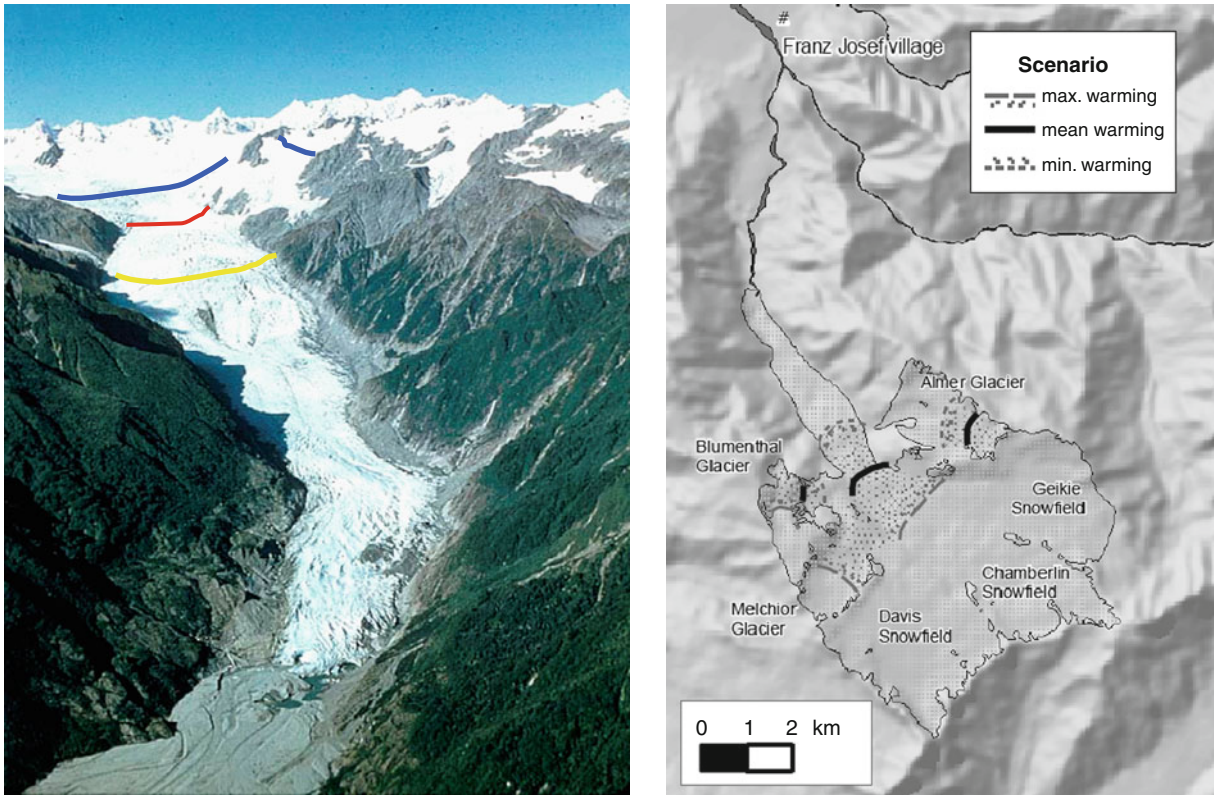
New Zealand Glaciers, Figure 2 Annual mean mass balance index and cumulative mass balance index for 50 index glaciers in New Zealand 1977–2009. The mass balance index is the difference in elevation between the ELA and the end-of-summer snowline, where positive values indicated positive mass balance.



New Zealand Glaciers, Figure 3 Mass balance index and directly measured mass balance for the Brewster glacier 1977–2009.

glacier, although up to 15 m w.e. of precipitation may be received (Anderson et al., 2006).

Between 1894 and 2005, the Franz Josef Glacier lost mass at an annual rate of 0.02 m a^{-1} w.e.. Between 2000 and 2005, the annual mass balance ranged from −0.75 to +1.5 m w.e., with only one of those years (2000/2001) experiencing negative balance. Modeling indicates that the climate sensitivity of mass balance at Franz Josef is −1.9 m w.e. a^{-1} $°C^{-1}$ (Anderson et al., 2006), and that regional climate change under a mean warming scenario



New Zealand Glaciers, Figure 4 Franz Josef Glacier Ka Roimate o Hine Hukatere, showing the approximate location of the terminus in 2100 under various warming scenarios (Source: diagram on *right* Anderson et al., 2008). In the photograph on the *left*, the *blue*, *red*, and *yellow lines* indicate the position of the terminus under maximum, mean, and minimum warming scenarios, respectively.

will cause terminus retreat of 5 km and mass loss of 40% by 2100 (Figure 4; Anderson et al., 2008).

Temperature exerts a stronger control than precipitation at the Franz Josef Glacier at a range of timescales (Anderson et al., 2006, Anderson and Mackintosh, 2006). The increase in glacier extent necessary to form the well-known Waiho Loop moraine (~13,000 year b.p.), which is 10 km downstream of the current glacier terminus, requires a cooling of 3–4°C. It is possible, in this highly tectonically active environment, that non-climatic factors have an important role in historical changes in extent of the Franz Josef Glacier (Tovar et al., 2008).

Summary

New Zealand's glaciers contain a relatively small volume of ice, but are highly sensitive to climate, with modeling suggesting some of the highest temperature sensitivities of the global glaciers. Proxy data indicate that the glaciers have experienced positive mass balance for most of the last 4 decades because of increasingly westerly air flow. Comparable environments are found in western Scandinavia, and Patagonia. The tectonically active landscape in New Zealand means that non-climatic factors also have a significant influence on terminus behavior.

NICHE GLACIER

D. P. Dobhal
Wadia Institute of Himalayan Geology, Dehradun, Uttarakhand, India

Niche glaciers are very small in size. Such glaciers occupy gullies and hollow on the slopes and appear as little more than large snow fields. They do not make image of a typical glacier. A niche glacier may develop into a corrie/cirque glacier if conditions are favorable, and it is common in glaciated areas to finds small niche glaciers between larger corrie/cirque glaciers.

NORMALIZED-DIFFERENCE SNOW INDEX (NDSI)

Dorothy K. Hall[1], George A. Riggs[2]
[1]Crysopheric Sciences Branch, Code 614.1, NASA/Goddard Space Flight Center, Greenbelt, MD, USA
[2]SSAI, Lanham, MD, USA

Definition

Normalized-Difference Snow Index (NDSI) – normalized difference of two bands (one in the visible and one in the near-infrared or short-wave infrared parts of the spectrum) is used to map snow. Snow is highly reflective in the visible part of the EM spectrum and highly absorptive in the near-infrared or short-wave infrared part of the spectrum, whereas the reflectance of most clouds remains high in those same parts of the spectrum, allowing good separation of most clouds and snow.

Introduction

The NDSI has a long history. The use of ratioing visible (VIS) and near-infrared (NIR) or short-wave infrared (SWIR) channels to separate snow and clouds was documented in the literature beginning in the mid-1970s by Valovcin (1976, 1978) and also by Kyle et al. (1978). A considerable amount of work on this subject was conducted at, and published by, the Air Force Geophysics Laboratory (AFGL) (e.g., see Bunting and d'Entremont, 1982). The objective of the AFGL work was to discriminate snow cover from cloud cover using an automated algorithm to improve global cloud analyses. Later, automated methods that relied on the VIS/NIR ratio were refined substantially using satellite data, by Crane and Anderson (1984), Dozier (1989), and Rosenthal and Dozier (1996) for regional scales, and by Riggs et al. (1993), Hall et al. (1995, 2002), and Hall and Riggs (2007) for global snow-cover mapping. In this section, we provide a brief history of the use of the NDSI for mapping snow cover.

Band ratios used to discriminate snow and clouds

Results of an investigation of snow reflectance characteristics using data from Skylab Earth Resources Experiment Package (EREP) S192 multispectral scanner are presented by Barnes and Smallwood (1975). For the first time, satellite study of snow from the spectral range extending from the VIS to the IR (0.41–12.5 μm) was possible, and this paved the way for automated snow-cover mapping. Shortly thereafter, Valovcin (1976) at AFGL introduced the idea of using the ratio of radiance values in the VNIR (0.68–0.76 μm) and NIR or SWIR (1.55–1.75 μm) to provide a method to discriminate between snow cover and clouds. Kyle et al. (1978) used the ratio of the 1.6–0.754 μm channels to distinguish snow and clouds using a cloud physics radiometer with 0.754–1.64 μm channels. They also used an IR band to test for surface temperature further distinguished snow and clouds.

Additional work done at AFGL by Bunting and d'Entremont (1982) employed a 1.6 μm sensor flown on the Defense Meteorological Satellite Program (DMSP) Special Sensor C (SSC) to separate snow and clouds. They also used 11% reflectance to define the lower bound of reflectance for snow cover. Crane and Anderson (1984) reviewed the previous work, mainly conducted at AFGL, and employed the DMSP Operational Linescan System (OLS), which operated in the 0.4–1.0 μm and 8–13 μm range, along with SSC data (1.51–1.63 μm). They

employed reflectances derived from the various sensors to map snow using a threshold technique.

More-sophisticated use of band ratios as applied with Landsat Thematic Mapper TM data was developed by Dozier (1987, 1989). The normalized difference of TM bands 2 (0.52–0.60 μm) and 5 (1.55–1.75 μm) was introduced in Dozier (1989). Dozier and Marks (1987) discuss automated snow mapping and threshold tests for shadowed snow, cloud, vegetation, and soil in sunlit areas.

With the anticipated launch of the Moderate Resolution Imaging Spectroradiometer (MODIS) at the end of the 1990s, a global snow-mapping algorithm needed to be developed that would perform automatically and not be computationally intensive. Using the heritage algorithms discussed above, Hall et al. (1995) coined the term normalized-difference snow index and outlined a snow-mapping algorithm that would be the basis of the MODIS standard snow-mapping product. The prototype algorithm, called Snowmap, used a normalized difference between MODIS band 4 (5.45–5.65 μm) and 6 (1.628–1.652 μm), as was done in Bunting and d'Entremont (1982), Crane and Anderson (1984), and Dozier (1989) using TM bands 2 and 5. The prototype MODIS algorithm also employed several spectral tests. A planetary reflectance $\leq$11% was a threshold test in which values $<$11% were mapped as "not snow," determined not to be snow.

The prototype MODIS snow-mapping algorithm was improved with additional spectral tests. One key modification is that the NDSI threshold was changed in forested areas based on results of a canopy reflectance model (Klein et al., 1998), using both the Normalized Difference Vegetation Index (NDVI) and NDSI in densely forested areas as determined from the NDVI test. A thermal mask was also included to remove erroneous "snow" in locations where snow is considered to be impossible. Small specks of erroneous snow that show up on an image may be due to sand. If the band 31 (10.780–11.280 μm) temperature is >283 K, then a pixel is considered "not snow." This type of thermal test of surface temperature had previously been used by Kyle et al. (1978) and Romanov and Gutman (2000). The standard MODIS cloud mask is also employed as an input to the snow algorithm.

Following the 1999 launch of the MODIS on the Terra spacecraft, the snow algorithm was modified several times, but the NDSI has remained the basis of the algorithm. The current algorithm is Version 005 (see Riggs et al., 2006).

Summary

The term normalized-difference snow index (NDSI) was coined by Hall et al. (1995), but the NDSI technique already had nearly a 20-year heritage as similar methods using various visible and near-infrared bands had been used since the mid-1970s to map snow and separate snow from most clouds. Following the launch of the MODIS in 1999, the NDSI approach to mapping snow cover became automated using an algorithm that utilizes the NDSI along with a variety of threshold tests.

NOVAYA ZEMLYA

Chris R. Stokes
Department of Geography, Durham University, Durham, UK

The Russian islands of Novaya Zemlya ("New Land") are situated in the *Arctic* Ocean between 70.5–77°N and E51–69°E. There are numerous small islets but the archipelago primarily consists of the South (Yuzhny) and North (Severny) Islands, separated by the narrow Matochkin Strait. They form an elongated arc stretching for almost 1,000 km and narrowing from 150 km in the southwest to 40 km in the northeast. Geologically, they are a northern extension of the *Ural Mountains*, characterized by a rugged terrain (maximum elevation: 1,547 m above sea level) and with large parts of the coastline incised by *fjords*. They represent a major orographic barrier between the Barents Sea to the west and the Kara Sea to the east.

The archipelago covers an area about of 90,000 km^2 of which ~24,400 km^2 is covered by *glacier ice* (Dowdeswell and Williams, 1997), dominated by a large *ice cap* on the North Island. The Catalogue of Glaciers of the USSR (Kotlyakov, 1978) lists 685 glaciers, most of which are relatively small *mountain/cirque glaciers*. There are, however, 60–70 large *tidewater glaciers* that drain the *ice caps* and *ice fields* in the north and *calve icebergs* along both the east and west coasts. Further south, smaller glaciers terminate at much higher elevations. Indeed, glacier *equilibrium line altitudes* (ELA), which broadly range from 300 to 700 m a.s.l., increase from north to south, concomitant with an increase in mean annual temperature of ~5°C (Kotlyakov, 1978; Zeeberg and Forman, 2001). ELAs also increase in a west-to-east direction, reflecting a decrease in precipitation away from the more maritime climate of the Barents Sea, which is heavily influenced by advection of warm North Atlantic water. *Sea ice* is also less persistent along the west coast, which can remain ice-free for much of the year. Interestingly, the different climatic regimes appear to influence the location *surging glaciers*, which are far more common in the west (Grant et al., 2009).

In the past, ice extent on Novaya Zemlya has been far more extensive. During the *Last Glacial Maximum*, for example, the archipelago was covered by the Barents Sea *Ice Sheet* (Svendsen et al., 2004). Following its *deglaciation* by the early Holocene (~9,500 cal year BP), there was a period of relatively high sea level between 7,500 and 6,000 cal year BP that created shorelines ~13 m above the present coastline (Forman et al., 1999). More recently, several relatively minor glacier fluctuations have taken place, with the latest readvance linked to "Little Ice Age" cooling in the second half of the nineteenth century (Zeeberg and Forman, 2001). Subsequent warming during the first half of the twentieth century resulted in rapid glacier recession (>300 m a^{-1}: Zeeberg and Forman, 2001). Perhaps surprisingly, mean annual temperatures appear to have decreased in the latter half of the twentieth century and, in addition to increased winter precipitation, some glaciers are thought to have stabilized, whereas others have continued to retreat (Zeeberg and Forman, 2001). However, more recent data from a sample of 692 glaciers suggests that widespread retreat has occurred in response to a marked increase in summer temperatures since the 1980s (Grant, 2010).

NYE (N) CHANNELS

D. P. Dobhal
Wadia Institute of Himalayan Geology, Dehradun, India

N-channels are the product of discrete or consolidated base flow which transports large volumes of meltwater. It is basically a subglacial melt water channel. Subglacial meltwater flow can occur in distributed or discrete system, and it includes sheet flow or linked cavity network. Nye channel cuts into bedrock or consolidated sediments and leaves the imprint on the land surface once the glacier is retreated.

O

OGIVES

Divya Dudeja
Department of Geology, DBS College, Dehradun, Uttarakhand, India

Synonyms

Alaskan bands; Forbes bands; Wave ogives

Ogives are surface features exposed on the surface of glaciers as repetitive dark and light arcs or waves. They are regarded as the indicators of glacier flow. Ogives attracted the attention of glaciologists in the mid-nineteenth century, when the fundamentals of glacier flow were first being established.

Ogives are of mainly two types: wave ogives and band/concealed ogives. In wave ogives, alternate light and dark bands are thick in width having wave-like structure and are convex in downflow side. Such wave ogives are observed in Sunder Bamak glacier, a tributary of Chatrungi Glacier of Uttarakhand, India (Raina and Srivastava, 2008). Concealed/band ogives have alternate dark and light bands in the shape of semicircular ring, instead of wavy structure. Similar to wave ogives, they also show convexity in the direction of glacier flow.

OPTICAL REMOTE SENSING OF ALPINE GLACIERS

Duncan J. Quincey[1], Michael P. Bishop[2]
[1]Institute of Geography and Earth Sciences, Penglais Campus, Aberystwyth University, Aberystwyth, Wales, UK
[2]Department of Geography and Geology, University of Nebraska-Omaha, Omaha, NE, USA

Definition

Optical remote sensing. The measurement of surface reflectance in the visible, near-infrared, middle-infrared, and thermal-infrared regions of the electromagnetic spectrum.
Spatial resolution. The effective ground dimensions in meters (x,y) of each picture element (pixel) within a remote sensing image.
Spectral resolution. The ability of a sensor to detect fine spectral differences.
Image classification. The labeling of pixels within a remote sensing image into a thematic scheme (e.g., land cover), usually based upon their spectral reflectance characteristics.
Stereo-pair. A pair of remote sensing images of the same ground area, acquired from different satellite or aircraft positions, from which elevation data can be extracted.
Orthorectified. A planimetrically correct image (i.e., with geometric and topographic distortions removed).

Introduction

Concerns over greenhouse-gas forcing and warmer temperatures have prompted investigations into climate forcing and Earth-system responses. There is considerable scientific debate regarding climate forcing and system response, as complex geodynamics regulate feedback mechanisms that couple atmospheric, geologic, and hydrologic processes. A significant component in the

Vijay P. Singh, Pratap Singh & Umesh K. Haritashya (eds.), *Encyclopedia of Snow, Ice and Glaciers*, DOI 10.1007/978-90-481-2642-2,

coupling of Earth's systems involves the cryosphere, as glaciological processes govern atmospheric, hydrospheric, and lithospheric responses (Meier and Wahr, 2002). Consequently, scientists have recognized the significance of understanding glacier fluctuations and their use as direct and indirect indicators of climate change.

The international scientific community is actively engaged in assessing ice sheet and glacier fluctuations at the global scale (Bishop et al., 2004; Kargel et al., 2005). Glaciological, remote sensing, and geographic information system (GIS) studies indicate that recent glacier retreat and wastage appear to be global in nature (Dyurgerov and Meier, 2005; Paul et al., 2004a). It is essential that we identify and characterize those regions that are changing most rapidly and that are having the most significant impact on sea level, water resources, economics, and geopolitics. Many regions have not been adequately studied, however, and detailed information on the number of ice masses, land-ice distributions, glacier-length changes, ice-volume changes, glacier sensitivity to forcing factors, mass balance, dynamic response time, ice-flow dynamics, and other important glaciological parameters and processes are required to better understand climate forcing and climate-glacier fluctuations.

Optical remote sensing data have provided information on alpine glaciers (Alpine) and how they have changed for more than 30 years, first through the use of aerial photography and, later, satellite sensors. Early satellite sensor imagery was limited by its coarse *spatial* and *spectral resolutions*, but as sensor technologies advanced, image data became increasingly detailed, and information extraction techniques and approaches evolved to generate an ever-increasing amount of land surface information. Contemporary satellite sensor measurements are commonly made at spatial resolutions comparable to aerial photographs but with wide swaths, on a repeat basis, and across many narrow spectral bands, offering quantitative biophysical information about the glacial environment that may not be available through field investigation alone. Fieldwork measurements can be further limited in high-mountain areas by their remoteness, harsh conditions, and, occasionally, restricted access for political reasons. Satellite remote sensing has therefore become an essential part of alpine glacial studies.

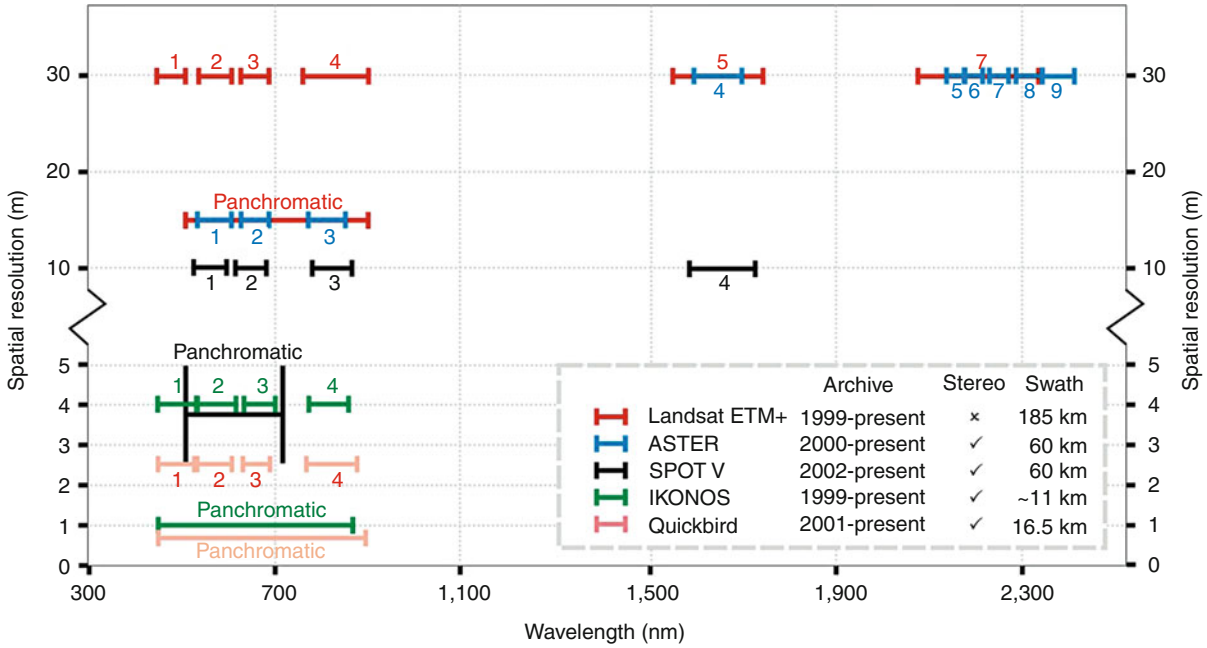
The availability of new satellite data, however, does not directly translate into accurate information extraction. There are numerous techniques and approaches that can be used to extract quantitative and thematic information, but the issue of producing accurate high-quality information is very dependent on the choice of algorithms and the analytical approach. Problems exist in ensuring the quality of input image data, as the level and exact nature of preprocessing is often not transparent. In addition, processing protocols have not been established, and many techniques are un-validated, meaning results can vary widely between analysts, even when employing the same data. Despite these information extraction issues, remote sensing has provided some of the greatest advances in our understanding of alpine glacial processes at a range of spatial scales, contributing to predictions of global sea-level rise (Meier et al., 2007), regional assessment of water resources (Singh and Bengtsson, 2005), and local monitoring of glacial hazards (Huggel et al., 2005).

We provide an overview of such advances and discuss the key optical remote sensing instruments and their characteristics that are of relevance in alpine glacier studies. Specifically, we present details of how remote sensing can be routinely used to analyze glacier areal fluctuations, the distribution of surface features and structures, glaciers flow rates, the degree to which they are melting or accumulating mass and, given atmospheric warming, the increasing emergence of glacial hazards. With issues of data quality and measurement accuracy in mind, we also summarize some of the major issues and concerns in remote sensing of alpine glaciers.

Optical remote sensing – key instruments for alpine glacier measurements

Optical remote sensing is defined as the measurement of surface reflectance at optical wavelengths, specifically at visible (0.4–0.7 μm), near-infrared (0.7–1.3 μm), shortwave infrared (1.3–3.0 μm) and thermal infrared (3.0–14.0 μm) wavelengths. Early satellite sensors collected measurements in a limited number of discrete spectral ranges that were characterized by coarse *spatial and spectral resolution*, such that small features on the ground were not discernible and broad wavelength ranges generalized spectral reflectance measurements. For example, the Landsat Multispectral Scanner (MSS) was one of the earliest satellite sensors available for nonmilitary purposes, and measured reflectance in the green, red, and near-infrared (two bands) regions of the electromagnetic spectrum, at 68 m × 82 m spatial resolution. Modern day satellite sensors collect data in many more, and narrower, spectral bands, and at increasingly fine spatial resolution. Some satellite sensors (e.g., Quickbird) even offer imagery at a spatial resolution comparable to aerial photography (<1 m), but generally with less spectral information than those coarser spatial resolution sensors.

A number of key optical sensors are useful for alpine glacier studies (Figure 1). The Landsat series of sensors provides a long archive of images acquired at various spatial resolutions (15–60 m), which since early 2009, have been available free of charge through the United States Geological Survey (USGS; http://www.glovis.usgs.gov). A similarly long archive of data is available from the Systeme pour Observation de la Terre (SPOT) series of sensors, with spatial resolution improving with time; currently, 2.5 m resolution images are available for most alpine areas. The data archive is available to browse at http://www.sirius.spotimage.fr and academic institutions can gain access to reduced cost imagery through the ISIS scheme (http://www.isis-cnes.spotimage.fr). Since 2000, the Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) has measured surface



Optical Remote Sensing of Alpine Glaciers, Figure 1 Key satellite sensors operating at optical wavelengths and commonly used in glaciological studies.

reflectance in 14 bands throughout the visible and infrared wavelengths, with a second sensor pointing backward to acquire a *stereo-pair*, facilitating the extraction of digital elevation data. ASTER data may be purchased through the Earth Remote Sensing Data Analysis Center (ERSDAC) at http://www.gds.aster.ersdac.or.jp, or acquired free of charge under a recognized researcher agreement with NASA. Most alpine glacier studies make use of one or more of these image sources because of their comprehensive archives, their low cost relative to other sensors, and the detailed information content they provide, which is well suited for assessing the surface characteristics of small to large glaciers.

As with ASTER, a number of other satellite sensors collect *stereo-pairs*, which can be used to extract the surface elevation value of every pixel in the image. The resulting image, which represents the surface topography (altitude field) of the area covered by the stereo-pair, is called a Digital Elevation Model (DEM; Digital Elevation Model Generation Over Glacierized Region). The process of deriving surface elevation data from satellite imagery in this way relies on recreating the geometry between the sensor and the terrain at the exact time of image acquisition. The user supplies approximate data relating to the aircraft location and the average terrain height above sea level in addition to accurate statistics on the camera geometry and image dimensions. Using "least squares" regression, it is possible to reduce the errors in the approximations and arrive at a stereo model that realistically represents the position and orientation (in three dimensions) of the sensor(s) at the time(s) of image acquisition. In much the same way that humans generate three-dimensional perspectives using information from both eyes, a spatial ray is generated from the first image that intersects in three dimensions with the corresponding point on the second image, thus giving a surface elevation value for each modeled pixel. The errors associated with producing DEMs from satellite imagery can be quite high; however, an increasing number of studies are therefore employing elevation measurements made by laser altimeter (see, for example, http://www.csr.utexas.edu/glas). These data, which are extremely accurate but currently limited in swath width, promise to be of great benefit to geomorphology and glaciology as they become more widely available.

Deriving glacier characteristics

Glacier outlines (debris-covered and non-debris covered)

Perhaps the most basic information that is required for assessing alpine glaciers is their spatial extent and the nature of temporal fluctuations. Its primary applications are in the local- to regional-scale measurement of glacier fluctuations in response to climatic warming, and in the regional- to global-scale mapping of ice and snow distributions for inclusion in global databases, with which both past and future comparisons can be made (Inventory of Glaciers; World Glacier Inventory (WGI): http://nsidc.org/data/g01130.html; Global Land Ice Measurements from Space (GLIMS): www.glims.org; and GlobGlacier: http://globglacier.ch).

The distinct spectral properties of snow and ice permit accurate semiautomatic delineation of debris-free glaciers using a variety of techniques. A simple example is using thresholded ratio images from Landsat TM bands 4 and 5 (TM4/TM5), as topographic effects (Topographic Normalization of Multispectral Satellite Imagery) are reduced, which facilitates mapping. Classification of debris-covered ice is more complex however (Bishop et al., 2001; Paul et al., 2004b), because of the spectral similarities between the supraglacial debris cover and the rocks and sediment in the ablation and proglacial valleys. This issue has often been addressed by using manual digitization as the predominant technique for delineating the glacier boundary for small samples.

It is important to note that the use of traditional statistical-based *image classification* algorithms to classify glaciers rely upon the concept of statistical separability in *n*-dimensional feature space to be able to distinguish between classes. In general, it is difficult to effectively utilize multispectral imagery and spectral features to permit spectral differentiation. Consequently, researchers are investigating other classification algorithms, which are based on fuzzy logic, and can incorporate inaccurate sensor measurements, vague class descriptions, and imprecise modeling into the analysis, by assigning values to each pixel representing the pixel's degree or probability of membership in each class. This method removes a large part of the error associated with mixed pixels, but does not necessarily provide a solution to distinguishing between spectrally identical materials. Artificial intelligence techniques such as neural networks and expert systems can also be employed, although researchers have recognized that additional information such as geomorphometric land surface parameters, texture, context, and spatial topology must be utilized (Bishop et al., 2001, 2004; Paul et al., 2004b). It is widely recognized that many approaches are empirical and require thresholding, which may not be universally applicable, and also require manual editing to ensure a satisfactory level of accuracy.

Several approaches can be used to address this problem that range in levels of sophistication and accuracy. Paul et al. (2004b) proposed an approach that followed five major steps: (1) the identification of clean ice using a TM4/TM5 ratio; (2) the classification of vegetation-free areas using the hue component of an intensity-hue-saturation image transformation; (3) the identification of flat ($<24°$) terrain, characteristic of low-angle debris-covered glacier tongues; (4) the removal of noise using a median filter; and (5) the removal of all pixel clusters not connected to classified clean ice. The authors concluded that the method could be rapidly applied to hundreds of glaciers, and that the accuracy obtained can be equal to pixel resolution (Figure 2).

Bishop et al. (2001) developed an automated approach that makes use of geomorphometry and object-oriented analysis of land surface parameters such as terrain slope angle, slope azimuth, curvature, and relief to diagnostically map and delineate debris-covered glaciers. They were able to accurately delineate the ablation zone of the heavily debris-covered Raikot Glacier in the Nanga Parbat Himalaya. Terrain-object properties were found to be diagnostic of glacier processes representing glacierization, thereby differentiating glacier topography from other surfaces governed by other surface processes. The approach has tremendous potential although it requires the use of high-quality DEMs, which may not always be available.

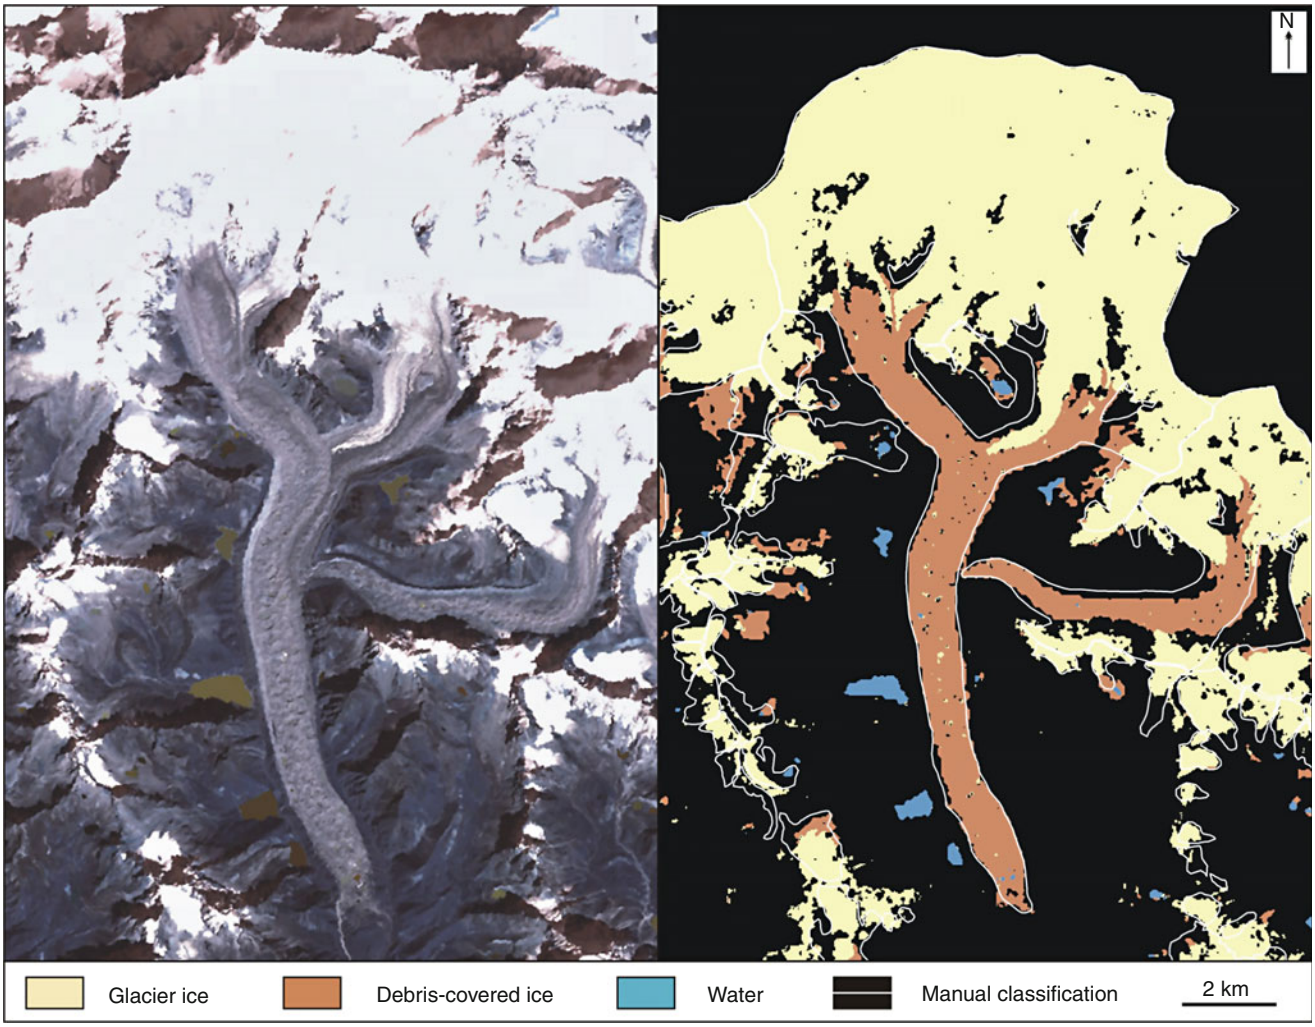
In general, studies of changes in alpine glacier extent indicate accelerated decline in recent decades, although glaciers in some regions of the world have been expanding (Hewitt, 2005). Small glaciers are disappearing, and in many places around the world large glaciers are fragmenting into a number of smaller glaciers. Recession has been shown to be particularly strong in the European Alps, where glaciers between 0.1 and 1 km^2 in area comprise approximately 25% of all glacierized area (Kääb et al., 2002). Here, wastage has been particularly strong since the 1970s, with a reduction in glacierized area of 22% from 1973 to 1999 being measured using digitized inventory data and Landsat TM imagery, respectively. Measurements of change in glacier area are not always representative of glacier recession, however, as the extent may remain relatively constant even though down-wasting (surface lowering) is rapidly occurring. This is the case with many debris-covered glaciers of Central and eastern Asia, where surface lowering is the major symptom of wastage, and multi-temporal measurements of surface topography (Glacier Elevation Changes) can give the most accurate indication of recession rates (Bolch et al., 2008).

Glacier geomorphology

Mountain topography is the result of complex interactions involving tectonism, climate, and surface processes. Glacier geomorphology refers to the influence of glaciers and glacier processes on landform development and landscape evolution (Evans, 2006). Mapping and assessing landforms and erosion in mountain environments is essential in order to understand landscape denudation and complex feedback mechanisms (Bishop et al., 2003).

Satellite imagery and digital elevation models can be used to obtain information about landforms, erosion potential, and tectonic impact on the topography. Traditional geomorphological mapping is conducted in the field, using an *orthorectified* satellite image or aerial photograph as a base layer, to aid interpretation and to provide a spatial reference for observations made in the field. The choice of scale and level of detail may be restricted by the spatial resolution of the base layer, which may also determine the locational accuracy of features placed on the resulting map. As a rule of thumb, the geomorphologist working on a 1:10,000-scale base should aim for a locational accuracy of 1 mm on the map, equivalent to 10 m on the ground.

With the advent of GIS, it is possible to conduct terrain analysis to segment the topography into functional units (e.g., drainage basins), generate a drainage network, and map a variety of glacial features and landforms (e.g., ice



Optical Remote Sensing of Alpine Glaciers, Figure 2 Semiautomatic classification of the Ngozumpa Glacier, Nepal Himalaya, following the method of Paul et al. (2004b).

cliffs, medial moraines, and lateral moraines). Terrain analysis combined with multispectral image analysis permits an assessment of the surface biophysical conditions. Hypsometric analysis of the topography and other geomorphometric techniques (see below) can facilitate an assessment of landscape dissection and erosion, thereby depicting the influence of glacial erosion in relation to relief production. Research indicates that glacier erosion reduces relief at intermediate altitudes, although the hypsometric integral may be relatively low. Other surface processes such as river incision and mass movement increase local relief and generate a relatively low integral value. Furthermore, object-oriented analysis of the morphology of drainage basins and valley profiles reveal those portions of the landscape that currently exhibit rapid uplift rates. Collectively, this information generated from satellite imagery permits geomorpholgical assessment and evaluation of the polygenetic nature of landscape evolution.

Glacier geomorphometry

Glacier geomorphometry refers to the three-dimensional topographic characteristics of the glacier surface including its size, shape, hypsometry, orientation, and position. Numerous geomorphometric parameters govern microclimatic conditions and have been shown to influence glacier fluctuations (Gellatly et al., 1986; Warren, 1991), ELA positions (Equilibrium-Line Altitude (ELA)) on a subregional scale (Allen, 1998), ablation rates, velocity gradients, supraglacial lake development, and possibly glacier surging (Barrand and Murray, 2006; Glacier Surging). Consequently, geomorphometric analysis is fundamental for understanding glacier form–process relationships and estimating glacier mass balance.

Digital elevation models of a glacier surface can be generated using terrestrial laser-scanning equipment; however, DEMs derived from airborne and satellite sensors are critical for synoptic coverage. Geomorphometric

analysis can be used to generate a large number of glacier surface parameters, although the accuracy of these parameters is dependent on the accuracy and level of detail represented in the DEM. Accuracy and uncertainties are governed by the image sources (aerial photography and satellite imagery) used to derive the DEM, as well as the quality of the input ground control and tie-point data. Land surface parameters can be used for glacier mapping, or as input into numerical models to simulate glacier dynamics.

Quantifying surface dynamics

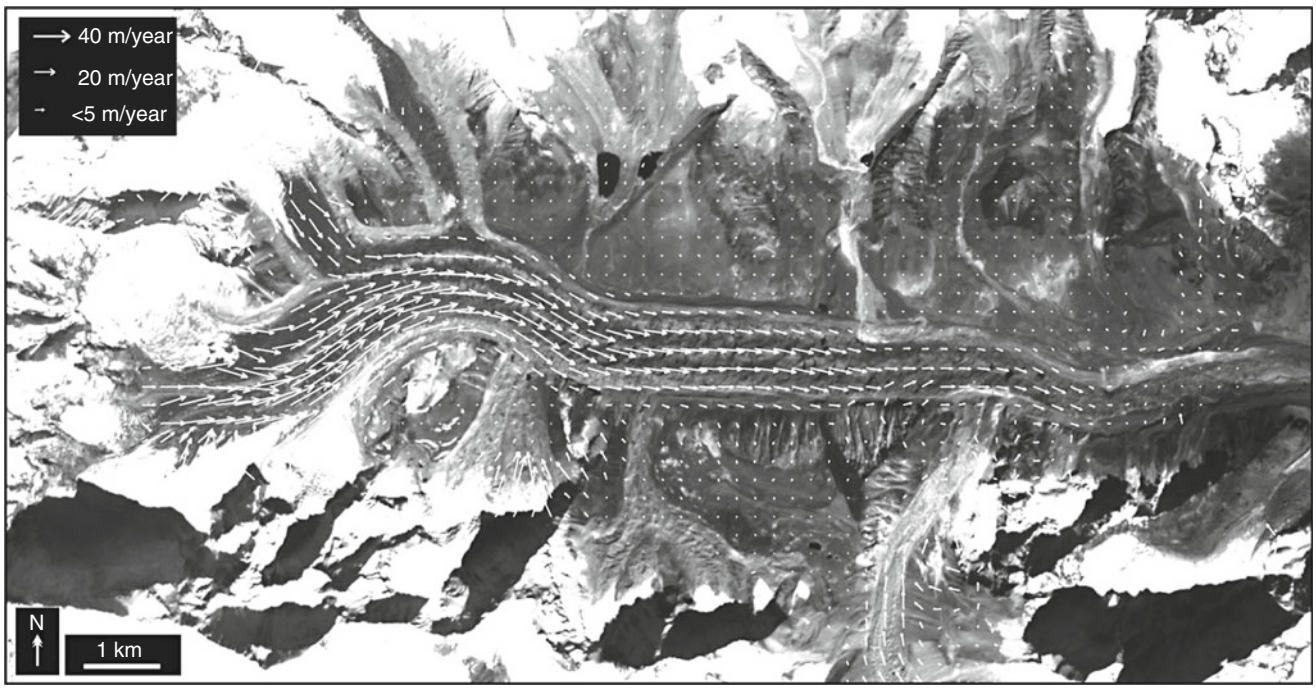
Glacier ice-flow velocity fields

Multitemporal aerial and satellite imagery are useful for detecting glacier surface changes and the movement of surface features caused by ice flow. Although the surface ice-flow speed of a glacier is not, strictly speaking, the same as glacier velocity (ice velocity profiles change significantly with depth (Glacier Motion/Ice Velocity)), it provides a useful surrogate for velocity where detailed field investigations are not possible. Early measurements of surface velocity were made using co-registered optical images and measuring the displacement of prominent features (e.g., large boulders, crevasses, and supraglacial ponds) over the imaged period, by hand. This resulted in a sparse, point-based velocity field, derived with a maximum accuracy of ± 1 pixel.

Improved methods for co-registering multi-temporal data and increased computational power has led to the emergence of automated feature tracking, which relies on the same fundamental principle as manual feature tracking – the identification of the same feature across an image pair – but provides a dense coverage of matched features with a reported sub-pixel accuracy (Scherler et al., 2008; LePrince et al., 2007; Figure 3). The first stage in feature tracking is to finely co-register the two images. This is achieved by selecting features known to be stationary (e.g., bedrock outcrops) and matching the images to sub-pixel accuracy using cross-correlation only in these stationary areas. In this way, ground control for zero velocities is provided, against which glacier movement can be compared, and velocities retrieved from stationary areas can provide a measure of error associated with the technique. Subsequently, cross-correlation is applied to the whole image (i.e., to both stationary and nonstationary areas). Robust correlations are accepted on the strength of their signal-to-noise ratio and by rejecting matches in regions of shadow. Errors in the technique arise from changes in the crevasse patterns through time and space, geometric transformations of the data, and errors in zero displacement reference points. The longer the time delay between images, the lower the error related to measured displacement but the larger the error in finding an exact match for a surface pattern that may have changed through time.

Glacier elevation changes

Many alpine glacier snouts are partially or completely debris-mantled (Debris-Mantled Glacier Snouts), and



Optical Remote Sensing of Alpine Glaciers, Figure 3 Glacier velocity field for the Kangshung Glacier, Nepal Himalaya, using multi-temporal ASTER imagery from October 2004 and December 2005.

sustained periods of negative mass balance result in extensive down-wasting and stagnation of low elevation glacier tongues. In such cases, frontal recession can be a poor indicator of glacier health, and measurements of volumetric change are thus required. Multi-temporal DEM data have been widely used to make assessments of glacier surface lowering (or thickening) and, consequently, calculations of mass wastage (or accumulation).

A major difficulty in using stereo satellite imagery to generate elevation data over glacier surfaces is that snow and ice often do not provide sufficient spectral variation to correlate image pairs. In such areas, the automatic extraction of elevation data can fail, or be subject to large error. Debris-covered glaciers normally exhibit a wide range of features on which tie points can be placed, but again problems can occur in accumulation areas where snow and ice make the surface cover homogeneous. Such problems can often be overcome by employing imagery acquired toward the end of the ablation season, when snow cover is at a minimum, and by choosing low-sun illumination angles, to enhance the sensitivity of the reflectivity to micro-topography (Berthier and Toutin, 2008). Large errors can also occur on sharp mountain peaks with steep slopes, narrow moraine ridges, and deep stream channels (Kääb, 2002), but can often be identified and rectified by manual editing of the resultant DEM.

Distortions between multi-temporal products can be minimized by processing all images within a single image block (Kääb, 2002). This is done by connecting multi-temporal stereo models to each other by a large number of tie points, the absolute coordinates of which do not need to be known. Model ground control points (GCPs; features identified on imagery with known x, y and z coordinates) introduce a second-order error that is small (in the order of a few percent) for the final vertical displacements, which is consistent between the two DEMs providing they are bundle adjusted as a single image block. Therefore, the technique can, in theory, be used without any ground control at all, while still producing accurate vertical displacement results from the relative image orientation alone.

Digital elevation data derived from separate sources can also be employed to measure glacier surface elevation displacements, but usually with reduced accuracy. Some of the oldest imagery available for DEM extraction comes from the CORONA satellite series (1960–1972), originally collected for American intelligence but recently declassified. The absolute errors associated with a single DEM extraction from CORONA data can be relatively high, but if surface changes are measured over a sufficiently long time period, the magnitude of displacement can still exceed any uncertainty in the combined datasets (Bolch et al., 2008). Contemporary DEM data are most often provided by the ASTER and SPOT HRS and HRG sensors, at a spatial resolution of ~15–30 m, much coarser than those available from IKONOS and Quickbird (~5–10 m), but at lower cost. In particular, the SPOT HRS sensor is capable of producing elevation data using only the sensor acquisition parameters (position and attitude), removing the requirement of a priori knowledge of ground-based feature locations (GCPs), which is of particular value for the study of remote glaciers, or those with limited accessibility (Berthier and Toutin, 2008).

Assessing accumulation and ablation

Snow grain size and albedo

Using sensor measurements in the visible and near-infrared portions of the electromagnetic spectrum, it is possible to derive information on snow grain size, from which albedo (Albedo) can also be estimated.

Snow grain size can crudely be estimated using reflectance data collected in the near-infrared and shortwave infrared portions of the spectrum, but the most accurate quantifications of grain size are available using reflectance data specifically collected in the range 1.0–1.3 μm. In particular, a prominent ice absorption feature exists at 1.03 μm, and reflectance measurements made in a continuum across this wavelength are most robust.

Albedo is primarily determined by snow grain size at near-infrared wavelengths, and by absorbing impurities in the visible portion of the spectrum. Albedo is the single most important input parameter for determining the surface energy balance of a glacier, which, in turn, can be used to model ablation, ultimately contributing to mass balance estimates (see below).

ELA assessment

The ELA (Equilibrium-Line Altitude (ELA)) marks the position where, over a period of 1 year, accumulation of snow is exactly balanced by ablation (Benn and Lehmkuhl, 2000). Measurements of the ELA over multiple years can provide an indication of glacier response to climate change, as well as allow reconstructions of former climates and the prediction of future glacier behavior. Remote sensing imagery can be useful for determining the transient snowline altitude (SLA – Transient Snowline), which itself is a reasonable proxy for ELA at the end of the ablation season (Clare et al., 2002).

The SLA can be defined as the boundary between snow and ice and can be delineated using, for example, the Normalized Difference Snow Index (NDSI). The NDSI exploits the high-reflectance properties of snow and ice in visible wavelengths and their high-absorption properties at shortwave infrared wavelengths:

$$\mathrm{NDSI} = (B_{\mathrm{Blue}} - B_{\mathrm{SWIR}})/(B_{\mathrm{Blue}} + B_{\mathrm{SWIR}})$$

In addition to the specific boundary between snow and ice, different snow facies may also be observed using the NDSI, for input to snowmelt runoff modeling simulations.

Mass balance

Local scale (i.e., single glacier) observations of mass balance (Glacier Mass Balance) are most commonly carried out using repeat measurements of accumulation and ablation at stakes and snow pits on the glacier surface to

determine summer and winter balances. This glaciological approach, however, does not account for the high spatial variability of ablation as controlled by debris cover, glacier surface topography, and mesoscale topographic variations. Consequently, remote sensing offers the only practical approach to address such high spatial variability and assessment of multiple glaciers within a region.

The simplest method for estimating glacier mass balance relies upon the successful identification of the AAR (Accumulation Area Ratio), which can be calculated when the ELA is known (see above) and the glacier extent is accurately delineated. Where measurements of AAR from remote sensing are combined with field measurements of mass balance, remote quantification of changes in the glacier mass balance becomes possible by observing changes in AAR. This method is locally specific, however, primarily because of the requirement for in situ calibration data, but also because the ELA may change from glacier to glacier due to the strong influence of avalanching, debris cover, and topographic effects on patterns of accumulation and ablation.

Similarly, observed changes in areal glacier extent may be used as a proxy for mass balance, but interpretation should be made with caution. Terminus recession is often taken as an indication of negative mass balance, but may not be truly reflective of mass changes across the glacier as a whole. A stable glacier terminus does not necessarily indicate equilibrium either; many glaciers, particularly those that are debris-covered, react to changes in mass by thickening or thinning. It has been suggested that for debris-covered glaciers in the Himalaya, the surface topographic profile may indicate an increasing or decreasing mass, with thickening/advancing glaciers indicated by a convex surface profile, and thinning/receding glaciers depicting a concave surface profile (Quincey et al., 2009).

The geodetic approach to measuring mass balance also uses glacier surface topography as an indication of long-term accumulation and ablation trends (e.g., Berthier et al., 2007). Glacier elevation changes (see above) are typically measured over multiple years, or even decades, to ensure short-term variabilities in accumulation and ablation do not bias the data, and also to ensure the errors in the technique do not exceed the magnitude of change to be measured. The change in elevation can then be translated into a change in mass assuming the surrounding terrain is stable (i.e., not tectonically active) and the density of the ice mass has not changed significantly between image acquisitions. For a more complete treatment of remote sensing methods for determining glacier mass balance, refer to Bamber and Rivera (2007).

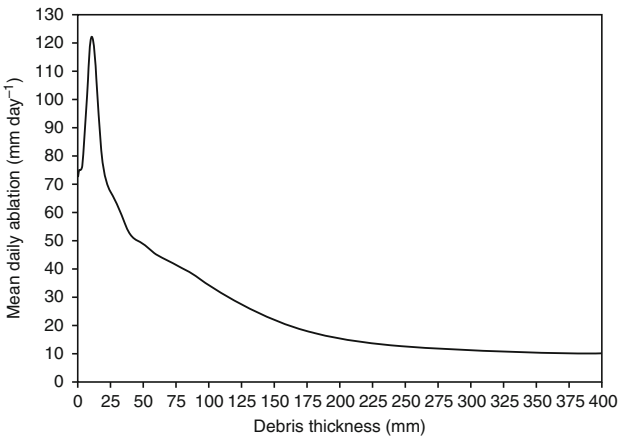
Debris-cover assessment

Supraglacial debris characteristics are known to play a significant role in governing glacier dynamics (Kirkbride, 2000). Specifically, the supraglacial lithologies, coverage, and debris cover thickness regulate ablation and the availability of meltwater. Consequently, remote sensing of supraglacial debris parameters is vital for (1) the assessment of surface energy-balance and estimation of ablation rates, (2) runoff modeling in mountain catchments, (3) the assessment of glacier lake development and catastrophic flooding, (4) understanding glacier response to climate forcing, and (5) estimating the magnitude of sea-level rise caused by alpine glaciers.

Supraglacial debris lithology dictates thermal properties and heat flux that control ablation beneath the debris. This supraglacial parameter can frequently be assessed using satellite imagery acquired from the visible, near-infrared, and middle-infrared regions of the spectrum. Igneous, sedimentary, and metamorphic lithologies can often be differentiated and mapped, given spectral variations caused by felsic versus mafic minerals. This capability is significantly improved when using hyperspectral data, such that diagnostic mineral spectral absorption features can be utilized. The ability to uniquely map supraglacial lithologies is highly dependent upon the spatial, spectral, and radiometric characteristics of the sensor. In general, dominant lithologies and debris-cover estimates can be generated using a variety of methodological approaches.

The most significant supraglacial debris parameter related to ablation is debris-cover thickness. The relationship between debris thickness and ablation is nonlinear, as a thin layer of debris enhances ablation, while thick debris reduces ablation. Empirical studies indicate hyperbolic trends exist between debris-cover thickness and ablation (Figure 4), although different magnitudes and gradients in the relationship are common due to geographic location and many other variables (Mattson et al., 1993).

Assessing this variable via remote sensing can be complex, as numerous processes regulate the debris thickness



Optical Remote Sensing of Alpine Glaciers,
Figure 4 Relationship between debris-cover thickness and ablation for the Raikot Glacier, located in the Nanga Parbat Himalaya, Pakistan. The general nonlinear trend in ablation has been reported on other debris-covered glaciers. Ablation data for the period June 22 to August 8, 1986. From Mattson et al. (1993).

and the amount of energy available to melt ice. The geographic location (x,y,z) and local topographic parameters (i.e., slope and slope azimuth) govern solar geometry and the magnitude of incident shortwave and long-wave radiation. Lithological differences influence the surface albedo and net radiation flux. Sediment transfer due to ice motion and slopes alters sediment depth and compressive ice flow results in a thickening of the debris layer. Thinning and thickening of the debris can also result from sediment settling and englacial-load meltout. Supraglacial debris is also transported and deposited via meltwater, while variations in debris moisture content alter the surface albedo and the thermal conductivity. Differential ablation also exhibits feedbacks with topography and sediment transport. Consequently, glaciers can exhibit extreme spatiotemporal variability in debris-cover thickness, making this a complex parameter to accurately estimate.

Nevertheless, thermal imagery can be used to estimate debris-cover thickness and thermal resistivity (Suzuki et al., 2007; Mihalcea et al., 2008). The approach is based upon using the thermal resistance of a debris layer as an index for ice melting, where thermal resistance (R) is defined as

$$R = \frac{h}{k}$$

where R is in units of m^2 K W^{-1}, h is debris thickness (m), and k is thermal conductivity (m^{-1} K^{-1} W). The thermal resistance can be estimated assuming a linear trend in the temperature profile within the debris layer given an ice temperature of 0°C such that

$$Q_m = \frac{T_s}{R}$$

where Q_m is the amount of energy available for melting (conductive heat flux, W m^{-2}), and T_s is the surface temperature of the debris (°C). Field measurements can be used to derive empirical equations for computing the effective thermal resistance (e.g., Mihalcea et al., 2008), and Q_m can be estimated using field weather station data or distributed models that account for the net radiation, sensible, latent, and turbulent energy fluxes. Furthermore, researchers have found linear and nonlinear relationships between T_s and h (Mihalcea et al., 2008). Consequently, surface temperature estimates generated from thermal imagery can be used to map debris depths and thermal resistance.

Ultimately, the ablation rate beneath a debris layer can be computed as

$$A = \frac{Q_m}{\rho_i L_f}$$

where A is the ablation rate (m s^{-1}), ρ_i is the density of ice (900 kg m^{-3}), and L_f is the latent heat of fusion (334 kJ kg^{-1}).

Hazard evaluation – glacial lakes

Glacial lake formation

Glacier-related floods occur when water is released from the glacial drainage system (subglacially, englacially, or supraglacially) or from lakes dammed behind glacier ice or moraine material (Richardson and Reynolds, 2000). Supraglacial lakes tend to form on debris-covered (rather than clean ice) glaciers, and begin as a number of small, supraglacial ponds where insulating debris cover is absent because of crevassing or sink holes. These small ponds expand rapidly because of subaerial melt and then by subaqueous calving, increasing in size until they coalesce with adjacent water bodies, or intercept an englacial conduit and drain. Rapid lake growth follows once hydrological base level is reached and the ponds cease to be ephemeral (Benn et al., 2001).

Remote sensing can be used to rapidly identify existing glacial lake locations, lake sizes, and rates of expansion. Water has particularly low spectral reflectance at near-infrared wavelengths, so the automatic delineation of supraglacial ponds and streams is a relatively straightforward task. The NDWI (cf. Huggel et al., 2002) is commonly applied:

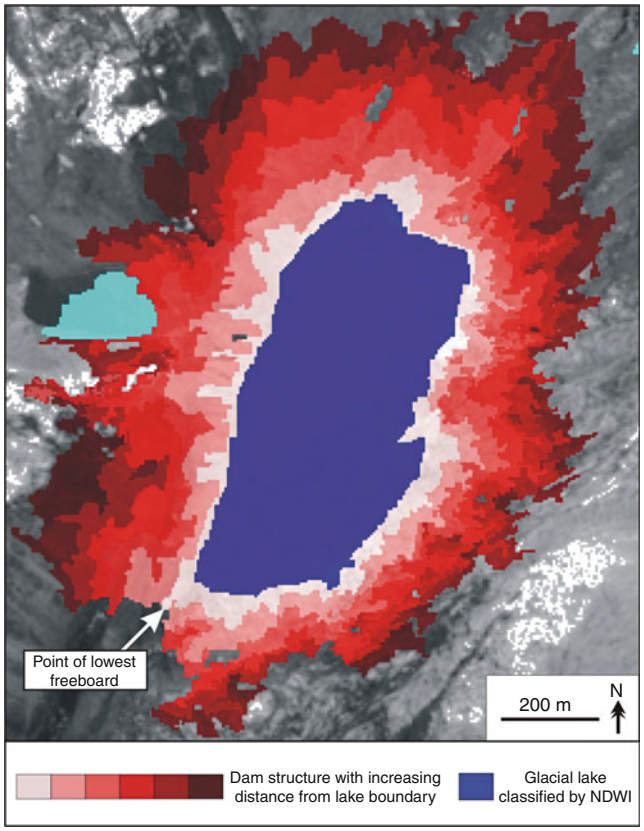
$$\mathrm{NDWI} = (B_{\mathrm{NIR}} - B_{\mathrm{Blue}})/(B_{\mathrm{NIR}} + B_{\mathrm{Blue}})$$

Predicting future lake development is a more complex task. It has been shown that lakes commonly form on flat glacier tongues, the identification of which is possible using digital elevation data, derived from overlapping remote sensing images. Other factors such as dam characteristics and trigger mechanisms also play an important role on lake development and outburst potential and can sometimes be identified or discounted by remote sensing image analysis where the imagery is sufficiently detailed.

Dam characteristics

The existence of a moraine dam to impound water represents one of the more important factors for predicting lake formation. However, automatic delineation of dam structures from remote sensing data can be problematic, because they usually comprise materials very similar or even identical to glacier debris and also the surrounding environment. Visual inspection is often the most appropriate method for detecting a dam structure although the integration of elevation data allows more detailed and precise information to be derived regarding (1) the height of the dam from the valley floor and (2) the dam crest relative to the glacier or lake surface. DEM data can also highlight the presence of any low points on the dam that could be exploited as a point of weakness should a lake-outburst occur (Figure 5).

The geometry and composition of a dam are the two most important parameters related to its stability and thus the susceptibility of a lake to overtopping or breaching. The height-to-width ratio of the moraine dam is an indicator of its ability to withstand displacement waves and can be determined from fine-resolution elevation data.



Optical Remote Sensing of Alpine Glaciers, Figure 5 Automatic delineation of a natural dam structure impounding a glacial lake in the Nepal Himalaya, and the identification of the point of lowest freeboard where overtopping is most likely to occur. Measurements were made using eCognition segmentation-based software and an ASTER-derived DEM.

Similarly, freeboard height can be determined once a lake has developed providing reliable elevation data can be extracted from the (usually featureless) water surface.

Trigger mechanisms

Ice avalanches are the most common source of displacement waves in many of the high-mountain ranges of the world. Where receding glaciers exist upstream of a large glacial lake, the possibility of displacement-wave generation from ice avalanching is substantially heightened. The positive identification of ice and rock avalanche sources is also difficult with current remote sensing imagery, however. Digital elevation models can aid in the identification of ice and rock slopes above a certain threshold (Salzmann et al., 2004), but their susceptibility to failure is difficult to assess without detailed fieldwork.

Issues and concerns

While optical remote sensing can provide a useful range of data at various spatial, spectral, and temporal scales for mapping and characterizing alpine glacial environments, analyses based solely on remote sensing can be limited by specific sensor system characteristics. First, fine spatial resolution data remain too costly for most users. Aerial photographs have been shown to provide very fine-resolution data on microscale glacial processes, but overflights are expensive to commission, and, although historical photography often exists, locating and purchasing the imagery can be difficult, particularly in politically sensitive regions. Even where data are available, their usefulness can be limited by missing or incomplete calibration parameters, poor reproduction, and an absence of coincident field data. Where fine-spatial resolution satellite data are available, swath widths are generally narrow (e.g., 60 km), limiting analyses to single, or at best a small number of glaciers. Given the scale of extensive mountain ranges around the world, the limited spatial coverage is problematic for glacier inventory compilation, as full coverage over a large area is not always available.

Second, many satellite sensors are limited to measuring spectral reflectance in a relatively small (often <10) number of discreet spectral bands that are not always appropriate for a given application. Hyperspectral satellite data are becoming increasingly available, but their value for glacial studies is yet to be fully evaluated and validated, particularly as these sensors may exhibit a relatively low spatial resolution (e.g., 60 m for the proposed HYSPIRI sensor). Regardless of spectral resolution, all optical sensors are hampered by atmospheric effects including aerosols and clouds. In areas with extreme relief (i.e., the majority of glacierized alpine terrain) this can be particularly problematic, with persistent cloud cover masking large areas for long periods. Where coincident data are collected in the SWIR part of the spectrum (e.g., by ASTER), cloud cover can be easily identified and removed from an image, although surface reflectance data are unavailable. Furthermore, the complex topography of mountain environments produces differential illumination and cast shadows, which limits selected areas from being analyzed. Therefore, most satellite imagery contains a topographic effect, such that surface reflectance variations are caused by multi-scale topographic effects and do not entirely represent surface matter biophysical conditions. Given these issues, the imagery must be carefully radiometrically calibrated to account for anisotropic reflectance variations caused by topography. This issue is usually addressed by utilizing spectral features such as image ratios and principal component images that reduce, but do not eliminate topographic variation.

Finally, for satellite sensor data to be used routinely for glacier observations, a range of temporal overpass frequencies is required. For example, the end of the ablation season (August/September for Northern Hemisphere) is usually the optimum time for extracting glacier-related information, but at midlatitudes satellite overpass frequency is lower than toward the poles and therefore coverage of an exact time period is not always possible. Optimum times even differ between regions, based upon

climate dynamics, for example (e.g., monsoon season). Furthermore, change detection studies usually require systematic time frames, and for many regions of the world the multi-temporal coverage is inadequate.

In addition to sensor system characteristics, problems exist in the methods used to process satellite imagery for information extraction. Scientists employ a wide range of analytical tools, algorithms and processing approaches when studying the glacial environment, but the exact methods followed are highly empirical, such that the accuracy of the derived information is highly dependent upon the analyst. This means that it can be difficult for remote sensing scientists to repeat analysis efforts presented elsewhere, and even more difficult to take existing methods and apply them to new areas. Standardization and protocols for information extraction are required if the quality of data, the accuracy of published results, and the validity of comparing measurements across different studies (and study areas), is to be assured.

Summary

The increasing availability of optical data (often without charge) and the range of potential applications in glaciological studies have made remote sensing an essential part of glaciology. It provides the only realistic means of conducting glaciological work over large areas, which is quite often necessary as an event, change, or feature in one part of the glacial system can be a product of processes interacting many kilometers away. Human interpretation of optical satellite imagery remains an important method of information extraction, although computer-assisted analysis and the development of new algorithms and processing procedures are increasingly improving our ability to accurately generate "higher-level" quantitative information that is not directly apparent from visualizations (e.g., surface velocity fields and debris-depth maps). While a number of limitations still exist in the use of remote sensing data for glaciological studies, remote sensing, terrain analysis, and GIS-based numerical modeling can be effectively utilized to generate a wealth of information about glacierized terrain that complements, and even in some cases improves upon, field investigations. Continuing advances in sensor technology, processing methods, and numerical models are expected to overcome the most significant of these limitations in coming years, and therefore yield even more detailed assessments of glacier characteristics and processes.

OROGRAPHIC PRECIPITATION

Justin R. Minder[1], Gerard H. Roe[1,2]
[1]Department of Atmospheric Science, University of Washington, Seattle, WA, USA
[2]Department of Earth and Space Sciences, University of Washington, Seattle, WA, USA

Definition

Precipitation that has been generated or modified by topography, typically through the forcing of vertical atmospheric motions.

Introduction

The influence of mountains upon rain and snowfall is often profound, creating some of the Earth's wettest places (e.g., Cherrapunji in India, where monsoon flow encounters the southern Himalayas, has received 26.5 m in 1 year) and driest places (e.g., the central valleys of the Atacama desert, shielded by surrounding mountains, can go for decades without rainfall). Orographic effects on precipitation are also responsible for some of the planet's sharpest climatic transitions. The classic example is the so-called rain shadow; for a mountain range oriented perpendicular to the prevailing winds, precipitation is greatly enhanced on the windward side and suppressed in the lee. However, the full gamut of orographic influences is much broader than this: precipitation can be enhanced in the lee, over the crest, or well upwind of a mountain.

The mass balance of Earth's snow and ice is strongly affected by orographic precipitation. Orographic snowfall is the source of mass that maintains mountain snowpacks and glaciers. The Greenland and Antarctic Ice sheets are themselves substantial topographic features responsible for orographic effects on precipitation. Avalanches are sensitive to the detailed stratigraphy of the snowpack, which is partly determined by the sequence of orographic graupel, rain, ice, and various snow crystals that fall during storms.

This article will focus on the important physical processes controlling orographic precipitation, and the observational and modeling techniques that have been used to characterize and understand it. More complete reviews may be found in Smith (1979), Roe (2005), and Smith (2006).

Fundamentals

Orographic precipitation is shaped by myriad nonlinear processes operating on scales ranging from the 1,000 km size of storms and major mountains to the sub-micron size of cloud droplets. Still, the most fundamental of these processes are thermodynamic in nature and are well understood. Almost all orographic influences on precipitation occur due to rising and descending atmospheric motions forced by topography. These motions can be forced mechanically, as air impinging on a mountain is lifted over it, or thermally, as heated mountain slopes trigger

buoyancy-driven circulations. Rising motion causes the air to expand and cool, which is important since the amount of water that may exist as vapor in air is an approximately exponential function of temperature (described by the Clausius Clayperon equation). Thus, if cooling is sufficient, air saturates and the water vapor condenses into cloud droplets or forms cloud ice crystals. These droplets and crystals grow by various processes until they become large enough to fall as rain and snow. It is important to emphasize that moist ascent over topography alone is typically insufficient to generate precipitation: these orographic effects mainly modify precipitation during preexisting storms (e.g., Browning et al., 1974; Smith, 2006). Conversely, when air descends it warms and dries, and both cloud and precipitation evaporate.

A useful tool for understanding some of the basic controls on orographic precipitation is the "upslope" model (e.g., Smith, 1979, 2006). This idealized and physically based model predicts the water condensed when flow with a given surface-specific humidity (q_v, expressed as a mixing ratio), density (ρ), and uniform wind velocity ($\bar{U}$) impinges upon topography (with height: $h(x,y)$). The model assumes saturated air, an idealized temperature profile, and flow that parallels the topography at all heights. Under these assumptions the vertically integrated source of condensed water per unit time is:

$$S(x,y) = \rho q_v \bar{U} \cdot \nabla h(x,y) \tag{1}$$

This is also the precipitation rate at the surface if it is further assumed that conversion of cloud condensate to precipitation and fallout of precipitation are instantaneous. This model reveals some key controlling parameters: the moisture flux ($\rho\, q_v \bar{U}$), which determines the vapor available for condensation, and the topographic slope (∇h) in the direction of the airflow, which determines the rate of the forced vertical motion.

Airflow dynamics

Actual flow over topography during precipitation is seldom as simple as that assumed in the upslope model. Atmospheric density and temperature stratification strongly control the flow, since the typically stable stratification of the atmosphere means that a parcel of air displaced upwards becomes negatively buoyant (since it is cooler and denser than its surroundings) and is pulled back downwards. The strength of this effect may be quantified by the Brunt-Vaisala buoyancy frequency:

$$N^2 = \frac{g}{T}(\gamma - \Gamma) \tag{2}$$

with γ representing the observed atmospheric lapse rate (i.e., the rate of decrease of temperature with height), and Γ the theoretical dry adiabatic lapse rate for a rising air parcel (-9.8 K km^{-1}). When stratification is stable ($N^2 > 0$) the buoyancy restoring force causes airflow over mountains to take the form of waves, which oscillate with frequency N. These wave motions cause orographic uplift to be displaced upstream by varying degrees (enhancing precipitation ahead of the mountain) or decay with height (limiting precipitation enhancement) depending on the strength of the incoming flow and stratification relative to the mountain width (Smith, 1979; Smith and Barstad, 2004).

Under conditions where N^2 is large and positive, the incoming flow is weak, and/or the mountain is high, the effects of stratification can be overwhelming and the low-level flow may be unable to surmount the mountain. In such cases the flow is said to be blocked, and air is forced to deflect around the mountain, stagnate, or even reverse (e.g., Smith, 1979; Marwitz, 1987). This can result in orographic enhancement that is limited or forced to occur further upstream (e.g., Houze and Rotunno, 2007). A parameter useful for predicting the onset of blocking is the nondimensional mountain height:

$$M = \frac{hN}{\bar{U}} \tag{3}$$

where $\bar{U}$ is the incoming flow speed and h is the mountain height. When M exceeds unity blocking is favored.

When the atmosphere is unstably stratified ($N^2 < 0$) convective overturning motions may be triggered. Convective cells embedded within a storm are a common feature in orographic precipitation (e.g., Browning et al., 1974). When the atmosphere is strongly unstable orographic thunderstorms may be triggered.

As air rises and moisture condenses latent heat is released. This heating effectively reduces the stratification. As a result, many flows that would be blocked are able to flow over mountains when condensation occurs, leading to important impacts on precipitation distributions (e.g., Jiang, 2003).

Microphysics

Conversion of water from vapor to cloud to precipitation is a substantial task. Typical cloud particles must grow about one-billion-fold in volume before they are large enough to fall as precipitation. The evolution of cloud and precipitation particles occurs on scales from millimeter to micron, earning it the term cloud microphysics. Cloud droplets initiate and grow on fine particulates known as cloud condensation nuclei or ice nuclei, the concentration of which determines the size and number of cloud drops. The growth of cloud particles to the size of rain and snow occurs by the diffusion of vapor onto cloud particles and by the collision, coalescence, and aggregation of droplets and crystals. These growth processes depend on temperature, humidity, and the character of the airflow.

Hobbs et al. (1973) demonstrated the importance of microphysical processes by simulating a winter orographic storm with varying initial ice crystal concentrations. For small concentrations of cloud ice, snow grew quickly and fell to the ground over the windward slopes, whereas for large concentrations growth was slow and

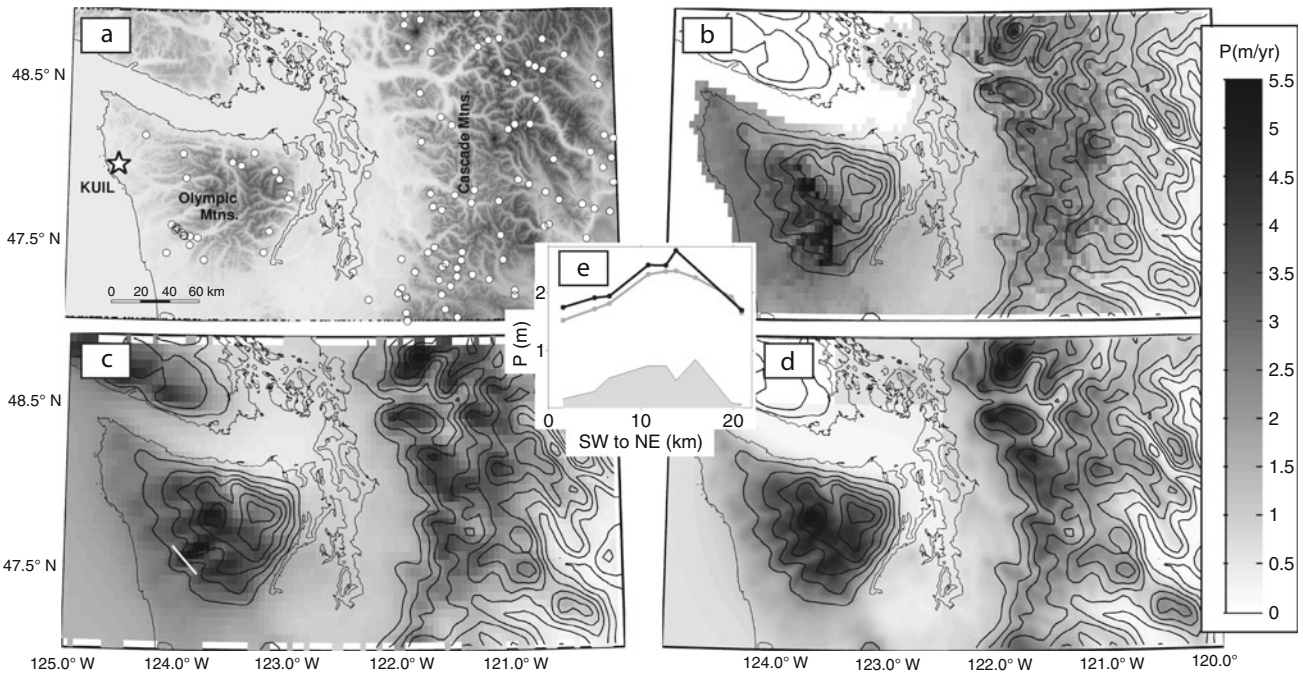
snow was blown nearly 100 km into the lee. Precipitation phase is also crucial, as snow falls much more slowly than rain (roughly 0.5–2 m s^{-1} vs 7–10 m s^{-1}), and snow rimed with super-cooled water (graupel) falls at intermediate speeds. These fall speeds determine how far downwind precipitation drifts as it falls.

The melting level

Knowing the melting level – the elevation at which snow turns to rain as it falls – is important for studies of mountain snow and glaciers. Characterizing the melting level over topography is not as simple as just measuring it upstream since orographic effects may modify melting levels during storms. The lifting of air on the upwind side of the mountain leads to expansion and cooling, while the phase change of orographic snow falling through the melting level causes latent cooling, both of which are responsible for observed depression of the melting level over windward slopes that can amount to 0.5 km or more (e.g., Marwitz, 1987). The thermal inertia of the land, cold air trapped in valleys, and the degree of turbulent mixing near the surface may all influence the melting level as well.

Observations

The most direct observations characterizing orographic precipitation come from rain and snow gauges that measure accumulation at mountain sites. For example, the Cascade and Olympic Mountains (Figure 1a), located in the northwestern USA, receive plentiful orographic rain and snow from the mid-latitude cyclones of the Pacific storm track. Rain and snowfall varies greatly over the Cascades, but fully characterizing these variations with gauges alone is quite challenging due to the paucity of observations located within the mountains away from the populated valleys and foothills (Figure 1a). The high concentration of gauges needed to characterize orographic precipitation is highlighted by observations from a dense gauge network in the southwestern Olympics (Figure 1a, Minder et al., 2008). These observations show large differences in annual mean precipitation over scales of a few kilometers, maximizing on ridge-tops (Figure 1e). This pattern of precipitation is distinct from the rain shadow predicted by the upslope model. It arises because precipitation from aloft falls through low-level orographic clouds and grows by colliding with and collecting cloud droplets, in what is termed the "seeder-feeder" mechanism (Bergeron, 1968).



Orographic Precipitation, Figure 1 Topography and precipitation for the Olympic and Cascade Mountains of northwestern Washington, USA. (**a**) Shows elevation in grayscale (*black* corresponds to 3.5 km) and the location of regularly reporting precipitation gauges located above 150 m elevation (*white dots*). (**b**–**d**) Shows precipitation from October 2000 – September 2007 in *gray* shading, and smoothed contours of elevation every 250 m. (**b**) Is the PRISM analysis of gauge observations (Daly et al., 1994; data from PRISM Group, Oregon State University, http://www.prismclimate.org). (**c**) Is from the operational MM5 numerical weather predictions (e.g., Minder et al., 2008; http://www.atmos.washington.edu/mm5rt/). (**d**) Is from the model of Smith and Barstad (2004) forced with data taken from atmospheric soundings at KUIL (shown in **a**). (**e**) Compares the observed (*gray*) and MM5 (*black*) precipitation for a gauge transect in the southwestern Olympics (location shown with *white line* in **c**) for the winter of 2004–2005. The topographic profile (peak elevation of 800 m) is shaded (Modified from Minder et al. (2008) and reproduced with permission from Wiley-Blackwell).

Statistical techniques can fill in gaps in observational networks. For example, the Parameter Regression on Independent Slopes Method (PRISM; Daly et al., 1994) uses localized regressions of elevation and precipitation to interpolate between observations. PRISM output is shown for the Cascades and Olympics in Figure 1c. Other gridded gauge analyses from the well-instrumented European Alps (Frei and Schär, 1998) reveal more complex large-scale patterns than shown in Figure 1c. The Alps receive storms arriving from a much wider range of directions, erasing any simple rain shadow and producing precipitation maxima on both sides of the range.

Remote sensing offers an alternative method for studying orographic precipitation. Satellite methods are particularly useful for remote, poorly instrumented regions. For example, the Tropical Rainfall Measuring Mission (TRMM) satellite operates by emitting pulses of microwave radiation, which are reflected by precipitation. Data from TRMM have been used to characterize the pattern of precipitation over the Himalayas at 10 km scales (Anders et al., 2006), revealing a broad double-band of maximum precipitation along the southern slopes and local enhancements within windward valleys relative to the 4-km-high flanking ridges where the moisture content is quite low (Anders et al., 2006). Additional remotely sensed data come from ground-based radars, a great number of which are deployed for weather forecasting. These can be used to make detailed observations of precipitation, including precipitation phase, with high spatial and temporal resolution. In a classic study, Browning et al. (1974) used radar over the coastal hills of Wales to show that intense periods of mountain precipitation occur when rainfall cells from upwind of the mountains are advected over the mountains and enhanced as instability is released and the seeder-feeder mechanism acts. Unfortunately, radar can be challenging to use in mountainous terrain where the beam is often blocked by topography.

Both in situ and remote observations from aircraft have been a central component of several field projects devoted to better understanding orographic precipitation. The most expansive of these efforts to date, the Mesoscale Alpine Programe (MAP), focused on the southern slopes of the European Alps. Results from MAP revealed "that detailed knowledge of the orographically-modified flow is crucial for predicting the intensity, location, and duration of orographic precipitation" (Houze and Rotunno, 2007, p. 811), and that this flow is a strong function of the low-level stratification. Furthermore, under different flow regimes contrasting microphysical growth mechanisms become important, influencing the enhancement and distribution of precipitation (Houze and Rotunno, 2007).

Models

A vast array of models, each with their own advantages and drawbacks, have been used to characterize and understand orographic precipitation. The most basic of these are statistical in nature, relying upon empirical relations to estimate precipitation as is done for PRISM. Such models can be quite quantitatively successful, but need adequate data for calibration and can fail dramatically when observations are sparse or when anomalous atmospheric conditions occur.

The upslope model, described above, is an example of a class of simple physically based models that rely upon a series of idealizing assumptions to estimate precipitation with only minimal information about the incoming flow. Such models can illuminate fundamental processes and make ballpark estimates of precipitation, but a neglect of airflow dynamics and cloud microphysics severely limits their physical realism.

Another class of models is intermediate in complexity, maintaining simplicity while incorporating more governing physics than the upslope model. An example of this is the linear theory model put forth by Smith and Barstad (2004), which builds on the upslope model to include linearized mountain wave airflow dynamics, microphysical conversion, and fallout timescales, and lee side evaporation of precipitation. Such models are useful for the same reasons as the upslope model, but offer a much more complete physical representation and better performance. Still, these models neglect important nonlinear processes such as airflow blocking and microphysical collection and must be calibrated to perform well. An application of Smith and Barstad (2004)'s model to the Cascades and Olympics is shown in Figure 1d.

Mesoscale numerical weather prediction models are the most sophisticated modeling tool used in the study of orographic precipitation. They solve the full time-dependent equations of atmospheric motion and thermodynamics numerically on a three-dimensional grid and use schemes that simulate the interactions occurring on the microphysical scale between vapor, clouds, and precipitation. These models are capable of realistically representing transient interactions between large-scale storms and mountains, and nonlinear effects of blocking and microphysics. Yet, this physical realism comes at a computational cost, and these models can take substantial time to run even on fast computers with parallelization. Precipitation from the MM5 mesoscale model, used for operational weather forecasting, is shown in Figure 1c over the Olympics and Cascades. For some regions the model performance is excellent even on small scales, as shown in Figure 1e. However, these models cannot be taken for truth as they can be configured in a multitude of ways that give differing results. Even the best models can still have major errors, for individual storms and climatological averages, due to the challenges of simulating microphysical processes as well as inherent limits that exist on atmospheric predictability.

Climate change and variability

The sensitivity of orographic precipitation to large-scale climate variability and climate change is an active area of research. It is well known that year-to-year variations

in mountain rain and snowfall for ranges such as the Cascades are largely due to variations in the intensity and location of the mid-latitude storminess, with some of those variations related to large-scale patterns of climate variability such as the El Nino Southern Oscillation. Understanding how orographic precipitation will be altered due to anthropogenic climate change requires understanding the temperature sensitivity of orographic precipitation processes, as well as knowledge of how storm tracks and large-scale circulation will change.

The temperature dependence of orographic precipitation was investigated in depth by Kirshbaum and Smith (2008) using a mesoscale model. They found that while precipitation increases with the temperature and humidity of the atmosphere, these increases are buffered since orographic precipitation becomes less efficient at extracting moisture from the flow, due both to thermodynamic and microphysical effects. Salathé et al. (2008) used a mesoscale model to downscale global climate model projections over the Cascade and Olympic mountains and showed that possible changes in the direction of airflow during storms may alter the intensity and distribution of precipitation over the region. Generally, orographic snowfall is very likely to decrease with climate warming as melting levels during storms rise and a larger fraction of precipitation falls as rain. Some loss may be offset by orographic precipitation rate increases, but for mountains like the Cascades and Olympics, where temperatures are not typically far below freezing during storms, this compensation can be only modest due to the substantial loss of snow accumulation area.

Summary

Orographic precipitation processes strongly shape the climate in and around mountainous regions. Orographic influences can be pronounced on spatial scales ranging from the size of individual hills to the scale of major mountain ranges, and on temporal scales from the duration of a brief snow squall to the long-term climatology. Almost all orographic influences are fundamentally caused by topographically driven ascending and descending atmospheric motions that force condensation and evaporation. However, these basic forcings combine with a wide range of dynamical and microphysical processes to shape the precipitation distribution. Since different physical processes can be important for different storms and for different mountain ranges, orographic precipitation influences may take many forms.

Characterizing and understanding the effects of topography on precipitation remains an active field of research. Current research questions include: How does orographic precipitation change with climate? How do turbulent atmospheric motions affect orographic enhancement? What are the limits on predictability of orographic precipitation? Synthesis of new theories, models, and observational techniques continues to aid us in trying to answer these and other important questions.

OUTLET GLACIER

Monohar Arora
National Institute of Hydrology (NIH), Roorkee, UA, India

The outlet glacier is confined to the narrow valley by the neighboring cliffs, and by lateral moraines deposited during a geologically recent period of glacier expansion. During that expansion, the outlet glacier reached the valley floor, pooled, and formed a piedmont lobe confined only by its own terminal moraine. In other words, it is a tongue of ice that extends radially from an ice dome. It may be identified within the dome as a rapidly moving ribbon of ice (an "ice stream"), while beyond the dome it typically occupies a shallow, irregular depression. The 700 km long Lambert Glacier, Antarctica, is one of the world's largest outlet glaciers.

OVERBURDEN PRESSURE

Prem Datt
Research and Development Center (RDC), Snow and Avalanche Study Establishment, Himparisar, Chandigarh, India

The compressive load imposed by overlying material on a layer of snow, ice, soil, or rock is called overburden pressure. If a snowpack is lying on a slope, the vertical component of the load is responsible for the densification which increases the cohesion and may increase snowpack strength. In glaciers, overburden pressure causes pressure melting from the basal plane. The overburden pressure at a depth z is given by

$$p(z) = p_0 + g\int_0^Z \rho(z)\,\mathrm{d}z$$

where $\rho(z)$ is the density of the overlying snow/ice at depth z and g is the acceleration due to gravity. p_0 is the datum pressure, like the pressure at the surface.

OXYGEN ISOTOPES

Bhishm Kumar
Hydrological Investigation Division, National Institute of Hydrology, Roorkee, Uttarakhand, India

Definition

Oxygen is the eighth element of the periodic table. Oxygen has 11 isotopes, ^{12}O, ^{13}O, ^{14}O, ^{15}O, ^{16}O, ^{17}O, ^{18}O, ^{19}O, ^{20}O, ^{21}O, and ^{22}O, but except ^{16}O, ^{17}O, and ^{18}O all other isotopes are radioactive and their existence in nature is very small (half life vary from 150 s to few femoseconds – of the order 10^{-15} s); therefore, we normally talk about only three isotopes of oxygen, that is, ^{16}O, ^{17}O, and ^{18}O.

Analytical principal

As the different isotopes have different masses, it is possible to separate them by passing a stream of the ionized sample (usually in a gas form) through a powerful magnetic field in a mass spectrometer. The heavier ions have greater momentum than the lighter ones, and hence are deflected to a lesser extent than the lighter ones. This splits the stream of ions into its heavy and light components – each of which can be measured using a Faraday collector. The abundance of the ^{18}O isotope is expressed as a percentage of the ^{18}O isotope relative to ^{16}O. For oxygen, on average, the natural abundance of ^{18}O relative to ^{16}O is 0.204% (Clark and Fritz, 1997).

Uses

$\delta^{18}O$ and $\delta^{2}H$ can be used to trace the hydrological cycle from evaporation in the oceans to local precipitation and groundwater. Because $\delta^{18}O$ and $\delta^{2}H$ values have a strong positive correlation with temperature, their measurements in ice cores are valuable indicators of climate variability. $\delta^{18}O$ and $\delta^{2}H$ values can be used to date snow and determine average snow accumulation rates. Dansgaard (1954) proposed that the ^{18}O content in glacier might reflect climatic conditions of the past. The most successful work that has been done in this field is undoubtedly the establishment of the ^{18}O profile of the Camp Century ice core which is 1,390 m deep (Dansgaard et al., 1969).

PALAEO GLACIOFLUVIAL SEDIMENT SYSTEMS

Norm R. Catto
Department of Geography, Memorial University of Newfoundland, St. John's, NL, Canada

Definition

Palaeo-glaciofluvial sediment systems are defined as those that indicate the former presence of glaciofluvial activity but which are not associated with a modern or active glacier.

Introduction

Recognition and analysis of palaeo-glaciofluvial sediment systems provides details concerning the extent and nature of former glaciation. In many areas, glaciofluvial landforms are well preserved, forming distinct indications of both former ice-frontal positions and drainage patterns influenced by glaciation. Palaeo-glaciofluvial features can be both depositional and erosional.

Depositional features

Depositional features include all types of glaciofluvial landforms that can be found adjacent to modern glaciers, including eskers, kames, and outwash plains (also called sandur). In many instances, preservation of landforms has been affected by subsequent erosion. In addition, deposition in the glaciofluvial environment also commonly involves inclusion of blocks of detached glacial ice. Outwash discharged from a glacier may also be deposited on snow or winter ice. Subsequent melting of ice and snow will result in disruption of the sediment and landforms. Common internal sedimentary features include loading and collapse deformations, load casts, and diapers (Figure 1). Normal faulting is also common, as a result of differential melting or subsidence of trapped blocks of ice. Compaction structures can result as water-saturated glaciofluvial sediments are dewatered over time.

Cross-bedding and ripples initially deposited over ice can be displaced by subsequent melting. Displaced beds will exhibit angles of inclination substantially in excess of the critical angle of repose or the normal depositional attitude of the sediments, producing cross-strata inclined at angles in excess of 45° in some instances (Figure 2). Sand and gravel deposits showing anomalously high angles of cross-strata are considered an indicative of glaciofluvial deposition.

Eskers

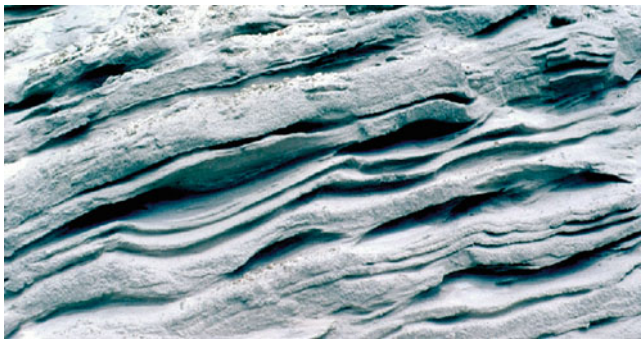
Preservation of eskers is influenced by the degree of erosion by running water, both penecontemporaneous with deposition and in the period following glacial retreat. Subglacially formed eskers are more likely to be preserved than are supraglacial features. Individual segments of a subglacially formed esker may exceed 20 m in height and 20 km in length. Adjacent segments indicate the direction of subglacial meltwater flow. Connection and correlation of adjacent segments, facilitated by an analysis of the mineralogy of sediments within the esker deposits, indicates that eskers can represent the remnants of river systems extending hundreds of kilometers. Eskers develop sequentially over time, however, so that not all segments were formed simultaneously. They may be single ridges or may be aligned in a braided or reticulate pattern. Eskers served as passage routes for animals through forests and are commonly used as sources of gravel and sand aggregate for road construction.

Kame complexes

Palaeo-glaciofluvial kame complexes also mark former ice-front positions (Figure 3). A kame is a deposit of stratified material adjacent to, within, or upon a glacier, formed by meltwater. Kame complexes develop where

Vijay P. Singh, Pratap Singh & Umesh K. Haritashya (eds.), *Encyclopedia of Snow, Ice and Glaciers*, DOI 10.1007/978-90-481-2642-2,

Palaeo Glaciofluvial Sediment Systems, Figure 1 Deformation structures in palaeo-glaciofluvial deposit, Ragged Harbor area, Newfoundland and Labrador, Canada.



Palaeo Glaciofluvial Sediment Systems, Figure 2 Inclined ripples indicate displacement as a result of melting of underlying ice. Terra Nova, Newfoundland and Labrador, Canada.

glaciofluvial sediments are accumulated during relatively prolonged stands of glacial ice, commonly tens to hundreds of years. Most large moraines contain substantial quantities of glaciofluvial deposits, as the original tills and debris flow deposits are reworked by running water from the melting ice. Mixed assemblages of glaciofluvial and glaciomarine (or glaciolacustrine) deposits form where the glacial front rested in relatively shallow marine (or lacustrine) waters. Typical frontal kame moraines consist of segmented ridges aligned parallel to the former ice frontal position, with interspersed glacial, glaciomarine, or glaciofluvial sediments, situated in the belts of several kilometers width.

Crevasse fills

Crevasse fills also are indicative of palaeo-glaciofluvial activity. Crevasse fills are elongate ridges formed by the infilling of crevasses by glaciofluvial sediment. Crevasse fills often are characterized by angular bends and wide, level tops. The infill material may be sand, gravel, diamicton, or a combination of all the three. Crevasse fills commonly occur in groups. Preservation depends upon melting of glacial ice predominantly from below, coupled with minimal reworking subsequent to formation.

Palaeo Glaciofluvial Sediment Systems, Figure 3 Kame Complex, Carrot Creek, Alberta, Canada.

Erosional features

Palaeo-glaciofluvial erosional features are also indicative of former glacial activity. Meltwater channels represent drainage routes that formerly were occupied by meltwater derived from glacial ice but which have subsequently been partially or totally abandoned. Meltwater channel orientations indicate the effects of disruption and blockage of drainage by glacial ice. Channels which developed adjacent to an ice front may be carved into the sides of hills, with one bank having been formerly supported by an adjacent glacial ice.

Summary

Palaeo-glaciofluvial sediment features and landforms are frequently the best-preserved remnants of glaciation. Depositional features include all types of glaciofluvial landforms that can be found adjacent to modern glaciers, including eskers, kames, crevasse fills, and outwash deposits. Erosional features formed by running water in glacial environments, including meltwater channels, also indicate the former presence of glaciers.

PALAEO-CHANNEL

Vijay Kumar
National Institute of Hydrology, Roorkee, India

The word paleo-channel is formed from the words "paleo" or "old," and channel; i.e., a paleo-channel is an old channel. Paleo-channels are deposits of unconsolidated sediments or semi-consolidated sedimentary rocks deposited in ancient, currently inactive river and stream channel systems. These are typical riverine geomorphic features in a location representing drainage streams, rivers, rivulets which were flowing either ephemeral or perennial during the past time and now stands either buried or lost or shifted due to tectonic, geomorphologic, anthropogenic process/activities, as well as climatic changes. When a channel ceases to be part of an active river system, it becomes a paleo-channel. Paleo-channels are also identified as remnants of stream channels cut in older rocks/sediments and filled by younger overlying sediments, representing the distribution of valley systems as these existed at a given geological time in the past (Bates and Jackson, 1980). Paleo-channel is synonymous with paleo-river, paleo-drainage, lost river, buried river, buried channel, or buried valley. Paleo-channels vary greatly in age. Those from the recent geological past (perhaps tens to hundreds of years old) include meander cut-offs and longer reaches. A paleo-channel is distinct from the overbank deposits of currently active river channels, including ephemeral water courses which do not regularly flow. A paleo-channel is distinct from such watercourses because the river bed is filled with sedimentary deposits which are unrelated to the normal bed load of the current drainage pattern.

The water-bearing rock characteristics of paleo-channels are highly porous gravel, coarse-medium sand (in the alluvial fan area), medium fine sand, fine silt (in the river channel zones), and silt (in the delta). The paleo-channels are potential sources of recharge, as they commonly serve as flood channels or aqueducts. They have good paths of infiltration as they have usually sandy soil or sandy loam on the surface. The main features which govern the hydrology and recharge of paleo-channels are the size (spatial extent and depth) of the feature and the stratigraphy (layering of soil properties) within the profile. Most of the paleo-channels are interlinked with present rivers or canals, which is beneficial to lateral recharge of the groundwater. Relict fluvial channels that are filled with high permeability sediments act as preferred pathways for groundwater flow and solute transport. In coastal regions, such paleo-channels can provide a hydraulic connection between freshwater aquifers and the sea, resulting in saltwater intrusion landward or freshwater discharge offshore.

Paleo-channels have long attracted scientific and practical interest. Where paleo-channels are well preserved they provide valuable information about past flow regimes. They can also provide information about the response of catchments and rivers to past climatic changes, with implications for projected changes to climate in the future. Paleo-channels are important in geology for understanding the movements of faults; for preserving the old and recent sediments and fossils within them; and for preserving sedimentary records useful for understanding climatic conditions, including various isotopic indicators of past rainfall, temperature, and climates. Amongst other things, these abandoned channels are economically important because they often contain deposits of Tin, Tungston, Uranium, Lignite, Gold, Platinum, Silver, and Diamonds besides permeable fills which form excellent aquifers. The presence of paleo-channel can pose serious threats to engineering projects within the region. A large number of geophysical methods – electrical resistivity, electromagnetic potential, seismic refraction, and reflection – are being successfully used in delineating and exploiting paleo-channel.

PALAEO-ICE STREAM

Chris R. Stokes
Department of Geography, Durham University, Durham, UK

Introduction

An *ice stream* is a region in a grounded ice sheet that flows at an order of magnitude faster than the slow-flowing ice that borders it. The term *paleo-ice stream* is used to describe ice streams that no longer exist as a result of deglaciation. Ice streams have been referred to as the "arteries" of an ice sheet (Bennett, 2003) because their high velocities are responsible for the vast majority of ice sheet discharge, despite representing a relatively small component of their surface area (Bamber et al., 2000). It is for this reason that they are viewed as a critical component of ice sheet mass balance and have important implications for sea-level change (Shepherd and Wingham, 2007). The dynamic nature of ice streams is further emphasized by the relatively recent discoveries that they are capable of accelerating, decelerating, migrating, and shutting down over very short timescales (e.g., Joughin et al., 2004; Conway et al., 2002).

Perhaps surprising, given their undoubted importance, is that ice streams are a relatively recent discovery. They were formally defined in the 1950s (Swithinbank, 1954) but only began to be intensively studied as late as the 1970s (e.g., Rose, 1979). Since that time, however, their identification in modern ice sheets has been enhanced by remote sensing techniques that enable a large-scale view of the flow features on the ice sheet surface (e.g., flow-stripes, crevasse patterns) and, more recently, the calculation of ice velocities

and elevation (e.g., Joughin et al., 2004). These studies reveal that ice streams are typically large features (100s km long; 10s km wide) and possess very abrupt lateral shear margins, where intense crevassing is generated at the border with slow-flowing ice. Their rapid velocity is a defining characteristic and observations of their bed, whilst logistically very difficult, suggests that their motion is facilitated by a layer of saturated, deformable sediments that deform beneath the ice and offers minimal frictional resistance to basal sliding (Alley et al., 1986; Engelhardt and Kamb, 1998). Where subglacial sediment deformation is pervasive, high sediment transport rates are known to produce "till" wedges at the terminus of the ice stream (Anandakrishnan et al., 2007).

Identification of paleo-ice streams

Ice streams are a fundamental property of the flow structure of modern-day continental ice sheets and it can be assumed that they played a similar role in past (paleo-) ice sheets. It was the recognition of their significance to ice sheet dynamics in the late 1970s and 1980s (e.g., Rose, 1979; Alley et al., 1986) that prompted several workers to attempt to reconstruct their location and behavior in paleo-ice sheets (e.g., Denton and Hughes, 1981; Dyke and Prest, 1987). These pioneering workers recognized that ice streams should leave behind geological/geomorphological evidence of their activity that would be very different from the slow-flowing regions of the ice sheet, and cited evidence of distinctive erratic dispersal trains with abrupt lateral margins (Hicock, 1988; Dyke and Morris, 1988). The discovery of highly elongated subglacial bedforms on paleo-ice sheet beds, known as mega-scale glacial lineations (cf. Clark, 1993), was also linked to paleo-ice stream activity. Despite these important advances, the identification of paleo-ice streams was somewhat subjective, with a wide variety of evidence used to infer their location in former ice sheets (e.g., see review in Stokes and Clark, 2001).

Mathews (1991) highlighted the need for some objective criteria to identify paleo-ice streams and Stokes and Clark (1999) later proposed some "geomorphological" criteria based on the characteristics of modern-day ice streams. These criteria are listed in Table 1 and, where several are identified together on a paleo-ice sheet bed, are likely to indicate robust evidence of ice streaming.

The criteria, listed in Table 1, can be grouped together into a glacial landsystem, which represents the unique imprint (or 'footprint') of paleo-ice stream activity (see Stokes and Clark, 2001). Indeed, numerous paleo-ice stream imprints have now been recognized from all of the major paleo-ice sheets from the last ice age (e.g., Laurentide, Scandinavian-Barents Sea, British-Irish; see special issue introduced by Clark et al., 2003) and even those from more ancient glaciations 100s of millions of years ago (Moreau et al., 2005). Paleo-ice stream imprints have also been reported from predominantly bedrock terrain (e.g., Roberts and Long, 2003), including in mountainous areas (cf. Evans, 1996), based on the morphometry and pattern of streamlined erosional landforms.

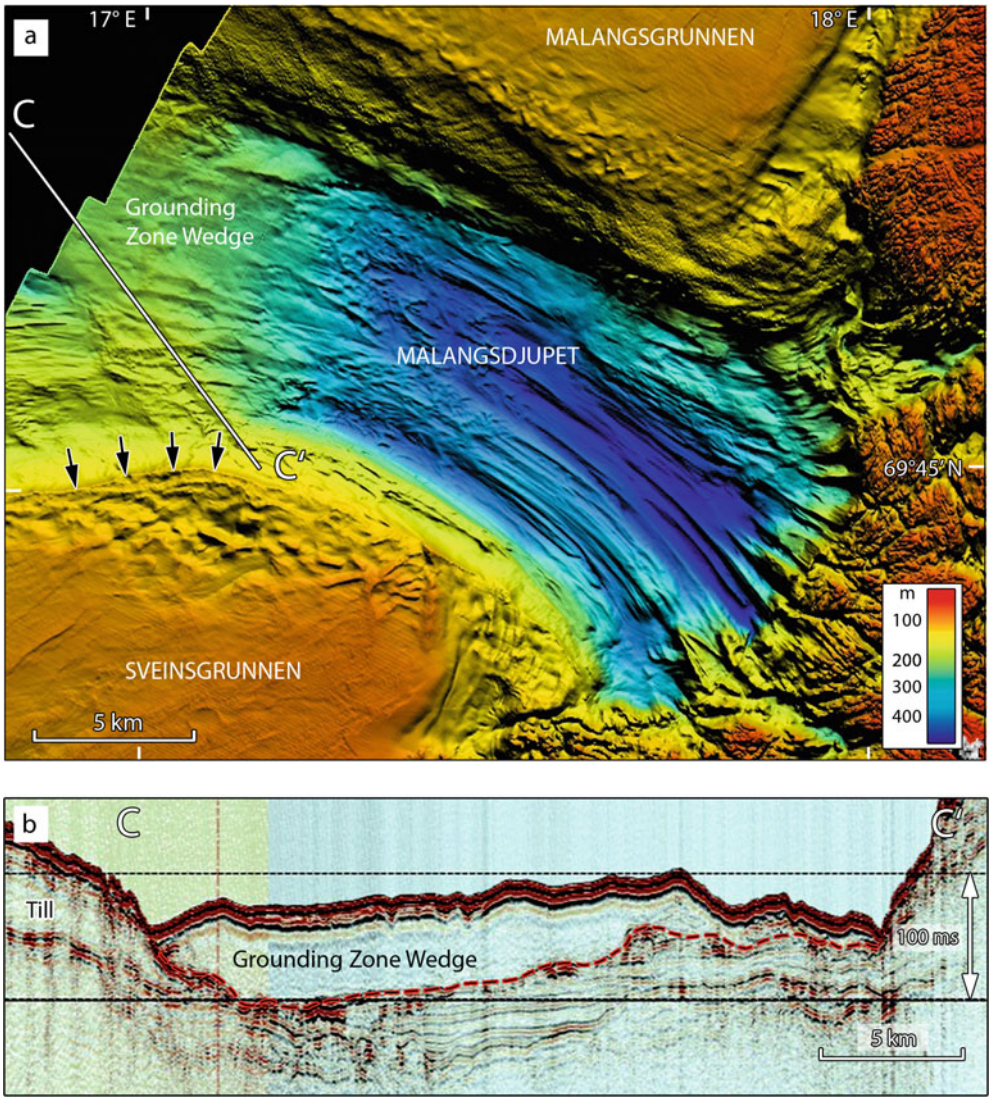
Palaeo-Ice Stream, Table 1 Geomorphological criteria for identifying paleo-ice streams (From Stokes and Clark, 1999)

Contemporary ice stream characteristic	Proposed geomorphological signature
A. Characteristic shape and dimensions	1. Characteristic shape and dimensions (>20 km wide and >150 km long)
	2. Highly convergent flow patterns
B. Rapid velocity	3. Highly attenuated subglacial bedforms
	4. Boothia-type erratic dispersal trains (see Dyke and Morris, 1988)
C. Sharply delineated shear margins	5. Abrupt lateral margins (<2 km)
	6. Ice stream marginal moraines
D. Deformable bed conditions	7. Glaciotectonic and geotechnical evidence of pervasively deformed till
E. Focused sediment delivery	8. Submarine accumulation of sediment, e.g., "trough mouth fan" or "till delta," (only marine-terminating ice streams)

Arguably, the best preserved paleo-ice stream imprints have been identified on the sea-floor of the continental shelf surrounding modern-day ice sheets (e.g., in Antarctica) and associated with paleo-ice sheets. Figure 1 shows an exceptionally well-preserved submarine paleo-ice stream bed off the coast of northern Norway in Malangsdjupet. This ice stream 'footprint' contains many of the geomorphological criteria shown in Table 1.

Paleo-ice streams in marine settings (e.g., see Figure 1) have been shown to exhibit a characteristic evolution of subglacial bedforms along their length (Wellner et al., 2001; Ó Cofaigh et al., 2002). The inner shelf is usually characterized by bedrock drumlins, crag-and-tails, and meltwater channels, which progress downstream into more elongated drumlins and highly attenuated mega-scale glacial lineations in major cross-shelf troughs. Significantly, the deglaciation signature may also be superimposed on this pattern, offering crucial insights into the style of ice stream retreat (Ó Cofaigh et al., 2008). Where ice retreat was slow and steady, a series of closely spaced transverse recessional ridges are found superimposed on top of the mega-scale glacial lineations. Major still-stand positions are marked by the intermittent building of 'grounding zone wedges' (GZWs), and a series of such features, with no recessional ridges in between, is thought to represent episodic retreat. Other imprints have been identified with very few recessional features (GZWs or recessional moraines) and with only a thin veneer of deglacial sediments. Such an imprint is thought to represent a rapid retreat of the ice stream (Ó Cofaigh et al., 2008).

The other broad approach to reconstructing paleo-ice streams is through the use of numerical ice sheet models (e.g., Tarasov and Peltier, 2004). Incorporating ice stream processes into ice sheet models represents a major scientific and computational challenge, which has been described as "one of the key goals of theoretical glaciology" (Hindmarsh, 2009). The challenge for numerical



Palaeo-Ice Stream, Figure 1 (**a**) Malangsdjupet paleo-ice stream from the former Fennoscandian Ice Sheet. This ice stream bed contains almost all of the geomorphological criteria for a paleo-ice stream imprint (see Table 1), including the characteristic shape and dimensions with a convergent onset zone, highly attenuated mega-scale glacial lineations on the floor of the trough, and abrupt lateral margins with lateral shear margin moraines (identified with *black arrows*). The trough also contains evidence of focused sediment delivery in the form of a grounding zone wedge, shown in a seismic profile in (**b**) (transect C to C′ shown in (**a**)) Sun illumination from NE (From Ottesen et al., 2008).

ice sheet models is to be able to incorporate the physics of ice streaming and reproduce the 'known' location of paleo-ice streams identified from geological/geomorphological evidence. This is a robust way in which the success of ice sheet models can be evaluated and tested (e.g., Stokes and Tarasov, 2010). Furthermore, there may be some paleo-ice streams where evidence is either scarce, obscured, or yet to be discovered. Numerical ice sheet models have the potential to predict these paleo-ice stream locations and guide the search for new discoveries.

Once identified, paleo-ice streams hold huge potential for advancing our understanding of past ice sheet dynamics and their links to the ocean-climate system. If we can reproduce a robust reconstruction of paleo-ice stream activity, it is possible to learn about their behavior over much longer timescales than present-day observations permit and their links to paleoceanography and abrupt climate change. Moreover, the exposed beds of paleo-ice streams permit access to the basal environment and facilitate investigation of subglacial sedimentary processes beneath ice streams, which is logistically very difficult beneath modern ice streams. The following sections briefly highlight the importance of paleo-ice stream research in each of these key areas.

Paleo-ice streams and past ice sheet dynamics

Any attempt to reconstruct the behavior of a paleo-ice sheet that ignores ice streaming is likely to be unrealistic. The large ice flux of ice streams has a profound impact on ice sheet configuration (e.g., thickness, margin extent, and ice divide locations) and so it is important to know where and when they operated in order to reconcile ice sheet reconstructions with their geological evidence. A good example to illustrate this point is the former North American Laurentide Ice Sheet (LIS).

Several workers reconstructed the low-surface profile of the LIS in many of its marginal areas, particularly where the underlying geology was characterized by relatively 'soft,' fine grained sediments (e.g., Mathews, 1974). These areas of thin ice were in conflict with models of the LIS that required a thick, single-domed ice sheet, centered over Hudson Bay (e.g., Denton and Hughes, 1981). However, the low surface slopes of the ice sheet are easily explained by the presence of ice streams whose rapid velocity was induced by the deformation of soft water-saturated sediments (Fisher et al., 1985). Indeed, the higher velocities of these ice streams can also explain the lobate nature of the ice sheet margin and subsequent work has reported clear evidence of paleo-ice stream imprints associated with such lobes (Patterson, 1998).

It has also been suggested that, once the LIS margin retreated back on to the more resistant ('hard') Canadian Shield rocks, ice stream activity was inhibited and ice sheet retreat was more stable (Clark, 1994). This geological control on ice streaming (which, incidentally, has also been suggested from work on modern-day ice streams: Winsborrow et al., 2010) has since been questioned; because robust evidence for ice streaming during deglaciation has been found on the Canadian Shield (Stokes and Clark, 2003). This discovery demonstrates that the spatial controls on ice streaming may be more complex than previously thought and highlights the importance of paleo-ice stream research in contributing to our overall understanding of their behavior. Indeed, a recent review by Winsborrow et al. (2010) identified seven potential controls on ice stream activity: topographic focusing, topographic steps, macroscale bed roughness, calving margins, 'soft' subglacial geology, geothermal heat flux, and subglacial meltwater routing.

Reconstruction of paleo-ice stream histories is also an excellent approach to understanding the temporal controls on ice streaming. Modern-day observations of their behavior are often limited to several decades, but reconstructions of paleo-ice streams are capable of spanning thousands of years of activity. For example, whilst much research is focused on the mass balance of ice streams draining into the Ross Ice Shelf in West Antarctica, examination of the paleo-ice stream tracks in their foregrounds indicates that they have been receding since the early Holocene and could continue to retreat even in the absence of further external forcing (Conway et al., 1999). Thus, paleo-ice stream research can provide a useful context in which to assess the significance of relatively small changes in their behavior that have been and will continue to be observed in modern-day ice sheets. Moreover, whilst it is known from contemporary ice stream research that ice streams are capable of switching positions and shutting down, research on paleo-ice streams has revealed equally dramatic switches in ice stream position from one glacial cycle to the next (e.g., Dowdeswell et al., 2006) and even during deglaciation of a single glacial cycle (e.g., Stokes et al., 2009).

Paleo-ice streams and subglacial processes

Although great progress has been made in understanding the subglacial environment beneath ice streams and the mechanisms that lead to their rapid flow (e.g., Alley et al., 1986; Engelhardt and Kamb, 1998), most information from the bed of modern-day ice streams is limited by the spatial and temporal resolution (e.g., indirect geophysical studies or borehole investigation). For this reason, many workers have recognized the potential that the now-exposed beds of paleo-ice streams hold for understanding their basal processes. The sediments and landforms they have left behind preserve important information regarding their basal processes and operation.

As noted above, the arrangement and morphometry of subglacial bedforms on paleo-ice stream beds has been used to hypothesize that highly elongate bedforms are associated with fast ice flow (e.g., Clark, 1993; Stokes and Clark, 2002). Due to the inaccessibility of modern-day ice stream beds, this hypothesis has been difficult to test. However, advances in geophysical techniques have led to their recent discovery beneath Rutford Ice Stream in West Antarctica, providing the first conclusive evidence of this relationship (King et al., 2009). Moreover, because ice streaming results in such a distinct subglacial landscape (characterized by elongated subglacial bedforms), it should be possible to identify and investigate the nature of localized 'sticky spots,' which are known to be important from studies of modern-day ice streams (e.g., Alley, 1993) but which, to date, have been very difficult to observe and characterize. Sticky spots should interrupt the predictable pattern of landforms that characterize a paleo-ice stream bed and be easily recognizable (cf. Stokes et al., 2007). They should also be manifest in the sediments preserved on the paleo-ice stream bed, which may even provide a 'smoking gun' of the mechanisms that led to ice stream shutdown. For example, Christoffersen and Tulaczyk (2003) reported an unusual till sequence from beneath the Baltic Ice Stream in southern Scandinavia, consisting of a strong and well-consolidated till crust, underlain by weak and poorly consolidated till. They hypothesized that this sequence could be associated with the processes of basal freeze-on, whereby meltwater is extracted from the subglacial till and accreted to the base of the ice stream. Such a process can starve the ice stream of its layer of lubricating water, leading ice stream shutdown.

Paleo-ice stream sediment transport and deposition

Paleo-ice streams can be extremely powerful erosional agents, especially those that extend across continental shelves and operate over soft, deformable, marine sediments (Vorren and Laberg, 1997). These ice streams can be very efficient at eroding and transporting subglacial sediment, and their sediment flux is comparable to the largest fluvial systems, despite their far shorter duration of operation. Moreover, the focused sediment discharge toward the shelf edge can create huge depocentres, known as 'trough mouth fans' (Vorren and Laberg, 1997; Vorren et al., 1998). Significantly, investigation of the architecture of these trough mount fans has enabled investigators to reconstruct past sediment fluxes and the long-term record of ice stream activity (ice discharge, velocity), sometimes extending back through several glacial cycles (Vorren et al., 1998). For example, the Norwegian Channel paleo-ice stream in southern Norway is thought to have transported $>3.2 \times 10^4$ km^3 of sediment on to the North Sea Fan during the last 0.5 million years, with extreme and punctuated sediment discharges as high as 1.1 Gt a-1 during the last glacial cycle (Nygård et al., 2007).

The extreme sedimentation rates associated with paleo-ice stream trough mouth fans also holds implications for geohazards, such as submarine debris slides and flows. It is known that the high sediment supply can lead to unstable deposits and an increased likelihood of slope failures in these areas, particularly after seismic activity and/or decomposition of gas hydrates (Vorren et al., 1998).

Paleo-ice streams, paleoceanography, and abrupt climate change

Finally, the large ice flux of paleo-ice streams also holds important implications for the delivery of icebergs and freshwater fluxes into the ocean. Ocean circulation (e.g., the North Atlantic thermohaline circulation) is highly sensitive to such influxes of freshwater and perturbation of these systems can lead to major and abrupt climatic changes (Broecker, 1994). Because ice streams have the capacity to drain large portions of an ice sheet relatively rapidly, they have the potential to deliver huge amounts of icebergs into the ocean and represent a key link in the coupling of the ice sheet and ocean systems. Episodes of ice streaming in Hudson Strait, for example, are thought to be responsible for several large iceberg export events into the North Atlantic between 60 and 10 ka (Broecker et al., 1992). Evidence for these events comes from bands of ice-rafted debris in ocean cores, known as Heinrich layers, which have been specifically linked to sedimentary rocks beneath a paleo-ice stream in Hudson Strait (Andrews and Tedesco, 1992). The influx of freshwater resulting from these events was sufficient to cause changes in sea surface temperature and salinity, which had a considerable impact on ocean circulation and northern hemisphere climate (Broecker, 1994). Although the trigger for these episodes of ice streaming remain unclear, it is now recognized that they can be instrumental in driving abrupt changes in mid-high latitude climate and oceanography.

Elsewhere in the LIS, paleo-ice streams have been implicated in similar iceberg discharge events, particularly at the northwestern margin in the Canadian Arctic Archipelago (e.g., Stokes et al., 2005). Significantly, the timing of these events is similar to those issued from the Hudson Strait ice stream, hinting at the possibility that they were part of a pan-ice sheet destabilization. The large marine-terminating ice streams at the northern margin of the Laurentide Ice Sheet are also thought to have contributed to the development of a thick (>1,000 m) Arctic ice shelf, which may have occupied the Arctic Ocean several times during the Late Pleistocene (Polyak et al., 2001), further emphasizing their important role in the ice sheet-ocean-atmosphere system.

Definition

Palaeoclimate: climates of the past
Past glaciations: the presence and action of glaciers in the past

Past glaciations

Glaciers have been considerably larger in the recent geological past and regular fluctuations in global ice volume characterized the Pleistocene (2.6 million years to 11,700 years ago), as well as during much earlier episodes in Earth history. The effect of Pleistocene glaciations on land has left characteristic landforms and sediments and these can be used to reconstruct former glaciers and their associated climates. Many areas have experienced multiple glaciations and, since the 1970s, it has been widely accepted that the quasi-regular changes in global ice volume during the Pleistocene were paced by cyclical variations in the Earth's orbit (Hays et al., 1976). However, the best-preserved glacial landforms and sediments are typically those formed during the Middle and Late Pleistocene. Glaciers have also fluctuated in size during the Holocene too, and moraine positions can be used to reconstruct even very recent climates, such as during the Little Ice Age (Grove, 2004).

Reconstructing former glaciers

Glaciers leave their mark by eroding, transporting, and depositing rock and sediment leaving a characteristic imprint on the landscape: glaciation. While glaciations have occurred on numerous occasions at different times through the geological column, the clearest evidence of glaciation is the product of the Quaternary glaciations: especially during the last cold stage and through the Holocene to the present day.

Geomorphological evidence of glaciation includes, among others, classic features such as cirques, arêtes, moraines, glacial lakes, and hanging valleys. The basis of glacier reconstruction rests on the accurate depiction of glacial features on a geomorphological map. The most important elements of glacial geomorphology for glacier reconstruction are features that mark the lateral, terminal, and vertical limits of former glaciers such as moraine crests and trimlines. Moraine crests mark the margins of former glaciers during ice advance or ice front stabilization while trimlines mark the transition on land surfaces between subglacial erosional processes and subaerial periglacial weathering.

The limits of former glaciers marked on geomorphological maps can be used to build the former ice surface. This is done by drawing ice-surface contours on to the former glaciers. The shape of ice contours should follow that observed on modern glaciers, whereby ice-surface contours are concave toward the top of the glacier and convex toward the snout.

Once the ice surface is reconstructed, the equilibrium line altitude (ELA) can be reconstructed. The ELA is crucial for palaeoclimate reconstruction. The ELA of a glacier is the altitude at which accumulation and ablation are equal. It is a critical concept in the understanding of glacier dynamics and there is a very close relationship between the ELA and the local climate (Ohmura et al., 1992). Several methods have been applied to calculate the ELA on former glaciers and the choice of method depends on the former glacier morphometry, former climate regime, and the nature of the geomorphological evidence (Benn and Lehmkuhl, 2000). These methods are outlined in Table 1.

Reconstructing palaeoclimate using former glaciers

Empirical curved or linear relationships

The relationship between glaciers and climate is fundamental toward understanding glacier behaviour. There are well-established relationships between annual precipitation, or accumulation, and summer mean temperature at the equilibrium line altitude (ELA) on glaciers around the world (Ohmura et al., 1992 and references therein) (see Figure 1). Various forms of this relationship have been applied to reconstructions of Pleistocene glaciers and the relationship provides one of the most useful approaches for palaeoclimate reconstruction using glacial evidence. However, the utility of the relationship between annual precipitation, or accumulation, and summer mean temperature at the equilibrium line altitude (ELA) for palaeoclimate work is constrained by the need to isolate one of these variables in order to derive the other. In particular, it is frequently very difficult to isolate summer temperatures for palaeoglaciological work and it is even more difficult to isolate values of precipitation in mountainous regions.

Degree-day modelling

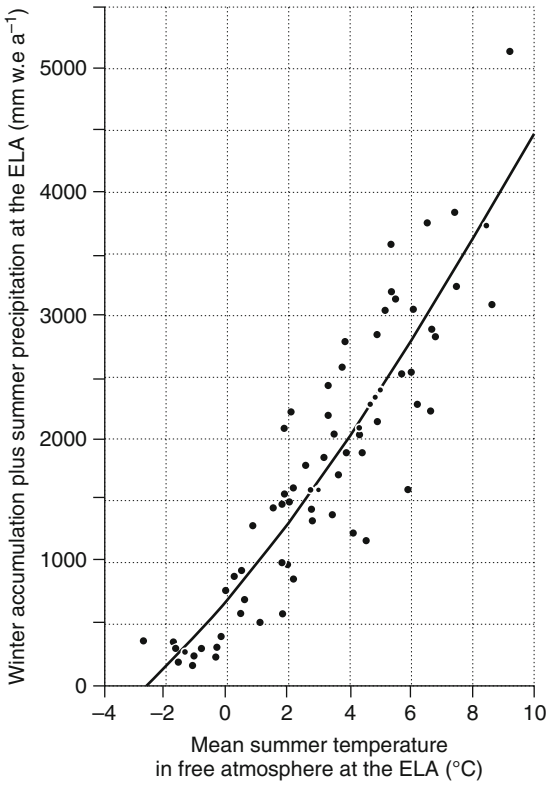
A degree-day model can be used to calculate the amount of accumulation required to sustain the glaciers. The degree-day model is based upon the notion that glacier melting occurs when air temperatures 1–2 m above the glacier surface are above the melting point (0°C). The total melt over a period at some point is therefore proportional to the sum of positive temperatures at the same point, i.e., the positive degree-day total. The annual accumulation required at the equilibrium line altitude to balance melting equals the sum of daily snowmelt, using a degree-day factor. Braithwaite (2008) found that degree-day factors for snow on 66 glaciers worldwide had averages of 3.5 ± 1.4 and 4.6 ± 1.4 mm day^{-1} K^{-1} in low- and high-accumulation conditions, respectively, with an overall mean of 4.1 ± 1.5 mm day^{-1} K^{-1}.

The degree-day model is widely used for modelling the mass balance of the Greenland ice sheet, but has also been applied to mountain glaciers and ice caps (Braithwaite et al., 2003). While the degree-day model has been used widely used in modern glacier-climate research, it has been utilized less so in palaeoglacier-climate research. However, degree-day modelling has been applied to reconstruct past climates associated with former glaciers in the USA (Brugger, 2006) and Greece (Hughes and Braithwaite, 2008).

Braithwaite (2008) used a degree-day model to demonstrate that the data underlying the single empirical curve of

Palaeoclimate and Past Glaciations, Table 1 Methods available for reconstructing palaeoglacier equilibrium line altitudes (ELAs). Sources are examples only and do not necessarily represent first usage

Method	Sources	Advantages	Disadvantages
Maximum elevation of lateral moraines	Benn and Lehmkuhl (2000, and references therein)	Simple, quick, and easy to apply in the field or using aerial photographs/satellite imagery	Inaccurate. Does not take into account lateral moraine formation during glacier recession
Toe-to-headwall altitude ratio (THAR)	Benn and Lehmkuhl (2000, and references therein)	Simple, quick, and easy to apply	Crude and takes no account of glacier hypsometry or climatic considerations. Requires some assumption on a suitable ratio
Toe-to-summit altitude method	Benn and Lehmkuhl (2000, and references therein)	Simple, quick, and easy to apply	Crude and takes no account of glacier hypsometry or climatic considerations
Median glacier elevation	Braithwaite and Müller (1980)	Appropriate for small cirque glaciers with even area/altitude distributions	Rarely applied on palaeoglaciers. Theoretically equivalent to an AAR of 0.5. Inflexible for different settings
Area-weighted mean altitude	Sissons (1974)	Appropriate for small cirque glaciers with even area/altitude distributions	Assumes a linear mass balance curve. Calculated ELA values tended to overestimate the real ELA
Accumulation area ratio (AAR)	Benn and Lehmkuhl (2000, and references therein)	Rigorously empirically tested. For modern mid- and high-latitude glaciers, steady state AARs generally lie in the range 0.5–0.8 with typical values lying in the range 0.6 ± 0.05	Does not take into account variations in glacier shape, particularly the distribution of glacier area over its altitudinal range, or hypsometry. AARs can be affected strongly by debris-covered glacier surfaces
Accumulation area ratio/ standard deviation	Kaser and Osmaston (2002, pp. 149–192)	Avoids problems of glacier hypsometry and defines a balance ratio by using standard deviation to isolate a statistical "best-fit" for the ELA	Not yet rigorously tested for accuracy on modern glaciers
Balance ratio	Furbish and Andrews (1984)	Takes into account both glacier hypsometry and the shape of the mass balance curve	Problems in defining analogous balance ratios



Palaeoclimate and Past Glaciations, Figure 1 Empirical curve relating mean summer temperature and winter accumulation + summer precipitation at 70 glaciers around the world (Redrawn using data from Ohmura et al. (1992)).

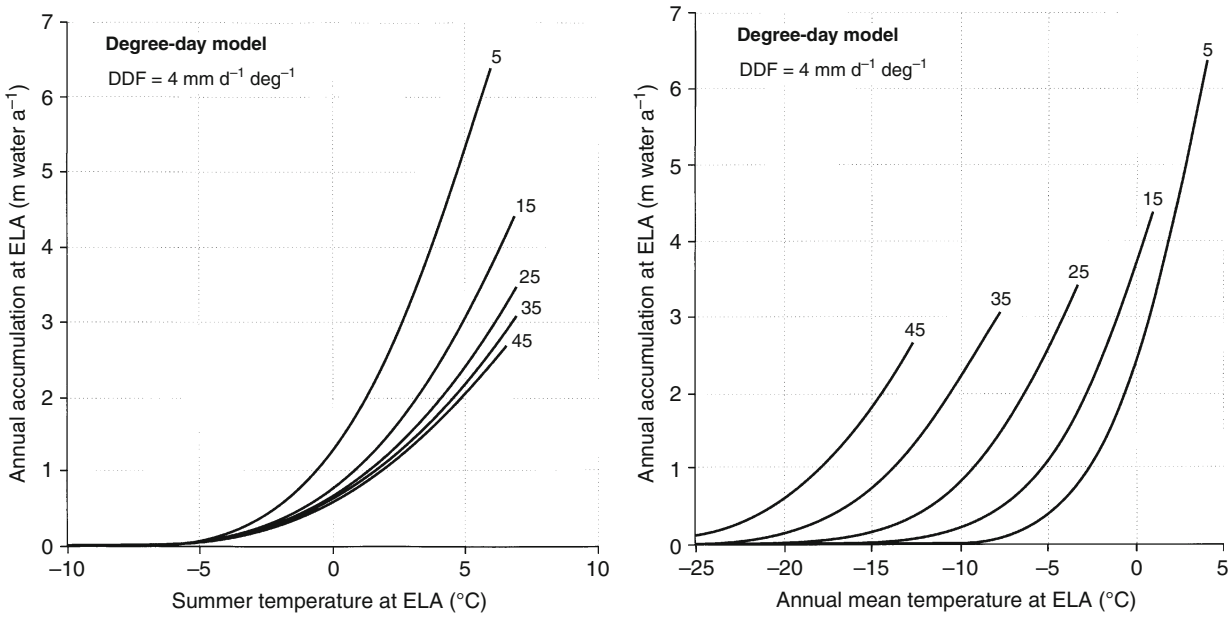
Ohmura et al. (1992) relating summer temperature and winter balance + summer precipitation is in fact better described by multiple curves, depending on the region. These different regional relationships are effectively determined by different annual temperature ranges (see Figure 2).

Energy balance modelling

This approach tends to be more complex than the previous two approaches and involves computation of different energy fluxes at the reconstructed glacier surface. Plummer and Phillips (2003) used a simple energy balance model to calculate the effects of topography on shortwave radiation, the largest component of the surface energy balance. Their model calculates the distribution of snow accumulation using a surface mass and energy balance approach and calculates the resultant glacier shapes with a two-dimensional flow model. However, this approach remains less widely used than simpler relationships between air temperature and mass balance, such as the Ohmura et al. (1992) regression. This is probably because of problems of complexity and uncertainties involved when reconstructing the former energy balance on palaeoglaciers.

Summary

Former glaciation can be interpreted using the geomorphological and geological record and used to reconstruct palaeoglaciers. In addition to glacier shape and form, the former equilibrium line altitude (ELA) can be reconstructed for past glaciers. The ELA of glaciers has a close relationship with climate and this fact can be utilized to reconstruct



Palaeoclimate and Past Glaciations, Figure 2 Annual accumulation at the equilibrium line altitude (ELA) as a function of summer mean temperature (June–August) and mean annual temperature (January–December). The degree-day model was applied assuming a sinusoidal temperature variation throughout the year with annual temperature ranges of 5, 15, 25, 35, and 45°C (Based on an approach described in Hughes and Braithwaite, 2008).

palaeoclimate on former glaciers. Three main approaches can be used: (1) empirical curved or linear relationships; (2) degree-day modelling; and (3) energy balance modelling. The first two are more widely used than energy balance – largely because of their simplicity, requiring relatively few inputs in order to model palaeoclimate.

PALAEOHYDROLOGY

Vijay Kumar
National Institute of Hydrology, Roorkee, India

Paleohydrology is the science of the waters of the earth, their composition, occurrences, distribution, and movement on ancient landscapes from the occurrence of the first precipitation to the beginning of continuous historic hydrological records. Paleohydrology provides a link between the scientific hydrology of the present with the sciences of Earth history and past environments (Schumm, 1967). The term "paleohydrology" was first used by Leopold and Miller (1954) in a study of alluvial chronology of valleys in Wyoming.

The major reason for the development of paleohydrology was to improve knowledge about hydrological conditions by providing information about events, conditions, and hydrological situations in periods prior to the availability of continuous records (Gregory, 1996). Paleohydrology enhances understanding of the impacts of human activity on the hydrological cycle, water balance, sediment yield, river channel morphology, and basin characteristics. A further purpose of paleohydrology has been to make a contribution to the understanding of the impacts of global climate change. As major impacts of global climate change are felt through the hydrological cycle, paleohydrology has a very important role to play in understanding these impacts.

Paleohydrology applies the knowledge of contemporary hydrology to information derived from geomorphological evidences, such as ancient channels and sediments. Paleohydrology involves several disciplines like meteorology and climatology, hydrology, hydrogeology, paleoecology, dendrochronology, archaeology, geomorphology, sedimentology, etc. to provide information about hydrological events prior to continuous hydrological records. Paleohydrological speculations and conclusions depend on existing knowledge of the effects of climatic, vegetational and geologic controls on runoff, sediment concentration and yield, water chemistry, groundwater and lake water levels, and the nature of flood events. There are three general modes of paleohydrological inferences. First, the general theories of hydrology are used to infer specific effects that can then be discerned in evidence of past hydrological processes. Second mode of paleohydrological inference uses empirical relationships that are developed from numerous observations of related hydrological phenomenon. Third mode of reasoning, which is used extensively in paleohydrology, is retro-deductive or abductive inferences (Baker, 1998).

PAMIRS

Vladimir Aizen
College of Science, University of Idaho, Moscow, USA

Synonyms

Alpine glaciers; Glaciers of central Asia; Glaciers of Kyrgyzstan, Tajikistan, China, Afghanistan; Glaciers of mid-latitudes; Pamir

Definition

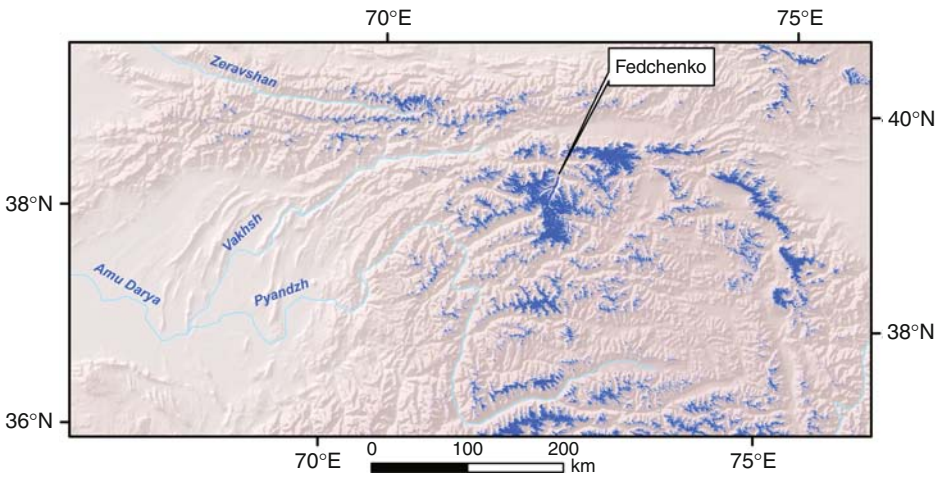
The alpine glaciers of the mid-latitudes that exist in the Pamir Mountains in sub-continental and arid continental climate.

The Pamir is one of the largest and highest mountain systems in Asia. It occupies the territory of Tajikistan, north-eastern Afghanistan, and the north-western part of China between 36° N and 40° N and 66° E and 76° E, 450 km from north to south and 850 km from west to east. The Pamir elevation and terrain is very diverse, ranging from 300 m at the lower Amu Dariya River to 7,700 m at the eastern Pamir in China. The Pamir Mountains are situated between the Aralo-Caspian and Tarim endorheic basins and the Indian Ocean. By 1990, Pamir glaciers covered approximately 12,000 km^2 (13,000 glaciers, 1,300 km^3 volume of ice) (Glacier Inventory of the USSR, 1979; Glacier Inventory of China. IV, 1987, Dolgushin and Osipova, 1989). Many Pamir glaciers including the giant Fedchenko Glacier are surging glaciers (Zabirov, 1955; Dolgushin and Osipova, 1989). Glaciers of the Pamir high mountains supply water to over 60 million people in Tajikistan, Uzbekistan, Turkmenistan, Afghanistan, and Xinjiang province of the PR of China. The Amu Dariya River is the largest central Asian river (2,400 km long, 534,739 km^2 total basin area), which originates in the Pamir Mountains of Tajikistan and Afghanistan. The Amu Dariya River provides 65% of inflow to the Aral Sea. The main moisture delivered to Pamir glaciers are from the Westerlies (southwestern cyclones). Indian monsoon occasionally reaches south eastern Pamir in summer (Aizen et al., 2009). Two thirds of annual precipitation occurred in the winter and spring seasons.

By glacio-climatic regime and landscape, Pamirs are divided into five major regions: Pamir-Alai, Western Pamir, Central Pamir, South-Eastern, and Eastern Pamir (Figure 1).

Western Pamir receives highest rate of annual precipitation (up to 2,000–2,500 mm) but only one fourth of precipitated snow gets accumulated and transferred to firn and ultimately to ice. Elevations of mountain ridges in the western Pamir are no more than 5,000 m. The Equilibrium Line Altitude (ELA) in this region ranges between 3,600 and 4,000 m a.s.l. and over 70% glacier covered area spread between 3,400 and 4,200 m a.s.l. Glaciers in western Pamir largely fed by avalanches and accumulation areas characterized by warm infiltration-recrystallization type of ice formation. Glaciers in western Pamir exist mainly at the northern slopes in deep high elevated valley, cirques, and niches.

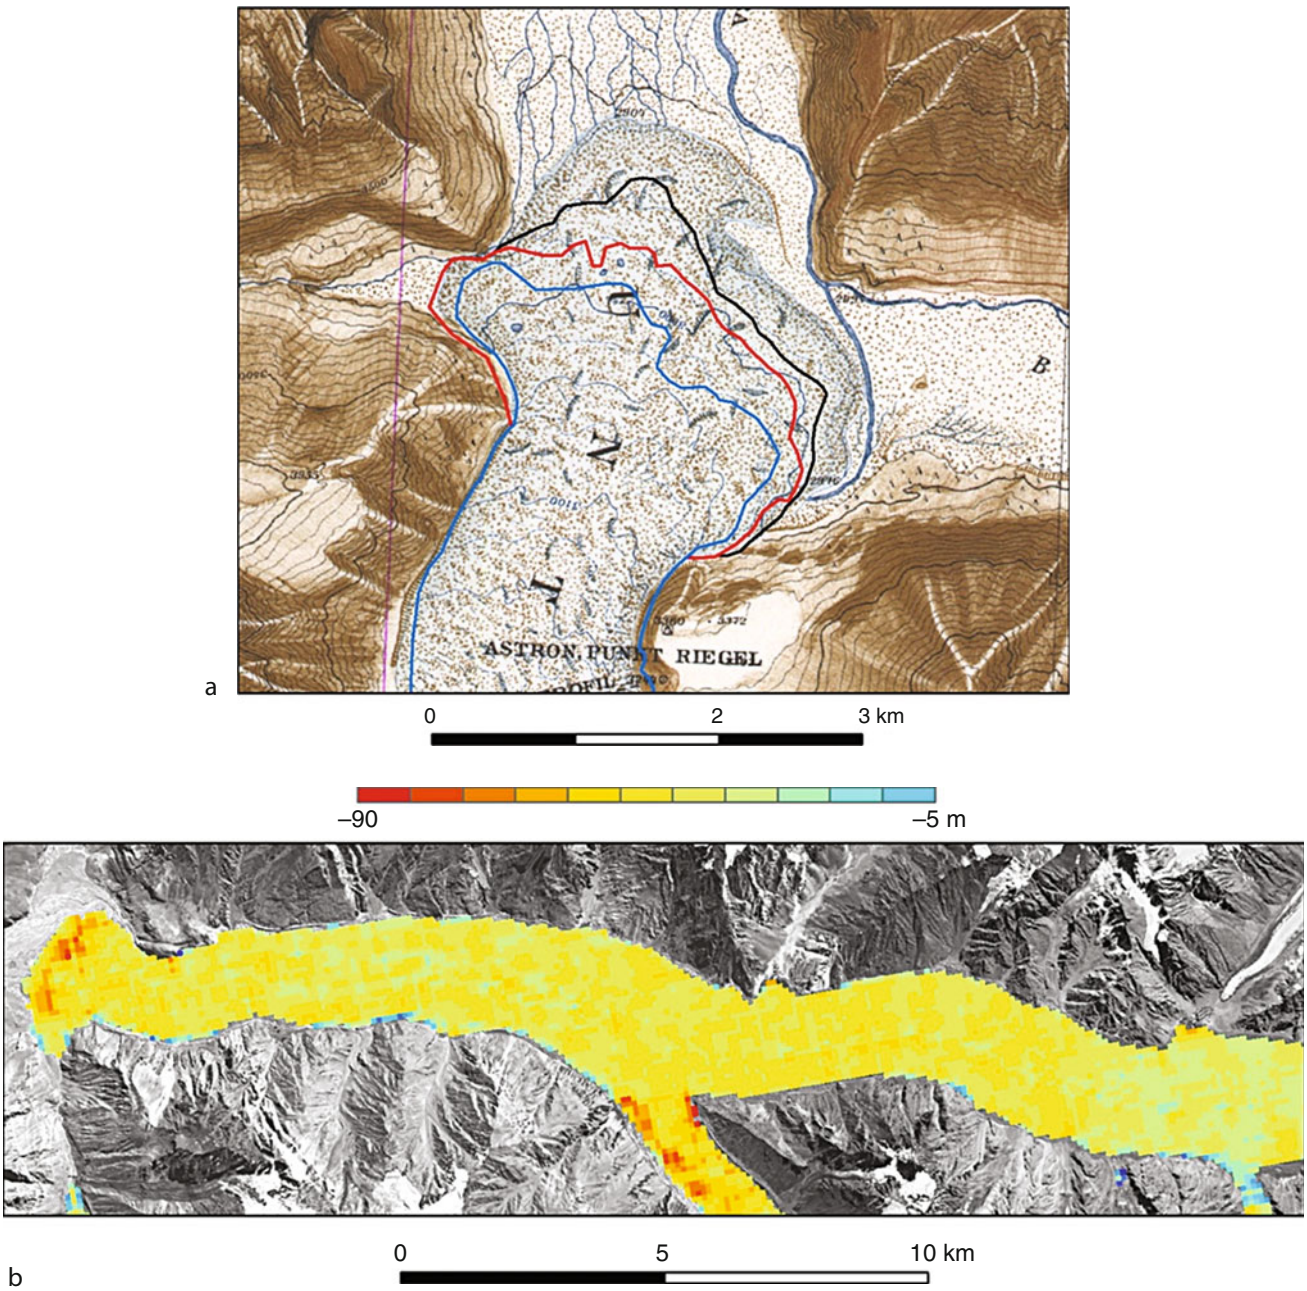
Central Pamir represents glacierized massifs with large dendrite glaciers and accumulation zone reaching 7,400 m a.s.l and ELA rises to 4,400–4,800 m a.s.l. Fedchenko Glacier in central Pamir is the world's largest alpine glacier outside of the polar regions, 72 km long, 714 km^2 total area and 900–1,000 m ice thickness at elevation over 5,000 m. Surface ice velocity of the Fedchenko glacier may reach 150–200 m a year. Annual precipitation in central Pamir varies between 800 and 1,500 mm. The cold infiltration-recrystallization zones of ice formation largely spread at the high elevated accumulation areas in central Pamir. Ten to fifteen percent of glacier tongues were surface covered by moraine debris in the western and central Pamir (Schetinnikov, 1998). Central Pamir has many surging glaciers including most



Pamirs, Figure 1 Glaciers of the Pamir Mountain system.

known Medvejiy Glacier, which has 12–15 years interval between the surges.

Eastern Pamir high elevation plateau spread over 4,000 m a.s.l. occupying approximately 100,000 km^2 and has extremely arid climate with annual precipitation between 50 and 150 mm similar to Tibetan Plateau. Glaciers in this area dispersed and existed mainly along high elevated ridges over 5,000 m. Glaciers in the eastern Pamir represented by ice-caps and slope niche glaciers, with small numbers of valley glaciers in eastern part of Zaalaiskiy Ridge at the eastern edge of Pamir and particularly in the Muztagata-Kongur glacierized massifs with the highest elevations in Pamir (7,500–7,700 m a.s.l.). ELA in eastern Pamir ranges between 4,800 and 5,200 m a.s.l. During summer, meltwater saturates through thin winter accumulation layers, refreezes, and forms ice during 1–2 years. Extremely dry air and high solar radiation create an ideal condition for moisture evaporation from



Pamirs, Figure 2 Glacier Fedchenko area changes between 1928 (*map in background*) and 1958 (*black line*), 1980 (*red line*) and 2009 (*blue line*) (**a**), and the glacier surface lowered between 1958 and 2009 (**b**) (Aizen et al., 2010b).

snow surface during ablation period. The eastern Pamir glaciers are covered very little by moraine debris in contrary to the western and central Pamir glaciers.

Since the end of Little Ice Age (LIA), glaciers of Pamir continue to retreat but the rate of glacier recession is different even within each of the regions that are described above. The largest recession (15%), during the last 50 years, was observed in western Pamir in Gissaro-Alai ridges and smallest in the central and eastern Pamir regions (3–5%). The largest Fedchenko Glacier retreated 1,131 m during the last 80 years (755 m from 1958 to 2000). The total area loss was 2 km^2 from 1958 to 2009 of the total 716.1 km^2 in 1958. However, the surface of this glacier melted and lowered to 90 m on the glacier tongue area at 2,896 m a.s.l. and 40 m at elevation of 4,000 m (Figure 2) (Aizen et al., 2010a). The river runoff in Pamir rivers increased by 2% during the last 10–20 years due to increase of air temperature and glacier ice melt and precipitation in high Pamir Mountains.

PANCAKE ICE

Chelamallu Hariprasad
Centre for Studies in Resource Engineering, Indian Institute of Technology, Bombay Powai, Powai, Mumbai, Maharashtra, India

Pancake ice is a form of ice that consists of round pieces of ice with diameters ranging from 30 cm to 3 m, depending on the local conditions that affect ice formation. It may have upto 10 m thickness. Pancake ice features elevated rims with a nearly uniform height of a few centimeters. These rims are the first indication of the onset of the formation of the pancake ice from less consolidated forms of ice.

Pancake Ice, Figure 1

Pancake ice may be formed in two ways. It may be formed on water covered to some degree in slush, shuga, or grease ice.

PAPUA

Ian Allison
Australian Antarctic Division and Antarctic Climate and Ecosystems CRC, Hobart, Tasmania, Australia

Definition

Papua is the official Indonesian and internationally recognized name for the province. After Indonesian annexation in 1969, the province became known as "West Irian" or "Irian Barat" until 1973, and thereafter was renamed "Irian Jaya" by the Suharto administration. The official name "Papua" was adopted in 2002.

Introduction

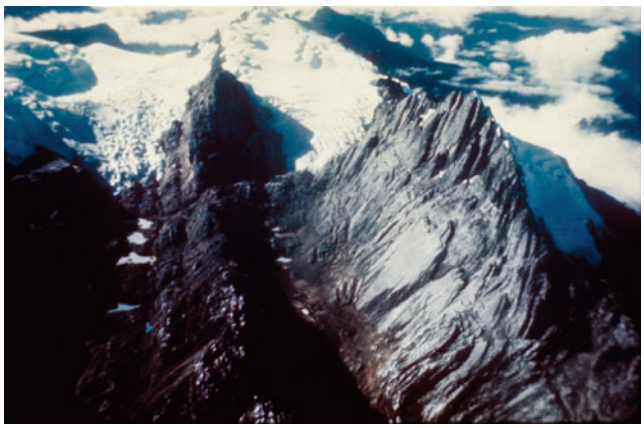
The only present-day equatorial glaciers in the Asian region are in the Indonesian province of Papua (formerly Irian Jaya) on the western part of the island of New Guinea. These small glaciers lie at elevations of over 4,400 m around the highest part of the Central Cordillera of New Guinea, Puncak Jaya (formerly Carstenz Pyramid or Mt. Carstensz). Located at 4°05′ S, 137°10′ E, the glaciers are only about 450 km south of the Equator.

Puncak Jaya Glaciers

Although native hunters have been active in the Puncak Jaya area for more than 5,000 years, the first westerner to report sighting these glaciers was the Dutch explorer, Jan Carstenz, sailing in the Arafura Sea to the south in 1623. It was not until 1936 that a European party, led by A.H. Colijn, reached the main glacier area with support from aircraft reconnaissance and food depots. During this visit, the geologist J.J. Dozy marked the location of the glacier snouts and obtained oblique aerial photographs of the glaciers. Expeditions from a consortium of Australian Universities made two visits to the area (December 1971 to March 1972 and January to February 1973) and undertook the first comprehensive scientific investigations of the glaciers and the surrounding region.

In 1972, there were five main glacier masses in the region, covering a total area of about 7 km^2 and an estimated total ice volume of about 0.25 km^3 (Allison and Peterson, 1976). These were the western and eastern portions of the Northwall Firn (3.6 km^2), divided by ice-free New Zealand Pass; two westward flowing valley glaciers, the Meren Glacier (2.2 km^2), and the Carstensz Glacier (1.4 km^2); and the Southwall Hanging Glacier (0.1 km^2) on the steep south face of Puncak Jaya (Figure 1). The Meren Glacier, which was contiguous with the eastern portion of the Northwall Firn, was so-called because of the large number of small englacial lakes that covered its ablation zone. The area for the Carstensz Glacier includes two small contiguous ice masses, the Wollaston and Van de Water glaciers that flow southward from the ice divide at the top of the Carstensz Glacier.

The Meren Glacier and the Carstensz Glacier have the morphology of classical valley glaciers. The centerline length of the Meren and Carstensz glaciers in 1972 were about 1.9 and 1.7 km respectively. The Meren Glacier had a mean ice thickness of 40 m, a maximum measured ice thickness of 81 m, an average of 25 m/year and a maximum measured surface velocity of 34 m/year. The Carstensz Glacier had a mean ice thickness of 38 m and a maximum measured ice thickness of 74 m. Because it was slightly thinner, and less steep than the Meren, ice movement was slower, with an average centerline surface velocity of 15 m/year and a maximum measured surface velocity of 18 m/year. The ablation zones of both glaciers were temperate. The morphology and dynamics of these glaciers are described by Allison (1975, 1976).



Papua, Figure 1 1972 oblique aerial photograph looking east and showing, from left to right, eastern portion of the Northwall Firn, Meren Glacier flowing into the Yellow Valley, Carstensz Glacier flowing into Carstensz Valley, and Southwall Hanging Glacier on the back of Puncak Jaya. (Photograph: Australian Universities' Carstensz Glaciers Expedition.)

Seasonal climatic variations on the Puncak Jaya massif are slight, and the monthly mean temperatures vary by less than 0.5°C over the year. There appears to be no marked seasonal variation in precipitation, radiation, or cloud cover (Allison and Bennett, 1976). Hence the net surface mass balance of the glaciers is relatively uniform over the year. Ablation tends to occur year round below the equilibrium line and accumulation occurs year round above it. Surface mass balance measurements over 1972 indicated an equilibrium line altitude of 4,580 m, with an accumulation area ratio of 0.59 for the Meren, and 0.66 for the Carstensz. The net annual balance in 1972 varied between +1 m/year water equivalent (w.e.) at 4,800 m elevation, near the top of the glaciers, and −5 m/year w.e. at 4,400 m, near the termini. Both the Meren and Carstensz Glaciers had a negative mass budget, consistent with their observed retreat.

Retreat of the Puncak Jaya glaciers since the mid-nineteenth Century

Peterson et al. (1973) estimated the mid 19th Century (approx. 1850) neoglacial extent of the Puncak Jaya ice masses from moraines and other geomorphologic features as 19.3 km^2. Since then a steady retreat of the glaciers has been recorded from cairns left by various expeditions to mark the glacier fronts, from aerial photographs, and more recently from satellite images. By 1942 the total ice area had reduced to 9.9 km^2 (Allison and Peterson, 1976); by 1972 it had reduced further to 7.3 km^2 (Allison and Peterson, 1989); and by 2002 there was only 2.1 km^2 of ice-covered area remaining (Klein and Kincaid, 2006). Allison and Kruss (1977) used a simple 2-D flow-line model of glacier dynamics to show that the retreat of the Meren and Carstensz glaciers between 1850 and 1972 was most likely due to a temperature increase of 0.6°C over the period, rather than to changes in snowfall.

Between 1992 and 2000 the Meren Glacier disappeared completely, the western Northwall Firn fragmented into several small remnants, and the Carstensz Glacier reduced to half its 1972 extent (Klein and Kincaid, 2006).

Other ice masses in Papua

As well as the glaciers of Puncak Jaya, the high peaks of Papua have supported other ice areas in the recent past. These have been rarely visited, but high resolution satellite monitoring provides a sketchy record of their retreat. On Ngga Pilimsit (Idenburg-top; 4°03′ S, 137°02′ E; 4,717 m), about 12 km west of Puncak Jaya, a small ice cap on the summit (several hundred meters in diameter) and a slightly

smaller glacier on an adjoining ledge existed until at least 1983 (Allison and Peterson, 1989), but had disappeared by 2003 (Klein and Kincaid, 2006). An ice cap on Puncak Trikora (Wilhelmina-top; 4°15′ S, 138°45′ E; 4,730 m) disappeared sometime between 1939 and 1962 (Peterson et al., 1973), and the small ice cap on Puncak Mandala (Juliana-top; 4°48′ S, 140°20′ E; 4,640 m) disappeared between 1989 and early 2003 (Klein and Kincaid, 2008).

Summary

All the small ice caps on the high mountains of Papua have disappeared over the last century, and only remnants of the larger ice fields in the Puncak Jaya area remain. Even here, by 2002 the total ice area had reduced to about 11% of its mid-nineteenth century extent, and one of the two valley glaciers, the Meren, had disappeared by 2003 (Klein and Kincaid, 2006). The retreat rate of the Papuan glaciers appears to be fairly uniform since ~1850, although Klein and Kincaid (2006) do report periods of more rapid retreat in total ice extent in the late 1930s and in the 1970s. With continuing retreat at the average rate over the last century, no significant ice masses will remain in Papua beyond the middle of the twenty-first century.

PARAGLACIAL LANDSCAPE TRANSFORMATIONS

Lasafam Iturrizaga
Geography/High Mountain Geomorphology, Institute of Geography, University of Göttingen, Göttingen, Germany

Synonyms

Glacially conditioned; Transglacial

Definition

The term paraglacial ("para" (prefix) from Greek, alongside, beyond, altered, contrary to) means literally "beyond the glacier" (Slaymaker, 2004) and has been defined as non-glacial processes, which are directly conditioned by glaciation (Church and Ryder, 1972).

Paraglacial landforms are formed during and after the deglaciation in the course of the readjustment toward an assumed environmental equilibrium stage. Besides its general meaning, the term "paraglacial" has been used in a temporal way ("paraglacial period," "paraglaciation") as well as in a spatial context.

Introduction: evolution of a geomorphological concept

The term "paraglacial" has been employed by Ryder (1971) for explaining the formation of alluvial fans by the fluvial redeposition of glacigenic till following the Wisconsinan deglaciation in the Fraser and Thompson Rivers (British Columbia) (Figure 1). In order to evaluate the findings, comparative studies have been carried out in a presently glaciated area in Baffin Island (Canadian Arctic) where paraglacial sedimentation supposed to be highly active (Church and Ryder, 1972). Subsequently "paraglacial" has been defined as "non-glacial processes, which are directly conditioned by glaciation" and referred "both to proglacial processes, and to those occurring around and within the margins of a former glacier that are the direct result of the earlier presence of the ice" (Church and Ryder, 1972). Even though this definition is already rather broad, its interpretation became in the following decades considerably extended beyond the application for the glacially conditioned formation of fluvial landforms.

Ballantyne (2002a) has compiled the main research studies concerned with the adaptation of the landscape after deglaciation and introduced an overall concept for "paraglacial geomorphology." It includes the study of earth-surface processes, sediments, landforms, landsystems, and landscapes that are directly conditioned by non-glacial earth-surface processes triggered by the former glaciation and deglaciation. Since then, research topics on paraglacial geomorphology increased significantly in number (Mercier and Étienne, 2008), especially in the light of global warming and the associated landscape response to deglaciation (André, 2009). The dominant glacier shrinkage since the Little Ice Age resulted in

Paraglacial Landscape Transformations, Figure 1 Paraglacial valley fill in the Fraser Valley (British Columbia). Photo: L. Iturrizaga Sept. 1999.

deglaciated terrain in the order of several kilometers in length and some hundred meters in absolute height which offers an excellent landscape setting to investigate the historical and most recent paraglacial geomorphological activity (e.g., Harrison and Winchester, 1997; Curry et al., 2006, Figure 2). Besides that, the overall landscape development after the Lateglacial deglaciation has been a major concern of paraglacial morphology challenging especially conventional periglacial landform interpretations.

Key issues of the paraglacial concept

In principle, the term "paraglacial" is not linked to a specific process, but includes a variety of non-glacial processes which might be conditioned directly by the former glaciation and occur during the adjustment of the landscape after deglaciation. The paraglacial concept cannot be pinpointed by processes (Ballantyne, 2003), even though the expression of "paraglacial processes" has been now in common use (André, 2009). It rather focuses on conditions of accelerated geomorphological activity after glacier retreat. A common feature of deglaciated landscape is the supply of additional sediment sources, such as unstable rock walls or glacigenic sediment storages, which are prone to further erosional processes. The paraglacial effect is materialized by the extraordinary sediment supply which exceeds by far the rate of debris produced by weathering. In turn, high sediment transfer rates result in different landforms of temporary storage. These landforms may often be identical with fluvial or mass movement landforms. Enhanced sediment transport continues as long as sediment supply areas remain accessible to fluvial activity. Therefore the paraglacial imprint can by far outlast the actual period of deglaciation.

Paraglacial sediment yield and sediment cycle

One of the key results of the study of Ryder (1971) is that the sedimentation of the alluvial fans in British Columbia River took place soon after deglaciation in the Early Holocene proved by a volcanic ash layer (Mazama ash, 6,000 years B.P.) in the top part of the alluvial fans. Thus, it was assumed that the rate of sediment yield is higher immediately after ice retreat, but later declines towards the regional average rate. (Church and Ryder, 1972).

Church and Slaymaker (1989) investigated the specific sediment yield of drainage basins of different sizes in British Columbia. In contrast to previous models, in which the specific sediment yield declines with increasing drainage basin area, they showed that the sediment yield increases for larger basins. The reason supposed to be that most of the sediment yield derives from reworked valley fill deposits from the Quaternary glaciation. Thus, they concluded that the rivers still respond to the deglaciation and extended the paraglacial period from some one thousand years as proposed earlier to more than 10,000 years. The crucial quintessence of this assumption is that the recent sediment yield does not reflect the erosion rate for the prevailing climatic and regional geology setting in the Holocene, but it is still influenced by the effects of the Quaternary glaciation. During the deglaciation occurs a shift from the redistribution of sediment material from the upland toward the major valleys, which was termed

Paraglacial Landscape Transformations, Figure 2 The Bualtar valley (Karakoram) has been deglaciated in the mid of the twentieth century. The slopes are covered with paraglacial talus cones of different ages. Photo: L. Iturrizaga Aug. 2000.

as paraglacial sediment cycle (Church and Slaymaker, 1989). This fact supposed to explain the downstream increase in sediment yield in river basins in British Columbia.

Jordan and Slaymaker (1991) considered perturbations of the paraglacial sedimentation cycle in form of volcanic activity and associated debris flows and human impacts. Harbour and Warburton (1993) have reflected the variation of catchment size in the paraglacial model and came up with varying relaxation times, which depend on the scale of the catchment. They proved that the different catchment sizes may show identical sediment yield. Moreover, the peaks in specific sediment yield may vary in time for different catchment sizes.

The glacially conditioned sediment release has been formalized by a sediment exhaustion model Ballantyne (2002b), which is based on steady-state conditions and the precondition that sediment sources are not replenished. Assuming that the rate of sediment release is dependent only on sediment availability, it declines approximately exponentially through time. New approaches have been undertaken to quantify the paraglacial sediment storage in order to allow conclusions on the sediment flux rates and finally on the landscape evolution (Otto, 2009).

Paraglacial period

The "paraglacial period" was originally referred to as the "time during which paraglacial processes occur" (Church and Ryder, 1972). Ballantyne (2003) has suggested a redefinition as "the timescale over which a glacially conditioned sediment source either becomes exhausted or attains stability in relation to particular reworking processes." The paraglacial period covers a time span of only 10–100 years up to more than several ten thousand years (Ballantyne, 2002a). The readjustment of sediments in recently deglaciated glacier forefields counts to the more short-term readjustments (Curry, 2000), whereas the valley flanks in solid rock may need a longer time for relaxation.

The time scale of the paraglacial period depends among others on the topographical setting, the intensity of the erosion and the occurrence of temporary storage areas. Vegetation is also a controlling factor in terms of the duration of paraglacial activity (Church and Ryder, 1972). Lakes, such as the suite of glacial lakes in the Tasman valley (New Zealand), may significantly delay the paraglacial influence on the lowlands. Here the rivers are still responding on the Quaternary glaciation, and the Canterbury Plains with their extensive braided river systems may be considered as the result of the Lateglacial ice retreat. However, intra-catchment variability has to be taken into account with respect to the magnitude-frequency regime in regard for the prediction of sediment fluxes in response to hydro-climatic forcing (Carrivick and Rushmer, 2009).

The paraglacial period supposed to start with the beginning with the glacial sedimentation. The effective duration of the paraglacial period may vary considerably, and its end is difficult to determine precisely, especially when including the secondary paraglacial systems. In general, it may extend the glaciation phase and ensue into the non-glacial interval (Slaymaker, 2004). A stratigraphical differentiation of this transitional period is not possible.

Paraglacial landsystems

Ballantyne (2002a) has extended the paraglacial concept so far, that it should become suitable for an own subdivision of geomorphology. Thus, paraglacial geomorphology encompasses landsystems, landforms, and associated processes as well as the paraglacial period, in which paraglacial processes take place. Using the landsystem approach, six paraglacial landsystems are distinguished: rock slopes, drift-mantled slopes, glacier foreland, alluvial, lacustrine and coastal systems.

Primary paraglacial systems are those in which the released sediment has been directly conditioned by glaciers. Secondary paraglacial systems includes the reworking of paraglacial sediment stores (Ballantyne, 2002b). Ballantyne (2003) has also proposed a paraglacial sediment cascade differentiating between (a) sediment sources (rockwalls, drift-mantled slopes, valley floor glacigenic deposits, and coastal glacigenic deposits), (b) primary sediment stores (i.e., talus cones, debris flow deposits, alluvial fans, barrier beaches), (c) secondary sediment stores (i.e., alluvial valley fill deposits, lacustrine deposits, coastal deltas), and (d) sediment sinks (alluvial valley fill deposits, lacustrine deposits, coastal and nearshore deposits, shelf and offshore deposits). The transport from the sediment source to the sediment sink is not linear, but may involve several cycles of deposition and resedimentation. External perturbations may complicate significantly the process succession in this simplified model. Besides the paraglacial fluvial landforms, Ballantyne (2002a) highlights among others the importance of the adjustment of rock slopes after deglaciation (Wyrwoll, 1977; Augustinus, 1995; Ballantyne, 2008). He distinguished the rock slope system by the mode of failure (catastrophic rock slope failure, rock mass creep and progressive small-scale rock fall activity). Rock slope failure at the glacially oversteepened valley flanks may be caused by debutressing and unloading processes in association with stress release after deglaciation (Cossart et al., 2008). The inclusion of coastal landsystems into the paraglacial concept has been one of the major extensions of glacially conditioned landscape transformation (Forbes and Syvitski, 1994). Therewith, the paraglacial concept has extended its focus from the mountainous areas toward the final sediment sink, the ocean, and made the model even more a holistic landscape approach.

Distribution of paraglacial landsystems and landforms

Paraglacial landforms occur in proglacial as well as in lateroglacial environments, i.e., in valley-side locations at the lateral margins of the glaciers. Paraglacial landscape transformation is most obvious in mountainous areas, where steep slopes provide the necessary relief energy for enhanced geomorphological processes. During the paraglacial period, an intensification of non-glacial processes takes place.

Each mountain region around the world possesses a specific paraglacial landform assemblage depending on the geological, topographical, and climatic setting (especially during the deglaciation); ice thickness; glacier type (topographical and thermal regime); and ratio of accumulation–ablation area. Thus, the individual mountain regions show in particular major differences in the distribution in moraine-mantled slopes.

The greatest altitudinal range of paraglacial landforms is achieved in High Asia, especially in the Karakoram (Iturrizaga, 1999a). The Karakoram represents a classical example of moraine-mantled slope environments (Li et al., 1984; Owen and Derbyshire, 1989). The topographical setting and therefore the glacier type and the ice thickness determine to some extent the availability of moraine-mantled valley slopes. Ice thicknesses of up to 2,900 m have been reconstructed in this mountain range (Kuhle, 2001). Despite the extensive glaciation, high amounts of relief still surmounted the ice stream network and delivered a large amount of debris into the lateroglacial environments (Iturrizaga, 2003). The vast sediment availability is a result of an ice stream network which disintegrated gradually into individual glaciers and which were still themselves dendritic glaciers types.

Tributary glaciers became disconnected with the main glacier and supplied sediment material mainly by glaciofluvial activity. Moreover, the immense ice thickness and increased stress pattern on the valley flanks resulted in major rock slope failures after deglaciation, especially in large-sized rock avalanches (Hewitt, 1999), but as well in the formation of glacially induced talus cones (Iturrizaga, 1999a).

The local ice thickness controls the center-to-periphery change of the distribution of paraglacial landforms. Ice thickness may generally be the highest in the upper middle part of the glacier stream. Thus, a reduced vertical relief amplitude has been transformed by glacial processes toward the mountain interior and the former glacier terminus. The glacially induced talus cones are replaced upvalley by talus cones originating from weathering processes on the parent rock.

A glacially history-based concept of the development of debris accumulations in High Asia (Hindukush, Karakoram, Himalayas) has been proposed by Iturrizaga (1999a, b). In this regard, the term "transglacial" has been introduced to address to landforms, which have been formed by the transformation of the glacially stressed valley flanks as well as by the postsedimentary transformation of slope moraines after the deglaciation in mountain areas (Iturrizaga, 2006, Figures 3 and 4). These transglacial landforms may be used in their topographical relationship as geomorphological indicators for the reconstruction of the former glacier extent. Moreover, high magnitude-low frequency events play an important role in the sediment transfer in this mountain region.

Some new insights of paraglacial geomorphology

An interesting issue is the interfingering and coexistence of periglacial and paraglacial landscape environments,

Paraglacial Landscape Transformations, Figure 3 Alluvial fan composed partly of fluvially reworked till in the Mastuj valley (Hindukush). The valley flanks are covered with slope moraines up to several hundred meters above the valley floor. Photo: L. Iturrizaga Aug. 2004.

particularly, in regard to time frames for the occurrence of periglacial processes (Coleman and Carr, 2008; Knight and Harrison, 2009). In the British upland, valley bottom drift was conventionally considered as periglacial solifluction deposits. They supposed to have been formed during the Loch Lomond Stadial, where favorable conditions occurred for permafrost environments. Harrison (1996) has proposed that the sediments are the result of debris flows which occurred shortly after the deglaciation during warm climatic conditions. The paraglacial hypothesis would imply a much older age of those deposits. Poorly investigated until now is the relationship between contemporary periglacial weathering regimes and those that prevailed during paraglaciation (Thorn, 2004).

Talus cones and talus slopes have been previously classified as key forms of the periglacial landscape environment assuming that frost-weathering processes are the principal form of mechanical rock disintegration. However, the rate of frost-weathering turned out to be much too low to account for the formation of talus cones in various high-mountain regions of the world (Rapp, 1960; Luckman and Fiske, 1997). Thus a paradigm shift takes place concerning the development of talus cones as they are no longer considered only as wholly climatic-controlled landforms, but also as paraglacial landforms or composite landform of periglacial and paraglacial origin (Iturrizaga, 1999b, 2008; Wilson, 2009, Figure 4).

A further trend of reassessment is recognizable in regard to terminal moraines. Some of them have been reinterpreted as deposits of rock avalanches (i.e., in the Andes, Abele, 1981, and in the Himalayas, Fort and Peulvast, 1995). In recent times, these large-sized mass movements have also been partly considered in a paraglacial context in the Karakoram and were linked to oversteepening by glaciation and debutressing of rock walls during deglaciation (Hewitt, 2009).

Critics and reassessment

The paraglacial concept has undergone a critical review in the last years (Knight and Harrison, 2009) and is therefore in a stage of reassessment (Wilson, 2009). On the one hand side, there is the argument that the term "paraglacial" should not only be referred to glacial processes but also to transitional forms in general (Slaymaker, 2009). It supports more the concept of a transient landscape which responds to environmental disturbances in general. On the other hand, as vague as the term "paraglacial" itself is, it has been applied in so many ways (spatially, temporally, genetically) in regard to the glacially conditioned landscape transition that the term faces almost to become redundant (Slaymaker, 2007). There is an apparent problem in referring the term "paraglacial" to processes, as "paraglacial processes" are identical with processes operating outside of glaciated areas, only in an accelerated way. Paraglacial geomorphology is a concept without distinctive processes.

Moreover, geomorphology is concerned about the explanation of distinct landforms and, in this respect, a lack of characteristic "paraglacial landforms" can be noticed. Looking at the individual landsystems (rock slopes, drift-mantled slopes, glacier foreland, alluvial, lacustrine and coastal systems) and the according landforms (i.e., catastrophic failure, mass movement, frost action), it is apparent that they are overlapping with existent landsystems, such as purely coastal, fluvial, or periglacial, and are rather unspecific. The use of "paraglacial" as an all-round term for landscape transformation conditioned by glaciation may be thus sometimes rather confusing.

Conclusions

The introduction of "paraglacial geomorphology" as a new proposed subdivision of geomorphology has been an important step in order to unify previous and current research studies concerned with the geomorphological adjustment of the landscape after deglaciation into one overall concept. The immense impact of glaciation and deglaciation on the geomorphological landscape evolution has been investigated before in different respects, but it has been mainly focused either on the transformation of the bedrock morphology, i.e., the transition from a V-shaped to an U-shaped valley, and associated rock slope failures, or on the deposition of specific glacigenic sediments. The paraglacial concept stresses the importance of the transformation of the landscape after the glaciations in terms of glacially conditioned sediment supply, sediment storage, and sediment flux. Thereby, one key element of this approach is that the landforms are not treated as individual landforms, but in their interconnectedness. These results have provided some reinterpretation of landforms, which have formerly considered as periglacial in origin. However, there exists a close interlinkage between glaciation, paraglaciation, and periglaciation, and many landforms may have faced a polygenetic origin.

On the whole, the paraglacial concept needs some basic reevaluation of its principal definition (e.g., differentiation between paraglacial and proglacial, inclusion of glacioisostatic rebound effects) and a clearer limitation in its application (Slaymaker, 2007). It remains to be seen whether paraglacial geomorphology will be only a temporal concept in an attempt to link glacial and periglacial landscape (Dixon and Thorn, 2005).

Catastrophic Rock Slope Failures and Mountain Glaciers

PATAGONIA

Stephan Harrison
School of Geography, Archaeology and Earth Resources, University of Exeter, Penryn, Cornwall, UK

Definition

Patagonia forms the southern regions of Argentina and Chile south of 40° S. The western sector of Patagonia is dominated by the southern Andes mountains and associated ice masses and fringes the Pacific Ocean. To the east, the land becomes increasingly arid, low-lying, and rolling.

Current knowledge of the Patagonian Ice Caps

Two major ice masses (the North and South Patagonian Icefields [NPI and SPI]) and numerous snow- and ice-capped volcanoes and mountain icefields currently exist in the region. The North Patagonian Icefield, called in Spanish, Hielo Patagónico Norte, (47°00′ S, 73°39′ W) is some 120-km long and 40–60-km wide, capping the Andean Cordillera between altitudes of 700 and 2,500 m above sea level. The icefield covers some 3,953 km^2 (Rivera et al., 2007). Much of the icefield is a plateau 1,100–1,500 m in elevation with mountains up to 4,000 m rising above it. Around 30 glaciers drain the icefield. The main ones draining the western sector into the Pacific Ocean are Glaciar San Rafael (the lowest latitude tidewater glacier in the world and the only tidewater glacier of the icefield) and Glaciar San Quintín (the largest outlet of the icefield and one which forms a piedmont lobe). With the largest catchment areas being on the west, these glaciers are the major ice discharge routes from the icefield. Draining the northern sector are Glaciars Exploradores and Grosse (the latter being one of the few debris-covered glaciers on the icefield). A strong west–east precipitation gradient exists across the region, and glaciers on the eastern side of the icefield are smaller than those on the west. Major glaciers here include Glaciars Nef and Leones (both of which calve into lakes) and Colonia which delivers ice from Glaciar Arenales into Rio Baker. The main outlet glaciers of the southern part of the ice field are Glaciar Benito and three unnamed glaciers that flow to the west (HPN 1–3) and Glaciar Steffen and Glaciares Pared (Norte and Sur) that flow to the south.

Annual precipitation on the western side of the icefield increases from 3,700 mm at sea level to an estimated maximum of 6,700 mm at 700 m a.s.l. before decreasing sharply on the eastern side (Escobar et al., 1992).

Other independent ice masses exist in the region. Cerro Hudson is an active volcano at latitude 45°55′ S, with a 10-km-wide icefield and several debris-covered outlet glaciers. To the southwest of the icefield is the glacierized mountain massif of Cerro San Lorenzo (3,700 m, latitude 47°36′ S, long 72°19′ W) with several large outlet glaciers.

The South Patagonian Icefield (Hielo Patagónico Sur in Spanish) covers an area of ca. 13,000 km^2 (Aniya, 1999) and runs north–south for 360 km between 48°50′ S and 51°30′ S, with a mean width of 40 km. North of latitude 49°S, most of the ice field is a uniform plateau with only a few mountains rising above it (Lliboutry, 1999). The main outlet glaciers are Glaciar Jorge Montt (with a surface area of around 464 km^2), flowing northward to Fiordo Calén; Glaciar Bernardo (536 km^2), flowing westward to Fiordo Bernardo; Glaciar Greve (438 km^2), flowing westward and then southward; and Glaciar O'Higgins (820 km^2). The largest glaciers are Glaciar Perito Moreno (255 km^2), which has a calving front in Lago Argentino (fig. 39), and Glaciares Grey (269 km^2) and Tyndall (331 km^2).

South of the SPI the elevation of the mountains drops. However, small mountain glaciers and icefields exist in many places. The largest of these is found on Tierra del Fuego. Here the Cordillera Darwin rises to 2,469 m at Monte Shipton and the glaciers form an icefield of around 2,300 km^2.

Pleistocene and Holocene behavior of the icefields

During much of the Quaternary, the NPI and SPI combined to form the Patagonian Icesheet (PI) and its fluctuations to the east throughout this time is recorded by a remarkable set of moraines and associated deposits, which constrain the eastern margin of large lakes such as Lago General Carrera/Buenos Aires and Lago Argentino (Caldenius, 1932; Coronato et al., 2004). Dating of the outermost moraine system shows it to have been formed between 1.1 and 2.3 Ma ago. The Last Glacial Maximum in Patagonia is dated to around 30–18 ka BP and marked by the innermost moraines in this moraine belt. Closer to the present icefields, glacier fluctuations during the Lateglacial are marked by moraines recording climate cooling during the Antarctic Cold Reversal (14.5 ka BP) and there are also moraines associated with glacier expansion during Younger Dryas times (12.8–11.5 ka BP). The geographical extent of these events, their climatic significance, and aspects of their chronology are the subjects of considerable debate. Further moraine systems close to the present ice fronts are dated to the mid and late Holocene (Harrison et al., 2007, 2008).

Contemporary glacier behavior

Until quite recently, fundamental glaciological data on the Patagonian icefields have been lacking; largely, the result of difficult access in this remote region. However, over the last decade, significant advances have been made in assessing the behavior of the icefields and their outlet glaciers over time using a variety of remote sensing techniques. Initial work using Synthetic Aperture Radar (SAR) analyzed glacier velocities surface topography and strain rates (e.g., Rignot et al., 1996). Subsequent research has used Advanced Spaceborne Thermal Emission Radiometers (ASTER) imagery to map the

glacial geomorphology of the icefields and surrounding areas (e.g., Glasser et al., 2005, 2008).

Many of the outlet glaciers from the icefields have calving margins. Warren and Aniya (1999) report that 76% of the major glaciers on the NPI calve into water bodies and 96% on the SPI. Remote sensing has allowed systematic investigations to be made of the behavior of these glaciers. As a result, velocity measurements from several calving glaciers are now available and show considerable short-term variability although, over seasonal timescales, the fluctuations in velocity are low. For instance, Shuttle Imaging radar has been used to assess glacier velocity on Glaciar Perito Moreno, which drains part of the eastern flank of the SPI (Michel and Rignot, 1999). They showed a flow rate of 800 m/year at the calving front and half of this in its terminal valley – comparable velocities to those measured in the 1980s. Similarly, at Glaciar Pío XI, a westward-flowing calving glacier on the SPI showed short-term velocities ranging from 15.2 to 36.8 m/day during 14–17 November 1995, although such high velocities do not appear to be maintained over long time periods. In contrast, sustained flow velocities at the rate of 17 m/day have been observed at Glaciar San Rafael on the NPI, making it one of the world's fastest non-surging glaciers (Warren and Aniya, 1999).

Recession

Recent work has used Digital Elevation Models of the NPI and SPI derived from the 2000 Shuttle Radar Topography Mission (SRTM) to assess the ice loss from the largest 63 glaciers of icefields since 1968 (Rignot et al., 2003). Most of the glaciers underwent considerable ice loss and frontal retreat over this period. The authors estimated that the NPI lost around 3.2 km^3 volume of ice per year throughout this time, whilst the SPI lost around four times this amount (around 13.5 km^3/year). The total combined volume loss from the icefields amounts to nearly 17 km^3/year, equivalent to a contribution to sea level rise of 0.042 ± 0.002 mm/year. Data from a restricted part of the SPI since 1995 showed an accelerated ice loss from both icefields at around 42 km^3/year, which is equivalent to a sea level rise (SLR) of 0.105 ± 0.011 mm/year.

The authors attributed this ice loss to negative mass balance caused by climate change associated with a temperature increase of 0.4–1.4°C south of 46°S during the twentieth century. However, rates of glacier thinning are larger than those that would be expected from the observed rise in regional temperatures. Rignot et al. (2003) suggest that the influence of calving processes on many of the glacier termini explains much of this anomalous behavior with calving glaciers having undergone rapid recession once pushed out of equilibrium by rising temperatures. They compare the behavior of Patagonian glaciers with those of Alaska and conclude that the contribution of Patagonian glaciers to sea level rise is disproportionately larger by a factor of around 1.5 than that indicated by their areas. They attribute this to the relatively low ELAs of Patagonian glaciers, their high ice fluxes, and the dominance of calving fronts.

Summary

The Patagonian icefields are the largest temperate ice masses on Earth and their outlet glaciers are also some of the most dynamic. Maintained by the southern Westerlies, the icefields have undergone considerable fluctuations throughout the Quaternary and over the past few decades, there has been a major research initiative to reconstruct this behavior and relate it to the climate change in the midlatitudes of the southern hemisphere. Modeling studies have also shown that the glaciers are likely to be highly responsive to continued global warming throughout this century, although accurate estimates of their behavior have not been worked out in detail.

Synonyms

Staircase lakes; String of beads

Definition

A series of lakes that are formed in the low depression of a U-shaped valley.

Paternoster lakes are erosional landforms formed by scouring a valley bed that contains rocks of varying resistance. When a glacier advances and moves downhill, it encounters all types of rocks, rocks that are softer and less resistant get eroded deeper than those that are more resistant, thus forming a depression on the valley bed. The scouring power of a glacier also depends on the basin relief, type of flow (extensive or compressive), and subglacial temperature and water availability. These eroded depressions later get filled with water as glacier starts receding and produces a series of lakes (Figure 1). These lakes are characteristics of alpine glaciation and show advancement and subsequent retreat of glaciers. Lakes are beaded together by a river running between them, which can be a part of single stream or a braided stream system. The number of lakes in any particular U-shaped valley depends mainly on the geological and structural characteristics of the bed material. Lake sediment can be extremely helpful in understanding the glaciation history of any basin, depending on the depth of the lake. In most cases, they are not deep enough to do any meaningful analysis.

PEAK FLOOD GLACIER DISCHARGE

Monohar Arora
National Institute of Hydrology (NIH), Roorkee, UA, India

Sudden release of glacially impounded water causes catastrophic floods (sometimes called by the Icelandic term "jôkulhlaup"), known as outburst floods, and occasionally spawn debris flow that pose significant hazards in mountainous areas. Commonly, the peak flow of an outburst flood may substantially exceed local conventional benchmarks, such as the 100-year flood peak, but predicting the peak discharge of these subglacial outburst floods is a very difficult task. Increasing human habitation and recreational use of alpine regions has significantly increased the hazard posed by such floods. Outburst floods released in steep, mountainous terrain commonly entrain loose sediment and transform into destructive debris flows.

PERCOLATION ZONE

Prem Datt
Research and Development Center (RDC),
Snow and Avalanche Study Establishment, Himparisar, Chandigarh, India

The area on a glacier or ice sheet or in a snowpack where a meltwater percolates are known as percolation zone. In case of glaciers, the upper part of the glacier (accumulation zone) where ice is covered by snow represents the percolation zone. As such water percolates through the snowpack because snow behaves like a porous media, while in the lower part of glacier (ablation zone) water flows over the ice because ice is not permeable and hardly allows any percolation. This is the reason the water channels are found in the ablation part of the glaciers where exposed ice surface is available.

PERENNIALLY FROZEN GROUND

Monohar Arora
National Institute of Hydrology (NIH), Roorkee, UA, India

Perennially frozen ground occurs wherever the ground temperatures remain continuously below 0°C for 2 or more years. Most permafrost is located in high latitudes (i.e., land in close proximity to the North and South poles), but alpine permafrost may exist at high altitudes in much lower latitudes. The extent of permafrost can vary as the climate changes. Permafrost, or perennially frozen ground, is a critical component of the cryosphere and the Arctic system. Permafrost regions occupy approximately 24% of the terrestrial surface of the Northern Hemisphere. Today, a considerable area of the Arctic is covered by permafrost (including discontinuous permafrost).

PERIGLACIAL

H. M. French
University of Ottawa (retired), North Saanich, BC, Canada

Synonyms

Cryogenic

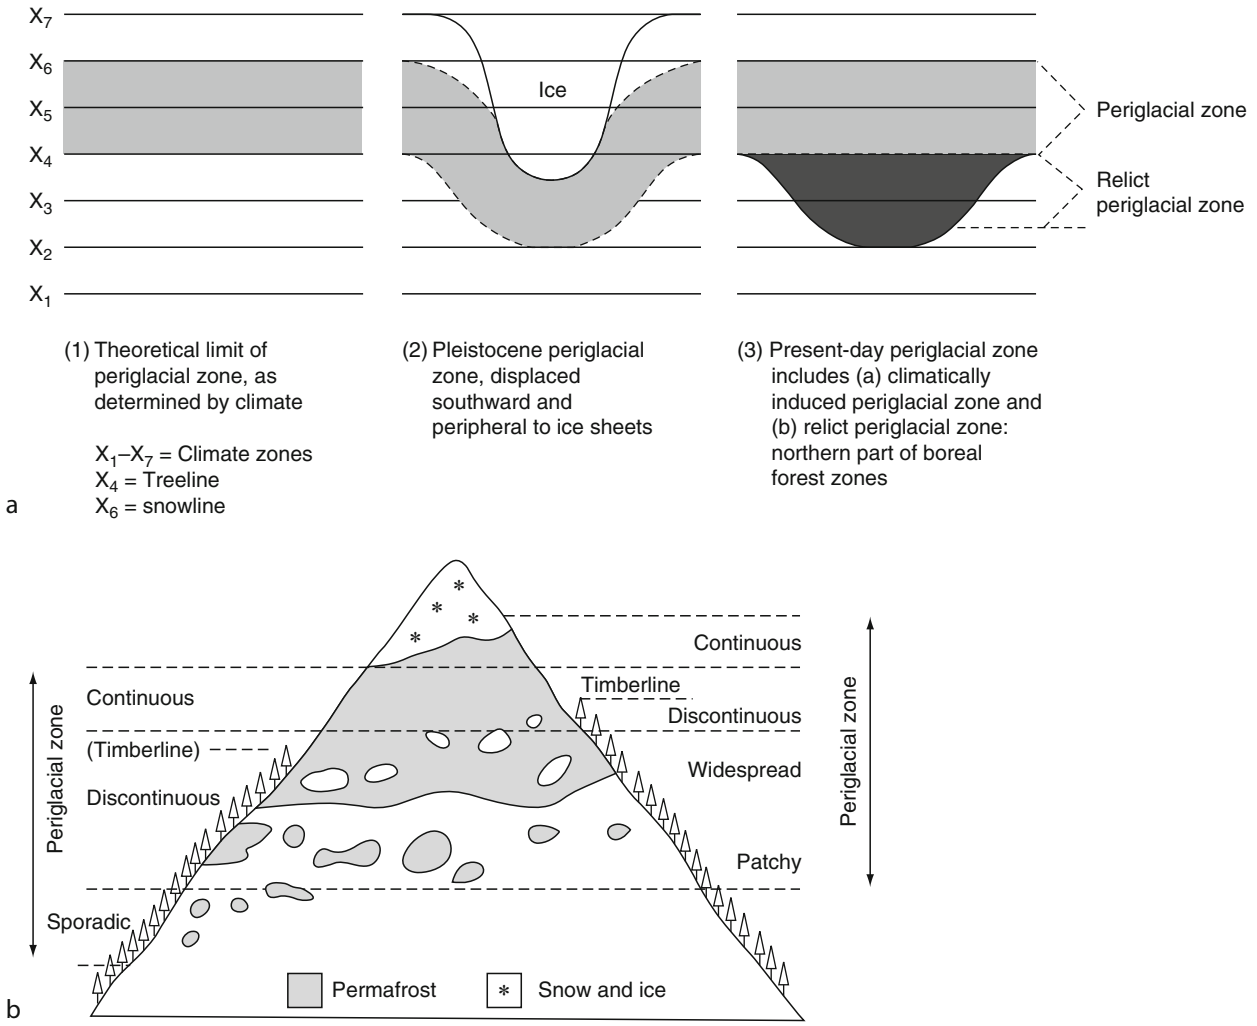
Definition

"Periglacial": an adjective used to refer to cold, nonglacial landforms, climates, geomorphic processes, or environments.
"Periglaciation": the degree or intensity to which periglacial conditions either dominate or affect a specific landscape or environment.

Origin

The term *periglacial* was first used by a Polish geologist, Walery von Łozinski, in the context of the mechanical disintegration of sandstones in the Gorgany Range of the southern Carpathian Mountains, a region now part of central Romania. Łozinski described the angular rock-rubble surfaces that characterize the mountain summits as *periglacial facies* formed by the previous action of intense frost (Łozinzki, 1909). Following the XI Geological Congress in Stockholm in 1910 and the subsequent field excursion to Svalbard in 1911 (Łozinzki, 1912), the concept of a *periglacial zone* was introduced to refer to the climatic and geomorphic conditions of areas peripheral to Pleistocene ice sheets and glaciers. Theoretically, this was a tundra zone that extended as far south as the tree-line. In the mountains, it was a zone between timberline and snow line (Figure 1).

Today, Łozinski's original definition is regarded as unnecessarily restricting; few, if any, modern analogs exist (French, 2000). There are two main reasons. First, frost action phenomena are known to occur at great distances from both present-day and Pleistocene ice margins. In fact, frost action phenomena can be completely unrelated to ice-marginal conditions. For example, parts of central Siberia and interior central Yukon remained unglaciated during the Pleistocene, yet these are regions in which frost action was, and is, very important. Second, although Łozinski used the term to refer primarily to areas rather than processes, the term has increasingly been understood to refer to a complex of cold-dominated geomorphic processes. These include not only unique frost action and permafrost-related processes but also the range of azonal processes, such as those associated with snow, running



Periglacial, Figure 1 Schematic diagram illustrating the concept of the periglacial zone in (**a**) high-latitude and (**b**) high-altitude (alpine) areas. (From French, 2007.)

water and wind, which demand neither a peripheral ice-marginal location nor excessive cold. Instead, they assume distinctive or extreme characteristics under cold, non-glacial (i.e., periglacial) conditions.

Historical context

Periglacial geomorphology developed in a relatively rapid fashion in the 2 decades after 1945 as a branch of a European-dominated, but somewhat unscientific, climatic geomorphology. It was aimed largely at Late-Pleistocene paleo-climatic reconstruction. This changed in the latter half of the twentieth century when isotopic dating techniques and the explosion of the Quaternary sciences came to dominate paleo-environmental reconstruction. At the same time, the growth of permafrost studies in Arctic North America and the emergence of Russian geocryology liberated periglacial geomorphology from its Pleistocene heritage.

Modern periglacial geomorphology is a branch not only of mainstream geomorphology but also of permafrost science or geocryology (Washburn, 1979; Romanovskii, 1980; Williams and Smith, 1989; Yershov, 1990; Zhou et al., 2000). Periglacial areas are regarded as cold-climate "zones" in which seasonal and perennial frost, snow, and normal azonal processes are all present to greater or lesser degrees (French, 2007). The reality is that many so-called periglacial landscapes inherit the imprint, in varying degrees, of previous glacial conditions.

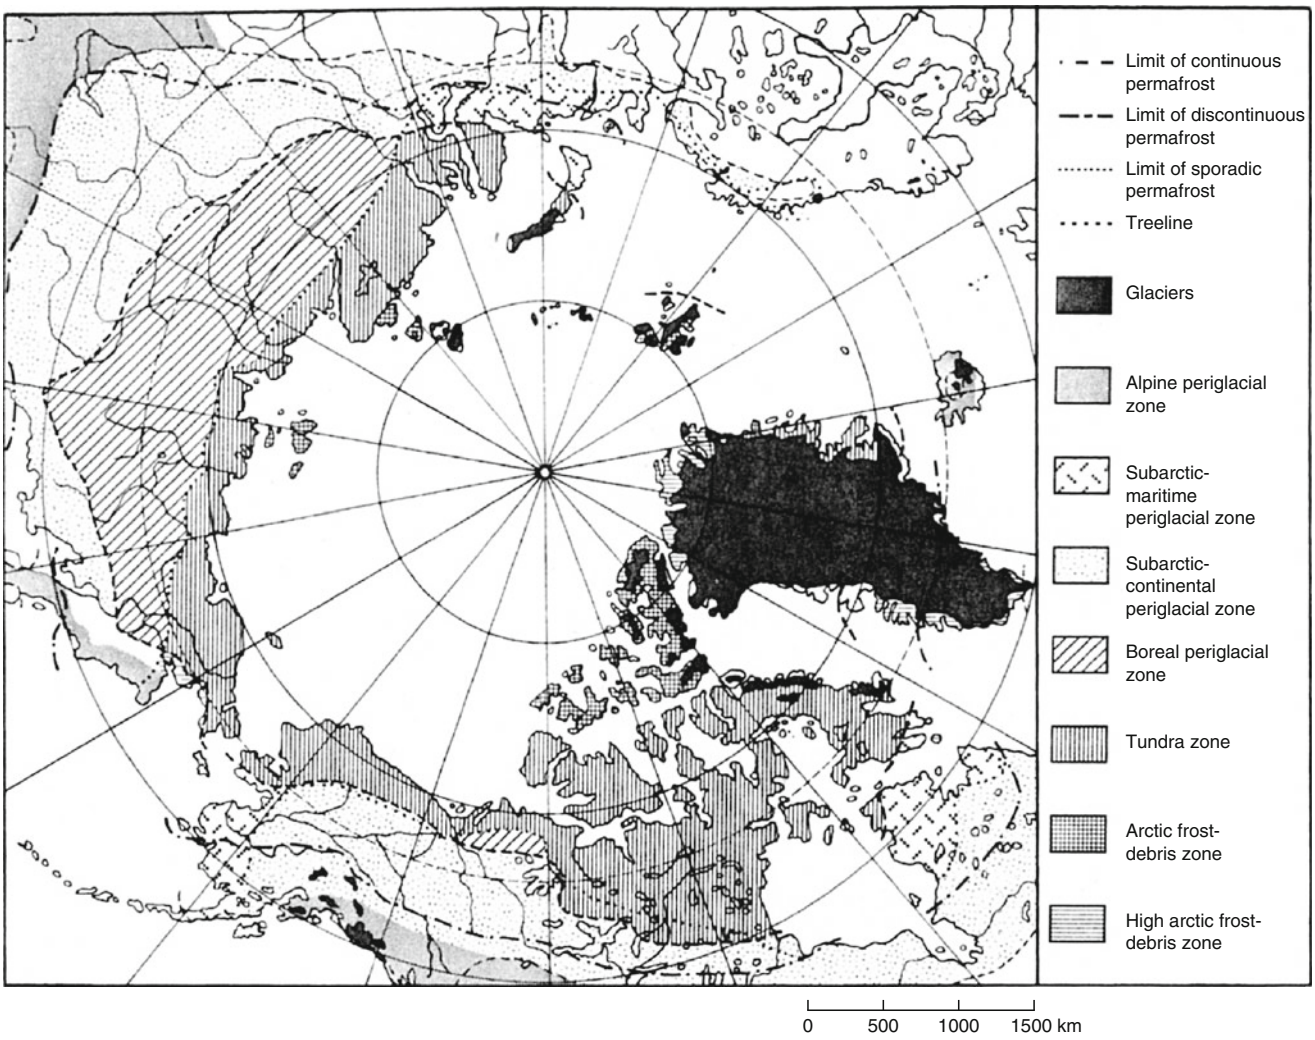
Extent and significance of periglacial environments

Periglacial environments are restricted to areas that experience cold, but essentially non-glacial, climates. They occur not only as tundra zones in the high latitudes, as defined by Łozinski`s concept, but also as forested areas south of tree-line and in the high-altitude (i.e., alpine) regions of

mid-latitudes (Figure 2). They include (a) the polar deserts and semi-deserts of the High Arctic, (b) the extensive tundra zones of high northern latitudes, (c) the northern parts of the boreal forests of North America and Eurasia, and (d) the alpine zones that lie above timberline and below snowline in mid-latitude and low-latitude mountains. To these must be added: (a) the ice-free areas of Antarctica, (b) the high-elevation montane environments of central Asia, the largest of which is the Qinghai-Xizang (Tibet) Plateau of China, and (c) small oceanic islands in the high latitudes of both Polar Regions.

Periglacial environments occur over approximately one quarter of the Earth's land surface. During the Pleistocene glacial periods, large areas of now-temperate mid-latitude experienced reduced temperatures because of their proximity to the continental ice sheets and glaciers. Permafrost and/or intense frost action would have characterized an additional 20–25% of the earth's land surface at some time during the Pleistocene.

As regards human occupance, the periglacial environments are relatively sparsely populated. A reasonable estimate is just seven to nine million people, mostly living in Russia, or only 0.3% of the world's population. Thus, the larger importance of periglacial environments lies not in their spatial extent, their snow and ice, or their proximity to glaciers but in their environment and their natural resources. For example, the Precambrian basement rocks that outcrop as huge tablelands in both Canada and Siberia contain precious minerals, such as gold and diamonds, and sizable deposits of lead, zinc, and copper, while the sedimentary basins of western Siberia, northern Alaska, and the Canadian High Arctic contain large hydrocarbon



Periglacial, Figure 2 Map showing the extent of the current periglacial domain in the northern hemisphere. Not included are the alpine areas of mid-latitude mountains and the high-altitude montane environment of central Asia. (From Karte and Liedtke, 1981. Reproduced in French, 2007.)

reserves. In the more distant future, the exploitation of gas hydrates that occur within permafrost and the freshwater resources associated with the large northern lakes and rivers will become important. A second reason why periglacial environments are of significance is their place within the cryosphere (snow, ice, frozen ground, sea ice) and the critical role which the cryosphere plays in the global climate system.

Periglacial climates

Periglacial environments experience mean annual air temperatures of less than +3°C. They can be subdivided by the −2°C mean annual air temperature into environments in which frost action dominates (mean annual air temperature less than −2°C) and those in which frost action occurs but does not necessarily dominate (mean annual air temperature between −2°C and +3°C). Fundamental to most periglacial environments is the freezing of water and its associated frost heaving and ice segregation.

Based upon temperature and solar radiation characteristics, the majority of periglacial environments can be categorized as being either (1) High Arctic (polar), (2) Continental, or (3) Alpine in nature. In both High Arctic and Continental environments, temperatures are dominated by a seasonal rhythm; summer temperatures range between 10°C and 30°C and winter temperatures may fall as low as −30°C. Perennially frozen ground (permafrost) is widespread. By contrast, the Alpine mid-latitude environment experiences both diurnal and seasonal rhythms. Permafrost may, or may not, be present.

Periglacial environments that do not fit the above classification are (1) the extensive high-altitude montane environments of central Asia that experience a mix of both seasonal and continental temperature rhythms, (2) Iceland, and other smaller islands in the subarctic oceans of both polar regions such as Jan Mayen, Kerguelen, and South Georgia that experience diurnal, seasonal and/or perennial frost, and (3) the high elevations and summits of mountains in South America and Africa that, lying near the equator, experience low annual temperature range and strong diurnal rhythms. The freezing and thawing conditions experienced by these different periglacial environments are summarized in Figure 3.

In terms of periglacial landscape dynamics, ground temperature is probably more important than air temperature. Typically, the depth of ground freezing varies from as little as 10–20 cm beneath organic materials to over 500 cm in areas of exposed bedrock. It is important to stress that relatively few freeze-thaw cycles occur at depths in excess of 30 cm; there, only the annual temperature cycle usually occurs. It is important to differentiate between the mean annual air temperature (MAAT) and the mean annual ground surface temperature (MAGST) that results in the so-called *surface offset* and the mean annual ground surface temperature (MAGST) and the temperature at the top of permafrost (TTOP) that results in the so-called *thermal offset* (Smith and Riseborough, 2002). The surface offset reflects primarily the influence of snow cover and vegetation, while the thermal offset is conditioned largely by the physical properties of the active layer (thermal conductivity and moisture content).

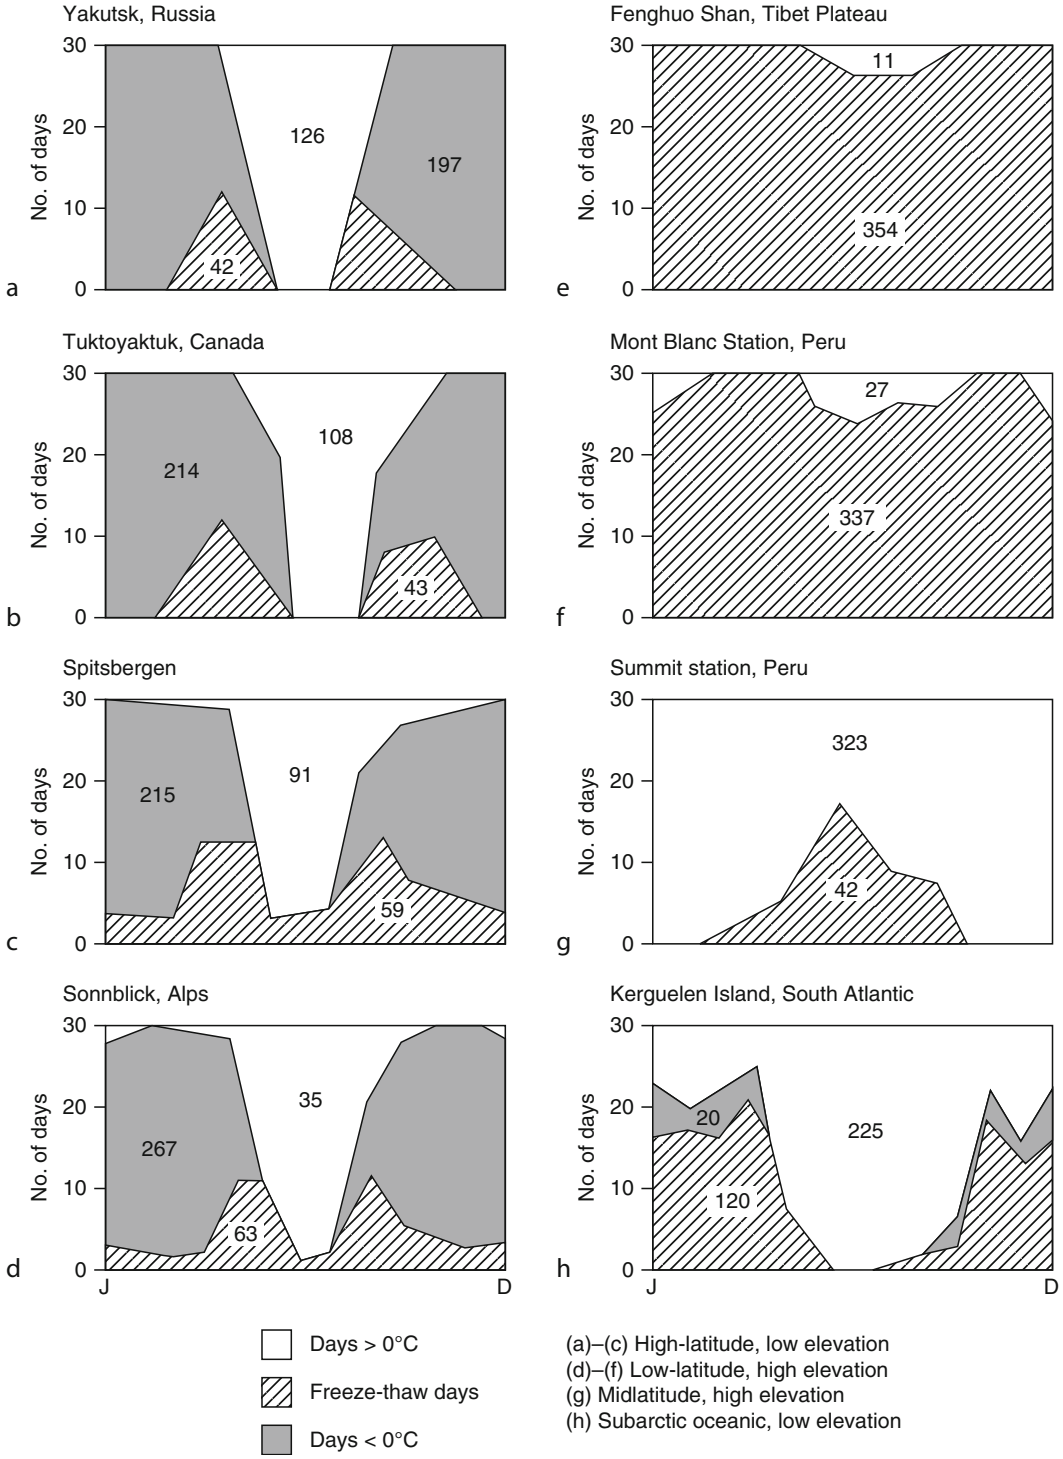
Periglacial ecosystems

Periglacial environments contain a range of ecosystems. The most extensive are those of the high northern latitudes. They can be regarded as being either arctic or subarctic in nature (Table 1). The boundary between the two approximates the northern limit of trees, the so-called tree-line. This is a zone, 30–150 km in extent, north of which trees are no longer able to survive. Ecologists refer to the barren, treeless Arctic as tundra. The tundra progressively changes into polar desert at extreme high latitude as climate becomes increasingly colder and drier. The tree-line also approximates the southern boundary of the zone of continuous permafrost; i.e., north of the tree-line, the terrain is perennially frozen and the surface thaws for a period of only 2–3 months each summer (see above).

The mid-latitude alpine environments are a localized and specialized periglacial environment. They are dominated by both diurnal and seasonal climatic effects, by steep slopes, tundra (alpine) plants, rocky outcrops, and snow and ice. In such environments, the timberline constitutes the boundary between the alpine and sub-alpine. The montane environments of central Asia are also distinct and consist of extensive steppe grasslands and intervening desert-like uplands. Finally, the ice-free areas of Antarctica and northeast Greenland are essentially polar deserts or rock-rubble surfaces.

The tundra and polar desert regions of both North America and Eurasia contain a surprisingly large number of plant and animal species. Plant cover varies from 5% in the polar deserts to over 60–75% in meadow tundra terrain (Figure 4a). In the western Canadian Arctic Archipelago, the diversity of flora and vascular plants is especially well documented (e.g., Porsild, 1957). Large mammals such as the polar bear, musk-oxen, and fox all manage to survive in the extreme high northern latitudes.

In the subarctic, two major ecological zones can be recognized. Near the tree-line is a zone of transition from tundra to forest, consisting of either open woodland or forest-tundra. Here, the trees are stunted and deformed, often being less than 3–4-m high (Figure 4b). Woodland caribou and grizzly bear replace polar bear and musk-oxen. This zone merges into the boreal forest, or *taiga*, an immense zone of almost continuous coniferous forest extending across both North America and Eurasia. It is regarded as a fire climax community (Figure 4c). In North America, the dominant tree is spruce (*Picea glauca* and *Picea mariana*) and in central Siberia, both pine (*Pinus silvestris*) and tamarack (*Larix dahurica*) are dominant. In northern Scandinavia, on account of the warm Gulf Stream, stunted birch forest (*Betula nana*) forms the tree-line (Figure 4d). The southern boundary of the subarctic is less clearly defined than its northern boundary;



Periglacial, Figure 3 Freezing and thawing conditions in various periglacial environments of the world. (From French, 2007.)

typically, coniferous species begin to be replaced by others of either local or temperate distribution, such as oak, hemlock, and beech, or by steppe, grassland, and semi-arid woodland in more continental areas. Ungulates such as bison and yak take advantage of these grasslands. Because these ecosystems experience deep seasonal frost, they represent the outer spatial extent of the periglacial environment.

Periglacial, Table 1 Summary characteristics of high-latitude periglacial ecosystems

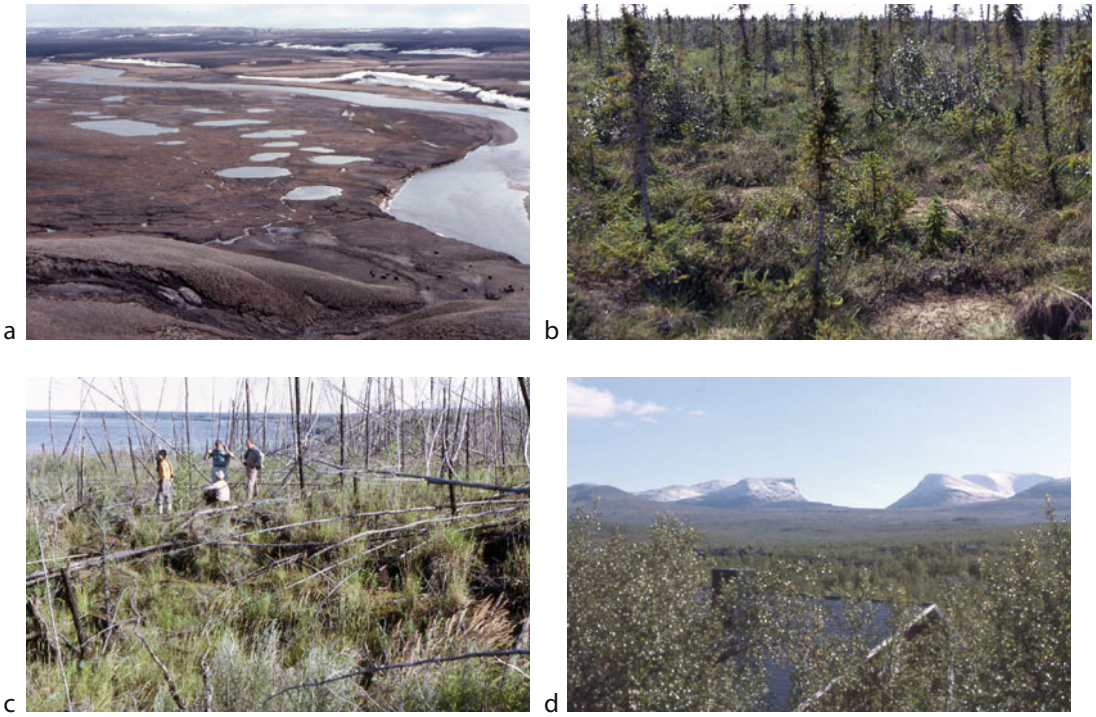
	Arctic		Antarctic
	Low Arctic	High Arctic	Continent, not Peninsula
Climate:	Very cold winters, cold summers, low precipitation, 3.5–5 months >0°C	Very cold winters, cold summers, very low precipitation, 2–3 months >0°C	Extremely cold, short summers, very low precipitation, strong winds ~ 1 month >0°C
Snow-free period	~3–4 months	~1–1.5 months	~1–2 months
Length of growing season	~3.5–5 months	~1–2 months	Negligible
Permafrost:	Continuous: temperature is ~−3 to −4°C at 10–30-m depth	Continuous: temperature is ~−10 to −14°C at 10–30-m depth	Continuous: temperature is ~−8 to −18°C at 10–30-m depth
Active-layer depth	~30–50 cm in silt/clay ~2–5m in sand	~30–50 cm in silt/clay ~70–120 cm in sand	30–50 cm in gravel and ablation till ~1–2 m in bedrock
Vascular plants:	400–600 species	50–350 species	Hair-grass, pearlwort
Mosses	Sphagnum common	Sphagnum minor	30+ types
Lichens	Foliose species abundant	Fruticose and crustose species common	125+ types
Total plant cover	80–100%	1–5% polar deserts 20–100% polar semi-deserts 80–100% sedge-moss tundra	<5% in most areas
Total plant production	200–500 g/m²	0.5 g/m² polar deserts 20–50 g/m² polar semi-deserts 150–300 g/m² sedge-moss tundra	0.5 g/m² in most areas
Vegetation:	Tundra types dominate Tall shrubs, 2.4 m Low shrubs, 0.5 m Cottongrass tussock- Dwarf shrub heath Dwarf shrub heath wet-edge sedge	Tundra types minor Polar semi-desert common Cushion plant – moss Cushion plant – lichen Herb-moss Polar desert common Herb-moss	Mosses, lichens
Mammals:	10–15 species	8 species	(1) Terrestrial: none (2) Southern Ocean: numerous marine mammals
Nesting Birds:	30–60 species	10–20 species	Penguins, skuas
Large herbivores:	Barren-ground caribou, musk-oxen, moose, Polar bear, fox, wolf	Peary's caribou, musk-oxen, Polar bear, wolf	None
Fishes: (lakes and rivers)	4–6+ species	1–2 species (Arctic char, trout)	(1) Rivers: none (2) Southern Ocean: numerous

The harsh, climatic environments of the ice-free areas of Antarctica support little life. However, these areas are adjacent to a highly productive marine ecosystem that results from the nutrients associated with upwelling of water along the Antarctic Divergence. Not surprisingly, a number of marine mammals (e.g., Antarctic elephant seal, southern fur seal) and birds (e.g., penguins, wondering albatross) use the ice-free areas for critical breeding purposes. However, the terrestrial flora and fauna are few; mainly mosses and lichens. There are no land mammals in Antarctica.

Periglacial landscapes

The geomorphic footprint of periglacial environments is not always achieved and most periglacial landscapes possess some degree of inherited paraglacial or proglacial characteristics. The reality is that periglacial landscapes range between those in which the entire landscape is fashioned by permafrost and frost-action processes and those in which frost-action processes are subservient to others. This diversity is accentuated by the fact that (1) certain rock types are more prone to frost weathering than others and (2) many regions currently experiencing periglacial conditions have only recently emerged from beneath continental ice sheets and are largely glacial landscapes. For example, certain areas of western Siberia and the northwestern Canadian Arctic possess large bodies of relict glacier ice, of Pleistocene age, partially preserved beneath ablation till (e.g., Astakov et al., 1996; Murton et al., 2005). It is clear that these so-called periglacial landscapes are largely relict and that periglacial processes are slowly modifying the landscape.

The only periglacial landscapes that are probably in geomorphic equilibrium are those that have protracted histories of cold non-glacial conditions. In the northern



Periglacial, Figure 4 Examples of typical periglacial ecosystems: (**a**) Lowland tundra, Kellett River, southern Banks Island, Canada, showing ice-wedge polygon terrain, thaw lakes, an active-layer detachment (in foreground) and grazing muskoxen; (**b**) Northern boreal forest near the tree-line, just south of Inuvik, NWT, Canada, showing stunted black spruce with non-sorted circles (mud/earth hummocks); (**c**) A recently burned area of taiga forest, Lena River valley, central Siberia, now subject to thermokarst erosion and willow/shrub revegetation; (**d**) Birch trees constitute the northern boreal forest in northern Finland.

hemisphere, these include (1) parts of central Alaska and interior Yukon, (2) much of central and eastern Siberia, and (3) much of the montane and steppe environments on, and surrounding, the Qinghai-Xizang (Tibet) Plateau. In the southern hemisphere, some of the ice-free areas of Victoria Land are thought to have been free of ice for several million years.

In all these areas, it is clear that geological structure and lithology largely control the macroscale periglacial landscape. For example, in areas of resistant igneous, metamorphic and sedimentary bedrock, the higher elevations consist of structurally-controlled rock outcrops. Everywhere, the upland surfaces and upper valley-side slopes are covered by angular rock-rubble accumulations (variously termed "mountain-top detritus," blockfields, or kurums). Bedrock is frequently disrupted by joint and fissure widening, the frost-jacking of blocks, and by brecciation. Typically, uplands are bordered by low-angle, pediment-like surfaces. In many ways, these landscapes resemble those of the hot deserts of the world. By contrast, areas of poorly-lithified bedrock and unconsolidated Tertiary- and Quaternary-age sediments form more undulating, poorly-drained, lowland terrain. Typically, the landscape is characterized by large-scale tundra polygons, thaw lakes and depressions, and widespread mass-wasting and patterned-ground phenomena.

Frost action and cold-climate weathering

The weathering of bedrock in periglacial areas is generally assumed to be mechanical in nature and the result of freezing and thawing of water within rock or mineral soil. Rates of cold-climate rock weathering are usually assumed to be as great, if not greater, than those in warmer environments but this has yet to be convincingly demonstrated.

Rock disintegration by frost action is generally assumed to be the result of either (1) volumetric expansion of ice or (2) ice segregation.

Volumetric expansion

The freezing of water is accompanied by a volumetric expansion of approximately 9%. In theory, this can generate pressures as high as 270 MPa inside cracks in a rock strong enough to withstand such pressures. While volumetric expansion was probably the mechanism that Łozinski envisaged when he talked of "periglacial facies," the dominant role attributed to simple volumetric expansion is probably incorrect. This is because the conditions necessary for frost weathering by volumetric expansion are somewhat unusual. Not only must the rock be water saturated but also freezing must occur rapidly from all side. On the other hand, there is no doubt that volumetric expansion of water within existing joints and other lines

of weakness within bedrock outcrops can lead to bedrock heave and joint widening, and that near-surface frost wedging in fissile sedimentary rocks is a common occurrence (Figure 5a).

A related mechanism is hydrofracturing, in which rock disintegration results from pressures generated by pore-water expulsion. For this to happen, the water-saturated rock must possess large interconnected pores, the expelled pore water is unable to drain away as quickly as it is expelled, and pore-water pressures must rise sufficiently to deform or "hydrofracture" the rock. Rapid inward freezing is the ideal circumstance; for example, there have been occasional instances where Arctic field observations indicate that boulders or rocks on the ground surface have burst or "exploded" during periods of rapid temperature drop during midwinter.

A third possible mechanism relates to the breakup of individual mineral particles by the wedging effect of ice formed in micro-cracks or by the freezing of water within gas–liquid inclusions at cryogenic (i.e., subzero) temperatures. For example, certain Russian laboratory experiments (e.g., Konishchev and Rogov, 1993) indicate that, during repeated freeze-thaw cycles, quartz sand breaks down more readily than feldspar and produces finer particles; this may also reflect the increasing brittleness of quartz at very low temperatures when compared to other minerals.

Ice segregation

There is increasing acceptance that the progressive growth of ice lenses as liquid water migrates to the freezing plane is the most likely cause of the widespread fracture of moist porous rocks (Walder and Hallet, 1986). This is because it is now understood that moisture migrates within freezing or frozen ground. It is the result of a temperature gradient-induced suction (dP_w) that affects the unfrozen water held in capillaries and adsorbed on the surfaces of mineral particles. In theory, a temperature drop of 1°C induces a cryosuction of 1.2 MPa (12 atm). According to Williams and Smith (1989):

$$dP_w = dTl/VT \quad (1)$$

where, dT is the lowering of the freezing point, l is the latent heat of fusion, V is the specific volume of water, and T is the absolute temperature.

The conditions needed for ice segregation are slow rates of freezing and sustained subzero temperatures. These are relatively common in most periglacial environments. In frost-susceptible sedimentary bedrock, long-continued ice segregation can lead to the brecciation of bedrock to a depth of several meters (Figure 5b). Ice segregation and rock fracture has also been verified in laboratory experiments that simulate natural uni- and bi-directional freezing; the most susceptible rock types

Periglacial, Figure 5 Examples of frost action and cold-climate rock weathering: (**a**) In situ bedrock disintegration and frost jacking of Devonian-age siltstone and sandstone, Rea Point, Melville Island, Arctic Canada; (**b**) An exposure of Late-Cretaceous shale in the wall of a drilling sump illustrates near-surface brecciation due to ice lensing, Sabine Peninsula, Melville Island, Arctic Canada; (**c**) Fractured, fine-grained diorite boulder lying on ablation till surface ("Younger Drift"), Simpson Crags, northern Victoria Land, Antarctica; (**d**) Taffoni weathering of coarse-grained monzogranite boulder, Terra Nova Bay, northern Victoria Land, Antarctica.

appear to be fine-grained porous rocks such as chalk and shale (Murton et al., 2006).

Other mechanisms

A number of other weathering mechanisms are also thought to operate in periglacial environments. These are briefly discussed below.

First, insolation weathering, or spalling, refers to cracking in bedrock thought to be caused by temperature-induced volume changes such as expansion and contraction. For many years these thermally-induced stresses were thought more appropriate for rock weathering in hot arid regions than for cold regions. However, laboratory studies suggest the threshold value for thermal shock approximates to a rate of temperature change of 2°C/min and experimental studies, using cold room facilities, have established that different minerals have varying coefficients of linear thermal expansion in the range of +10 to −10°C. These parameters certainly apply to many periglacial environments. For example, in parts of Antarctica, field studies document daily temperature ranges of 40°C–42°C, and rates of heating and cooling of 0.8°C/min and of 15–20°C/h. These measurements suggest that thermal stress, or fatigue, may be a viable rock-weathering process (Hall, 1999) (Figure 5c). Unfortunately, until further field, laboratory, and experimental studies are undertaken, this important mechanism is still largely speculative.

Second, equally perplexing is the relationship between salt, present in the snow in areas adjacent to marine environments and the granular disintegration of coarse-grained igneous rocks that results in cavernous weathering in the ice-free polar deserts of Antarctica (French and Guglielmin, 2000) (Figure 5d). These phenomena are similar to the more well-known "taffoni" of mediterranean and tropical regions.

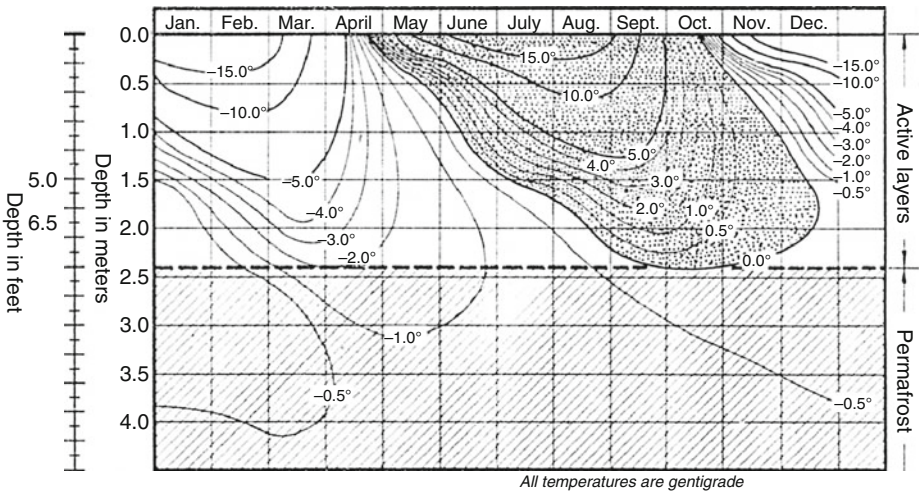
Third, the efficacy of chemical weathering at low temperatures is unclear, despite a number of recent detailed studies in northern Scandinavia (e.g., Dixon and Thorn, 2005), while the nature of the biological and biochemical weathering processes associated with rock-colonizing organisms and the formation of phenomena such as rock varnish are extremely poorly understood (e.g., Guglielmin et al., 2005; Etienne, 2002).

It would appear that cold-climate weathering is complex, frost action takes many forms, certain processes act alone, others in combination, and some may be physico-chemical in nature.

Frozen ground

Periglacial environments experience either seasonally frozen or perennially frozen ground. The latter, if it persists for more than 2 years, is termed permafrost (Muller, 1943) (Permafrost). In areas underlain by permafrost, the active layer refers to the near-surface layer of ground which thaws during summer. Where discontinuous permafrost is present, the active layer may be separated from underlying permafrost by an unfrozen layer (tálik), or by a residual thaw layer if permafrost is relict. If no permafrost is present, the active layer no longer exists and the near-surface layer is one of seasonal freezing and thawing.

The typical ground thermal regime of an area underlain by permafrost is illustrated in Figure 6. Thawing begins in early summer and the depth of thaw reaches a maximum in late summer at which point, freeze-back occurs. The freeze-back is slower than the thaw because the release of latent heat offsets the temperature drop. This gives rise



Periglacial, Figure 6 Diagram illustrating the typical ground thermal regime of a permafrost area, Skovorodino, Siberia, 1928–1930. (From Muller, 1943.)

to the so-called zero-curtain effect, in which near isothermal conditions persist in the active layer for several weeks. Both thawing and freezing are one-sided processes, from the surface downward. However, if permafrost was present, freezing is a two-sided process, occurring both downward from the surface and upward from the perennially frozen ground.

The Stefan equation is sometimes used to approximate the thickness of the active layer:

$$Z = \sqrt{2TKt/Q_i} \quad (2)$$

where Z = thickness of the active layer (m or cm), T = ground surface temperature during thaw season (°C), K = thermal conductivity of unfrozen soil (W/m K or kcal/m °C h), t = duration of the thawing season (day, h, s), and Q_i = volumetric latent heat of fusion (kJ/m³). The Stefan equation can also be used to calculate the depth of seasonal frost penetration. In this case, time t is the duration of the freezing season ($T <$ °C) and K represents the thermal conductivity of frozen soil.

The base of the active layer represents an unconformity between frozen and unfrozen earth material. Because the annual depth of thaw may vary from year to year, depending upon the variability of summer climate, the concept of the transient layer recognizes the different periodicities at which near-surface permafrost cycles through 0°C (Shur et al., 2005). The active-layer permafrost interface is commonly ice-rich. This is because, in summer, as the active layer thaws, moisture migrates downward and refreezes at the base while, during winter, unfrozen water migrates upward in response to the colder temperatures at the surface. Thus, the active layer not only limits the depth to which freeze-thaw action occurs but also its base acts as a slip plane for solifluction and other gravity-induced near-surface movements such as active-layer detachments and for slope instability.

Ground ice is an important component of permafrost. Many of the human occupance problems of periglacial environments relate to either frost heaving of the ground or thaw subsidence (thermokarst) of ice-rich material. Pore and segregated ice are the most widespread forms of ground ice but other types include vein ice and intrusive ice. In parts of western Siberia and the western North American Arctic, massive icy bodies of either an intra-sedimental (i.e., segregated ice) or glacier-ice origin are present (Astakov et al., 1996; Mackay and Dallimore, 1992). In general, fine-grained materials are often ice rich and frost-susceptible, whereas coarse-grained materials are ice poor and generally regarded as non-frost-susceptible. Typically, the base of the active layer and the upper 1–3 m of permafrost contain the highest amounts of ice, often exceeding 50% by volume. Ground ice is discussed more fully under Permafrost.

Periglacial processes and landforms

Geomorphological processes clearly unique to periglacial environments are those related to the formation and degradation of perennially frozen ground. Other processes, not necessarily restricted to periglacial environments, are important on account of their high magnitude or frequency in cold environments. They relate to the presence of snow, or lake and river ice. Other azonal processes, such as fluvial, eolian, and coastal processes, assume special characteristics in cold environments.

Permafrost-related processes

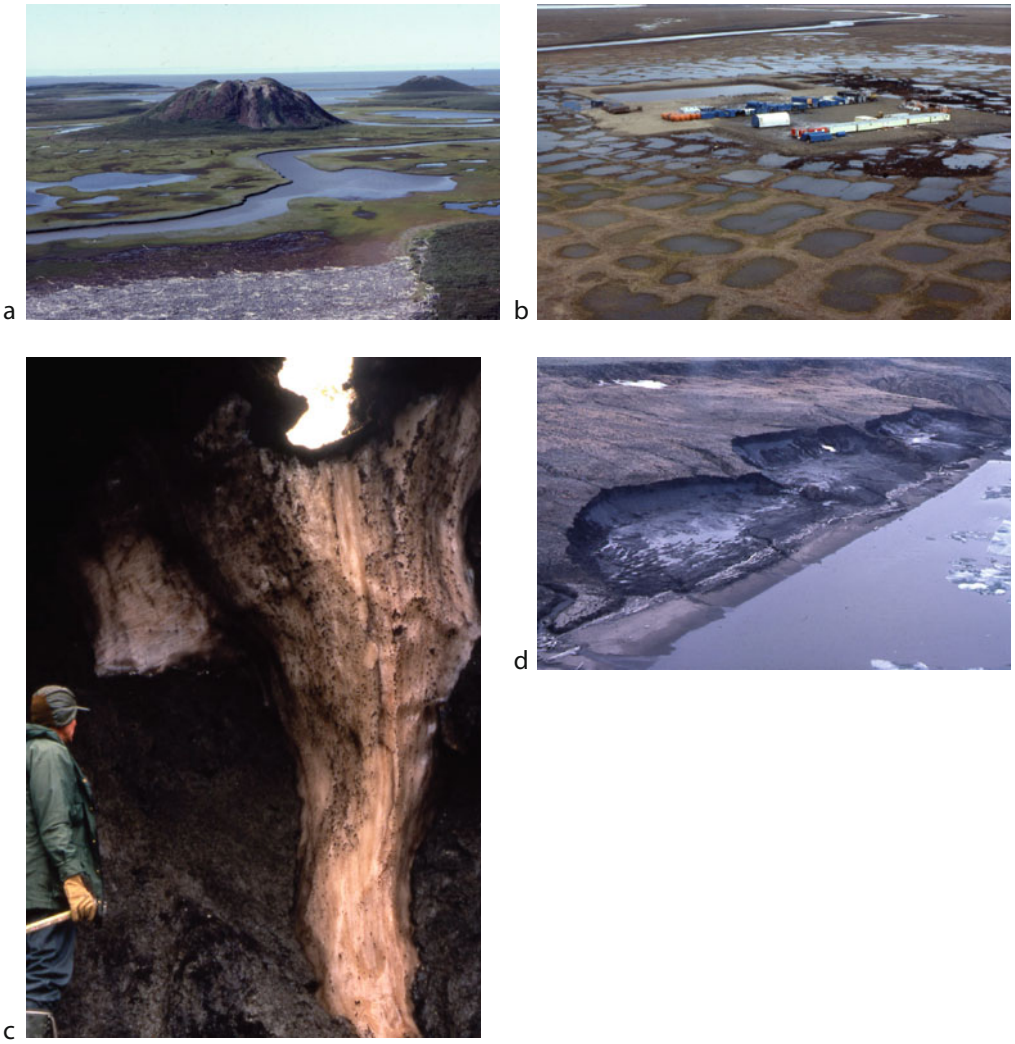
Permafrost-related processes include (1) the aggradation of permafrost and ground-ice bodies, (2) thermal contraction cracking of frozen ground, (3) thawing of permafrost (thermokarst), and (4) the creep of ice-rich permafrost. All are intimately related to the presence of ice within permafrost.

Much of our understanding of permafrost-related landforms and geomorphic processes is derived from the 50 years of field investigations undertaken by J. R. Mackay in the Mackenzie Delta region of the western Canadian Arctic (e.g., Mackay, 1963, 1998, 2000; Mackay and Burn, 2002).

Frost mounds, reflecting the growth of ground ice bodies, are aggradational permafrost features. A range of forms exists. The largest and most dramatic is the pingo, a perennial ice-cored mound. Pingos are of two types: either hydaulic (open) or hydrostatic (closed) in nature. Both cases require specific hydrologic conditions for their formation. Pingos are relatively rare in the majority of periglacial landscapes; however, the largest concentration of closed-system pingos, over 1,350, occurs in the Mackenzie Delta region of Canada (Figure 7a), while more isolated open-system pingos are found in central Yukon and interior Alaska, Svalbard, and central and northern Siberia. In many subarctic areas, the preferential growth of permafrost beneath organic material results in the formation of peat plateaus and palsas. A number of smaller frost mounds, mostly seasonal in nature, also occur.

The most widespread surface feature that is characteristic of permafrost is a network of thermal-contraction cracks, typically 15–30 m in dimensions, which divide the ground surface up into orthogonal or random-orthogonal patterns or polygons (Figure 7b). The cracks are caused by thermal contraction cracking of the ground during winter. In summer, the cracks fill with water from snow melt that subsequently freezes to form wedge-shaped bodies of foliated ice (Figure 7c). In lowland tundra terrain, ice-wedge ice may constitute between 10% and 20% by volume of the upper 5–10 m of permafrost.

The thaw of ice-rich permafrost gives rise to distinct features. These, and the complex of processes associated with thawing permafrost, are generally termed thermokarst. For example, snowmelt-induced runoff in spring results in gully erosion along the lines of ice wedges and where massive icy bodies become exposed, as along riverbanks and at coastal locations, retrogressive ground-ice slumps may develop (Figure 7d). On terrain underlain



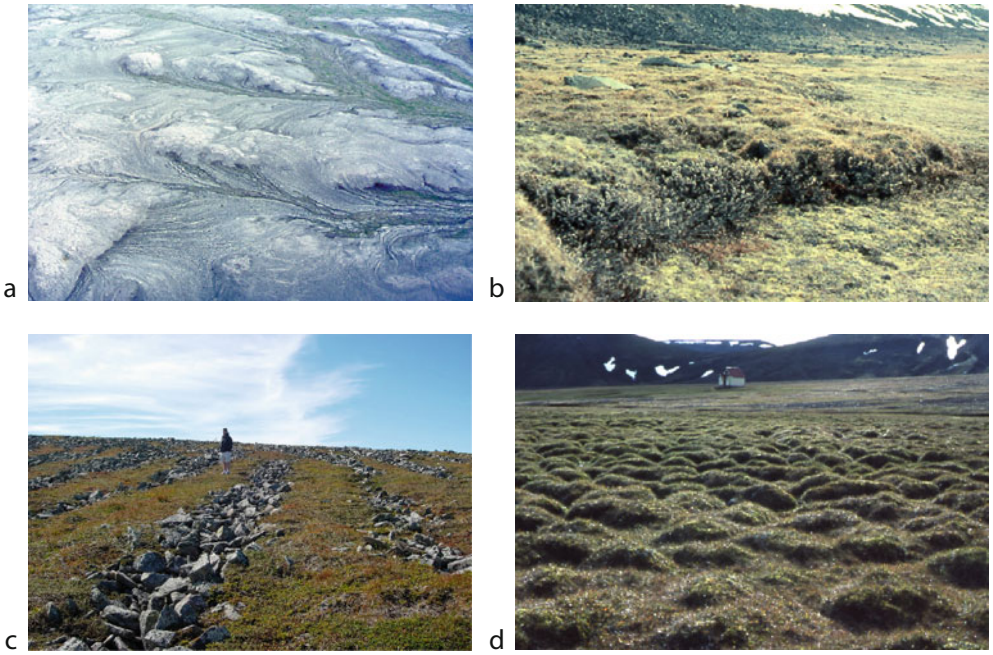
Periglacial, Figure 7 Features of permafrost terrain: (**a**) Closed-system pingo near Tuktoyaktuk, NWT, Canada; (**b**) Poorly drained tundra lowland, northern Alaska, showing low-centered ice-wedge polygons; (**c**) Epigenetic ice wedge, southern Banks Island, Arctic Canada; (**d**) Ground- ice slump, northern Yukon coast, Canada.

by fine-grained and ice-rich sediments, numerous shallow ponds or thaw lakes can develop (see Figure 4a). On gentle slopes, active-layer-detachment failures may occur in years of enhanced summer thaw (see Figure 4a). On bedrock outcrops, the thaw of ice within joints can lead to instability and enhanced rockfall activity.

The creep of permafrost refers to the long-term deformation of frozen ground under the influence of gravity. Fine-grained frozen sediments, such as silt and clay, which contain large unfrozen water content amounts, are especially suitable to frozen creep deformation. Rates of movement are slow, usually less than 0.5 cm/year. The most rapid creep deformation is recorded in rock glaciers, especially those that occur in mid-latitude mountains. For example, the Muragle rock glacier in Switzerland is reported to be deforming at a rate of 50 cm/year (Kaab and Kneisel, 2006).

Azonal processes

Mass-wasting processes are not unique to cold environments but can assume distinctive characteristics and enhanced importance. For example, in non-permafrost regions in summer there is slow mass wasting of the water-saturated thawed layer. This is termed solifluction. Where it occurs in permafrost regions, the process is called gelifluction (Figure 8a). The result is heterogeneous slope deposits, or diamicts, that mantle gentle and lower valley-side slopes. These may form lobes and terraces, usually with risers between 0.5 and 3 m in height (Figure 8b). More rapid movements involve rockfalls, debris flows, and avalanches. These are particularly common in humid alpine environments where steep bedrock outcrops are present. Frost-induced movements within the active layer, or in the zone of seasonal frost, leads to the formation of stone nets that, as slope angle increases, turn into stone



Periglacial, Figure 8 Examples of periglacial patterned-ground phenomena: (**a**) Oblique air view of mass wasting (non-sorted stripes) and gelifluction movement, Sachs Harbour, Banks Island, Canada; (**b**) Turf-banked gelifluction lobe, Holman, Victoria Island, Arctic Canada; (**c**) Stone stripes on low angled slopes (3–7°) are separated from each other by vegetated stripes of finer material; the patterned ground is relict, Mont Jacques-Cartier, Gaspésie, Québec, Canada; (**d**) Small earth or frost hummocks (thufur), central Iceland.

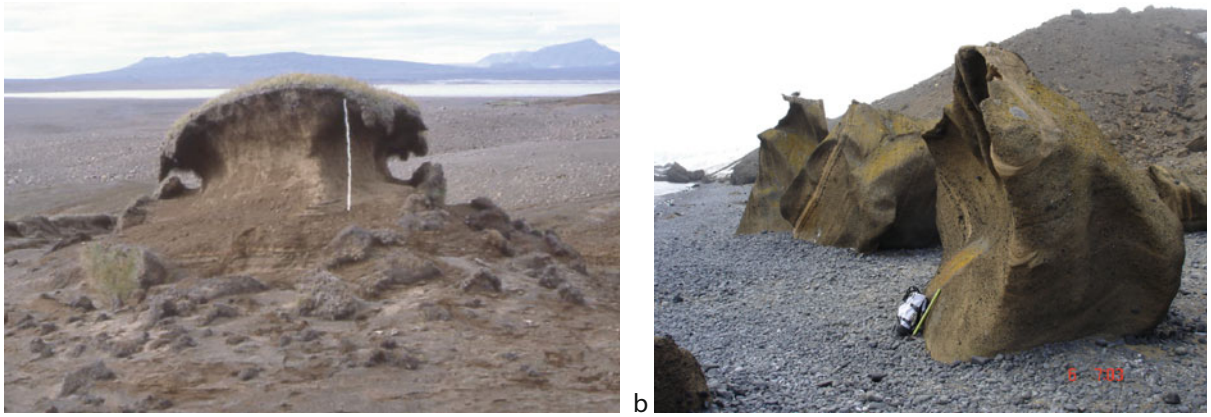
stripes (Figure 8c). Even in non-permafrost environments, frost action and ice segregation within the seasonally frozen layer gives rise to the formation of small-scale sorted and non-sorted patterned ground (circles, nets, stripes), frost heaving of bedrock, and the formation of small hummocks or frost mounds (thufurs, earth hummocks) (Figure 8d).

Wind plays an especially important geomorphic role in the tundra and polar desert environments (Seppala, 2004). For example, the depth and coverage of snow is determined by the prevailing wind regime. Typically, upland surfaces are blown clear of snow, while lee slopes and lower valley-side slopes are sites of snow-bank accumulation. In spring, the melt of snow banks promotes runoff or surface wash that transports sediment down slope. Solifluction or gelifluction is enhanced immediately below snow banks because of the saturated near-surface thaw layer. In some regions, preferential snow distribution results in enhanced solifluction on lee slopes and the development of asymmetrical valleys, with streams being progressively "pushed" toward the windward (steeper) slope. Elsewhere, localized wind erosion can occur in weakly consolidated sedimentary bedrock and deflation operates on fine-grained sediments.

In the absence of vegetation, deflation assumes local importance in many periglacial environments (Figure 9a). In more continental periglacial environments, loess and cover-sand deposition is widespread. For example, in parts of northwestern North America, long-continued mass wasting of loessic materials has led to the partial infilling of valleys with heterogenous organic-rich and ice-rich sediments known locally as "muck" while in parts of central Siberia, similar mass wasting combined with long-continued aggradation of alluvial sediments has created similar ice-rich sediments known locally as "Yedoma complex."

A special characteristic of periglacial areas immediately adjacent to the Antarctic and Greenland ice sheets, and to a lesser degree, the ice-marginal areas peripheral to all glaciers, is the presence of persistent and strong gravity-driven (katabatic) winds that flow outward from the ice. At extremely low temperatures, snow crystals become effective abrasive agents with MOH hardness values exceeding 4 at −40°C; as a result, wind-polished and fluted rocks and bedrock outcrops and wind-abraded cobbles (ventifacts) are common (Figure 9b). In the dry valleys of southern Victoria land and Antarctica, these winds promote sublimation to such an extent that perennial snow and ice is unable to form.

In spite of apparent aridity, fluvial activity is another important component of periglacial environments. This is because losses through evaporation and infiltration are minimized by low temperatures and frozen ground, respectively. The result is a highly seasonal discharge regime, dominated by a nival (snowmelt) peak in early spring. The fluvial dynamics are no different to other



Periglacial, Figure 9 Examples of wind action in periglacial environments: (**a**) Deflation caused by strong winds and an absence of surface vegetation, central Iceland; (**b**) Wind-sculpted bedrock blocks of welded volcanic ash, Brown Bluffs, Antarctic Peninsula.

environments, but high sediment loads and highly variable seasonal discharges lead to a dominance of braided channels as opposed to straight, meandering, and anastomozing patterns. In fact, the well-developed drainage networks and large-scale organization of periglacial landscapes are not dissimilar to those elsewhere. River and lake ice persists for several months of the year; at spring melt, ice jams may develop, causing flooding and damage to structures such as bridges. Where powerful perennial springs emerge, the freezing of discharge in the downstream direction forms tabular ice bodies (river icings) that may cover several square kilometers.

In the northern hemisphere, periglacial coasts experience wave action for a restricted period of the year and are often protected from erosion by an ice foot. Ice pushing is a common feature of many arctic coastlines. Where the coast is formed in ice-rich unconsolidated sediments, as along much of the Beaufort, Laptev, and East Siberian Seas, wave action and thermal erosion result in coastal retreat of several meters per year. The rapid formation of spits and offshore bars is characteristic. In Antarctica, wave action and coastal processes are relatively unimportant on account of the hard bedrock that forms the coastline and the extremely short open-water season.

Periglacial environments, environmental challenges, and global climate change

Periglacial environments constitute part of the cryosphere. As such, they play a critical role in global climate change (Lemke et al., 2007). It is now understood that the hydrological cycle of the big northern rivers of North America and Eurasia links snowmelt and precipitation with river runoff, sea ice, and ocean circulation in a single system. This influences deep water formation in the Arctic basin and the corresponding global thermohaline circulation of the oceans (Peterson et al., 2002). At the same time, any reduction in the extent of sea ice or snow cover reduces albedo, or reflectivity, of land or ocean surface and allows more solar radiation to be absorbed.

Periglacial environments are thought to act, therefore, as a positive feedback mechanism for climate warming. Already, there is speculation that this is the cause of recent reductions in snow cover and sea-ice extent. In the future, any thaw of the organic-rich upper layers of permafrost, especially in the subarctic, will release significant quantities of carbon dioxide and methane, both of which are important greenhouse gases. Finally, the significance of gas hydrates, which exist frozen within permafrost, is still not widely recognized. Yet, their eventual potential release to the atmosphere will lead to a dramatic increase in greenhouse gases and this could further accelerate any climate warming.

If climate warming proceeds as predicted, periglacial environments will be among the first to be affected. Warming will be enhanced because of (1) increased methane flux due to decomposition of organic matter frozen in near-surface permafrost and release of methane hydrates as permafrost bodies degrade, (2) increased biomass production and decay in tundra and taiga zones, and (3) decreased surface albedo as snow-cover extent and duration decrease. Already, there is evidence that warming of permafrost has been ongoing for over 30 years (e.g., Osterkamp, 2008; Brown and Romanovsky, 2008). This may lead to long-term changes. For example, at the southern (warm) limits of the discontinuous permafrost zone, permafrost bodies will progressively disappear, the tree-line will advance northward, and the active-layer thickness will increase. The latter, monitored by the CALM program of the International Permafrost Association (Brown et al., 2000), will probably lead to an increase in the frequency of active-layer detachment failures and slope instability, to changing snow-melt and hydrological regimes, and to enhanced mass wasting and landscape modification in high-latitude permafrost environments. In alpine periglacial environments, thawing permafrost

may lead to instability of rock outcrops that could threaten the foundations of ski lifts and other recreational installations at high elevation (Gruber and Haeberli, 2007; Haeberli, 1992).

A number of environmental concerns relate to global climate change and the impact of human activity in periglacial environments. Many centre around the various problems associated with natural resource management, exploitation, and ownership (e.g., Young, 2009; Tin et al., 2009). For example, the marine and terrestrial ecosystems are increasingly being subject to environmental stress. In the arctic, the marine food chain is linked to sea ice, nutrient availability, and water density. Any changes to these may induce changes to the marine ecosystem and the associated biochemical cycling of essential nutrients. The terrestrial food chain is limited by the short growing season, low temperatures, and low rates of nutrient cycling. Thus, climate warming in high latitudes will change plant and animal communities. This will affect the hunting and harvesting of animals and plants by northern indigenous peoples in Canada, Greenland, and northern Scandinavia. A second environmental concern for the northern high latitudes is the recent increase in industrial air pollution from mid-latitudes. Small particles, such as sulfur dioxide, are transported by atmospheric circulation toward high latitudes where they appear as "arctic haze." The harsh reality is that the northern high latitudes act as an atmospheric "sink" for industrial pollutants generated in the mid-latitudes, especially those of northern Europe and European Russia. Third, in Antarctica, the increasing number of cruise ships and related tourism activities will soon inadvertently impact upon certain of the critical marine- and bird-breeding localities in South Georgia and the Antarctic Peninsula. There is also the possibility of a major marine environmental disaster if a cruise ship were to hit an iceberg and sink in Antarctic waters. Finally, Chinese upgrading of the Qinghai-Xizang (Tibet) Highway in recent years and completion of the Qinghai-Tibet Railway in 2003 has opened the large montane periglacial environment of the Tibet Plateau to a potential increase in human occupancy and economic activity with, as yet, unknown consequences.

Synonyms

Duracrete

Definition

Permacrete is a versatile and unique resurfacing material that can be applied to concrete, masonry, foam, steel, stucco, and aggregate surfaces. Permacrete is an architectural, chemical-concrete with twice the strength of standard concrete (What is Permacrete, 2009). Permacrete is a very strong and heat-resistant material that can be used in a variety of applications.

Formation

Permacrete is a three part, acrylic polymer cementations system with strength of over 6,000 PSI (pounds force per square inch). These three parts include a matrix mix (early-strength concrete mixture), chemical bonding additive, and a stain sealer. It is sealed and nonporous, resists chemicals, and withstands freeze-thaw cycles as well as intense heat and ultraviolet rays (What is Permacrete, 2009; Kirk, 1998).

Thermal disturbance and exposure to solar heat considerably affect the physical and mechanical properties of the permafrost. Preservation of the thermal properties in the permafrost is the major challenge in building the engineering and construction work (Jumikis, 1983). Since the permacrete has the high insulating and heat-resistant properties, it is extensively used in permafrost regions to build the residential properties (houses) and commercial properties (oil, gas pipelines, and tunnels) in combination of soil and ice material.

The ancient form of similar material can be compared with use of snow by Eskimos where they used the block of ice to build the igloos for their shelters in high arctic environment. The application of permacrete as building material can be found when the US Army developed the artificial aggregates by mixing silicates and aluminum-silicate with snow to form "permacrete" while performing experiments in Greenland (Kirk, 1998).

Perennially cryotic ground

Definition

Permafrost. Ground (soil or rock and included ice and organic material) that remains at or below 0°C for at least 2 consecutive years.
Perennially cryotic ground. Soil or rock at or below 0°C for at least 2 consecutive years, but the material may not be frozen because of freezing-point depression.
Active layer. The layer of ground that is subject to annual thawing and freezing in areas underlain by permafrost.
Ice-rich permafrost. Thaw-sensitive permafrost containing excess ice.
Ground ice. Pore, segregated and/or massive ice that occurs in frozen ground.
Permafrost aggradation. A naturally or artificially caused increase in the thickness and/or areal extent of permafrost.

Permafrost definition

The term "*permafrost*" was introduced into the English literature by Muller (1947) as an abbreviation of the original Russian term "*Permanently frozen ground (soil)*" (Sumgin et al., 1940). North American and Russian concepts, however, have differed in how the terms differentiate the presence of frozen water in relation to cold temperatures. Both Muller and Sumgin defined permafrost as soil, bedrock, or other earth materials, whose temperature remains below 0°C for at least 2 consecutive years. This definition has been accepted by The Multi-language Glossary of Permafrost and Related Ground-ice Terms developed by the International Permafrost Association (van Everdingen, 1998). In contemporary Russian permafrost literature, however, permafrost is defined as soil which remains frozen (has ice as its component) for years. "The temperature alone is not a sufficient characteristic of ground to be considered as permafrost" (Baulin and Murzaeva, 2003). Thus, the main difference between Russian and English definitions of permafrost is the occurrence of ice in ground. In Russian permafrost science, permafrost is the perennially frozen ground. Ground can have temperatures below 0°C and not have ice because it does not contain water (usually bedrock) or its freezing point is below its temperature (e.g., saline ground).

To include soil or other earth materials with temperature at or below 0°C, with and without ice, Russian permafrost science uses the term "cryolithozone" (Baulin and Murzaeva, 2003). The permafrost glossary also has a term "*cryotic ground*," which defines soil or rock at temperature 0°C or lower. It also recommends a term "*perennially cryotic ground*," which is synonymous to permafrost. In the Glossary, perennially frozen ground differs from permafrost. "Permafrost is synonymous with perennially cryotic ground; it is defined on the basis of temperature. It is not necessarily frozen, because the freezing point of included water may be depressed several degrees below 0°C; moisture in the form of ice may or may not be present. In other words, perennially frozen ground is permafrost, but not all permafrost is perennially frozen" (van Everdingen, 1998). In the last definition, the word "*permafrost*" lost its origin as a short form for permanently (perennially) frozen ground.

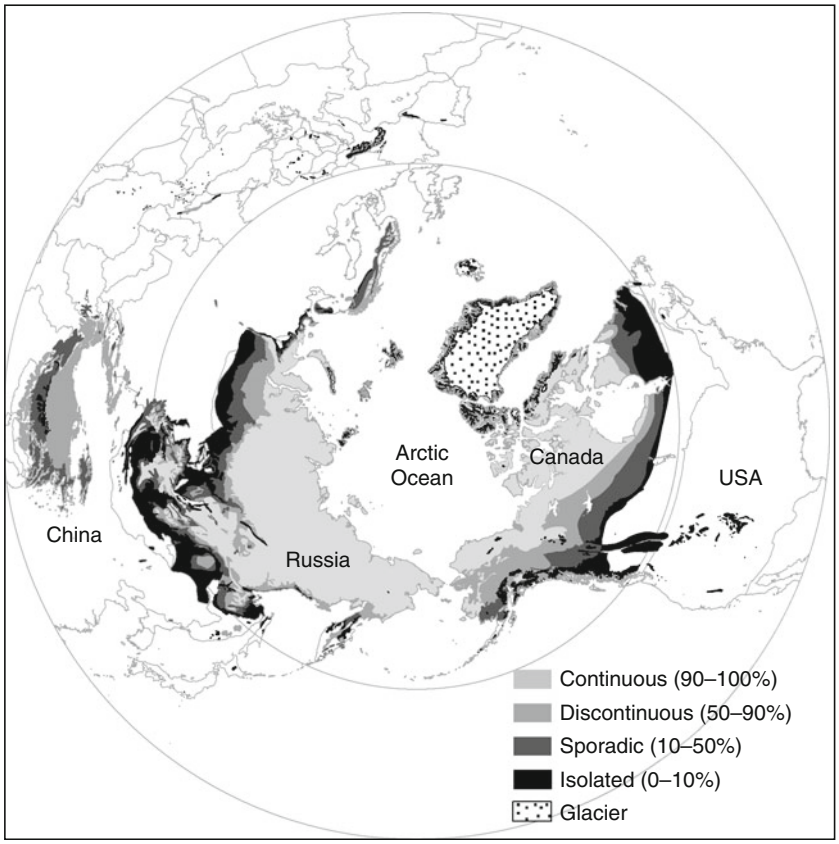
Permafrost distribution

Permafrost regions occupy almost 25% of global land area (Baranov, 1959; French, 2007; Washburn, 1980), about one half of Canada, and almost two thirds of Russia. Permafrost occurs also in China, USA (mostly Alaska), Mongolia, Greenland, Antarctica, and at high elevations in many mountain regions in Eurasia, Africa, and South America. Permafrost occurrence in the Northern hemisphere is shown in Figure 1.

Terrestrial permafrost includes four zones with different distribution of areas with and without permafrost: (1) continuous permafrost, where permafrost exists everywhere and can be interrupted by taliks under big water bodies (deep lakes and rivers); (2) discontinuous permafrost, where permafrost is interrupted or alternates with areas of unfrozen soil; (3) sporadic permafrost, where permafrost occurs as separate masses surrounded by unfrozen soil; (4) isolated permafrost, which occurs mainly in peat mounds and ridges surrounded by unfrozen bogs. The circumarctic map of permafrost and ground ice conditions (Brown et al., 1997) divides the permafrost region in four zones, based on the percentage of the area underlain by permafrost as continuous, 90–100%; discontinuous, 50–90%; sporadic, 10–50%; and isolated patches of permafrost, 0–10%. Figure 2 shows typical permafrost distribution in different permafrost zones. Similar classes of permafrost are often used for small areas. For example, the Copper River Lowland in Alaska is located in the discontinuous permafrost zone, but permafrost there is widespread and shown as continuous on permafrost maps (Ferrians, 1965). It is common to describe permafrost at construction sites located in the discontinuous permafrost zone as continuous, if permafrost underlies the entire site.

Continuous permafrost depends entirely on climate and the impact of local conditions on which permafrost distribution is minimal (except taliks beneath large water bodies). In the continuous permafrost zone, permafrost exists everywhere beneath the land surface and under shallow water, and it takes only 1 year to start permafrost formation after soil is newly exposed in drained lake basins. Impacts on the soil surface from disturbance, such as fire and development, increase the thickness of the active layer and trigger permafrost-related processes (e.g., thermokarst and thermal erosion), but do not lead to degradation of continuous permafrost. The permafrost table usually merges with the bottom of the active layer. Permafrost temperature in this zone varies widely and greatly depends on snow thickness and water depth.

Distribution of discontinuous and sporadic permafrost is affected by both climate and local factors (Shur and Jorgenson, 2007). In the Northern hemisphere south of the continuous permafrost zone, the effects of climate on permafrost decrease and permafrost temperature and distribution become more dependent on topography, soil



Permafrost, Figure 1 Permafrost occurrence in the Northern hemisphere (Based upon Brown et al., 1997).

properties, snow depth, and vegetation. Conditions of permafrost formation vary from favorable to unfavorable in a sequence of ground types involving peat, clay, silt, sand, and gravel. Transition from permafrost to unfrozen ground in the northern part of the discontinuous permafrost zone occurs first in gravel. At the southern boundary of the permafrost region, permafrost exists only in peat mounds, under dense coniferous forest with thick moss and peat layer on the soil surface, or in clay-rich glaciolacustrine sediments. For permafrost existence, composition and properties of the active layer are more important than composition and properties of underlying soil.

Vertical extent of permafrost sequences

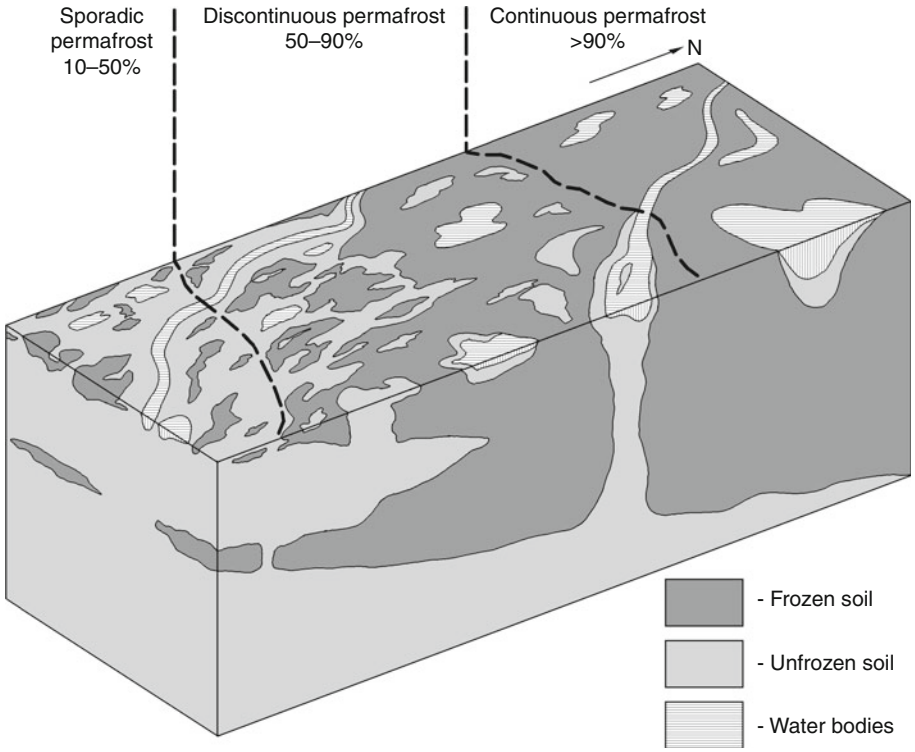
The upper boundary of permafrost is called the permafrost table. It is located at the base of the active layer (if it merges with the bottom of the active layer) or can be isolated from the bottom of the active layer by a layer of unfrozen soil (if the depth of seasonal freezing does not reach the upper boundary of permafrost). In the continuous permafrost zone, the lowered permafrost table often occurs beneath lakes and rivers, and also in areas with a very thick snow cover. In the discontinuous permafrost zone, the lowered permafrost table is often a sign of permafrost degradation.

Sequences of perennially cryotic ground (Figure 3) can be presented completely by perennially frozen ground; by perennially frozen ground underlain or overlaid by cryotic unfrozen ground; by perennially frozen ground overlaid by unfrozen ground (perennially frozen ground with lowered permafrost table); completely by cryotic unfrozen ground, and by several layers of perennially frozen ground alternating with unfrozen or cryotic ground.

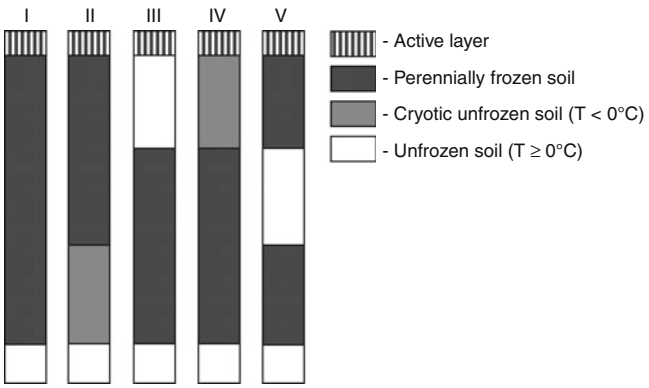
Active layer

The upper layer of ground in permafrost areas seasonally thaws and freezes. This layer is termed the "*active layer*" (Muller, 1947), after the Russian term "*deyatel'nyi sloy.*" In Russian permafrost science, the active layer is differentiated into a "*seasonally thawed layer*" if the bottom of this layer merges with the permafrost table and a "*seasonally frozen layer*" if the layer of seasonal freezing does not merge the permafrost table or if permafrost at a site is absent.

The active-layer thickness (maximum depth reached in the end of summer before freezing) greatly depends on local conditions, such as vegetation and soil composition. Local factors often have greater impact on the thickness of the active layer than regional ones. The impact of climate on active-layer depth is greater in areas with a thin organic layer. In the high Arctic, the thickness of the active layer



Permafrost, Figure 2 Typical permafrost distribution in continuous, discontinuous, and sporadic permafrost zones.

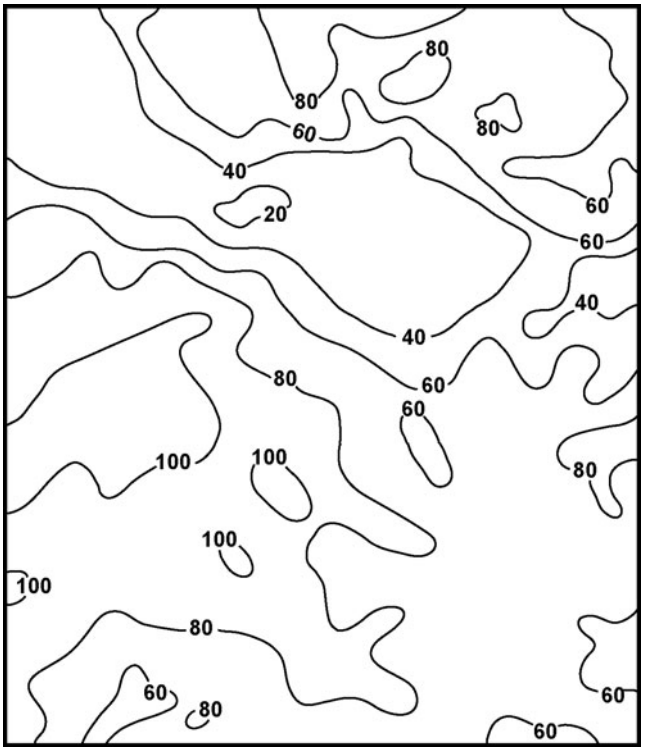


Permafrost, Figure 3 Main sequences of the perennially cryotic ground. *T* = soil temperature.

varies from about 1 m in coarse mineral ground to about 0.2 m in peat. In the discontinuous and sporadic permafrost zones, the thickness of the active layer in areas with a thick organic layer typically varies from 0.3 to 0.7 m. Active-layer depth is greatest for unvegetated or highly disturbed areas with coarse ground located near the southern boundary of the continuous permafrost zone. In the discontinuous permafrost zone, such areas are either free of permafrost or have degrading permafrost with the lowered table. In the continuous permafrost zone, active-layer thickness is determined by summer factors and about 80% of the active-layer depth can be reached in the first half of the summer. In the discontinuous permafrost zone, the thickness of the active layer is determined by winter factors. The lower part of the active layer can remain unfrozen in warm winters and winters with high snowfall (especially when significant snow accumulation happens in the first part of winter).

The thickness of the active layer varies in space and time. For example, a large-scale map of active-layer thickness within a 7 by 6 m grid located in the forest tundra zone of West Siberia (Moskalenko et al., 1978) shows thickness varying from 20 to 100 cm over short distances (Figure 4). It creates an irregular relief of the permafrost table, which is often more prominent than a local relief of the soil surface at the site. Such relief affects lateral water flow in the active layer, with accumulation of water in depressions of the permafrost table.

Active-layer thickness varies from year to year even in stable climate conditions. In mineral soils, variations are usually about 10–15% of the annual mean, but they can be as much as 30%. In organic soils, they can reach about 40% of the annual mean. A layer of soil that belongs to permafrost for several years and joins the active layer in other years is called "*transient layer*." It has a profound impact on the processes in the upper permafrost, on the formation of soil, and the thermal stability of permafrost in the face of climatic variations (Shur et al., 2005).



Permafrost, Figure 4 Thickness (cm) of the active layer at the transect 7 by 6 m in forest tundra zone of West Siberia (Based upon Moskalenko et al., 1978) .

Permafrost, Figure 5 Ataxitic (suspended) cryostructure of the intermediate layer, Northern Alaska.

Active-layer thickness usually decreases along with development of an ecosystem, mainly because of accumulation of organic matter on the soil surface. During this process, the bottom part of an initial active layer joins permafrost. This layer of permafrost is termed the "*intermediate layer*" (Shur, 1988). It is usually extremely ice-rich and has a unique cryostructure (pattern of ice inclusions in soil) called "*ataxitic*" or "*suspended*" (Figure 5).

Permafrost, Table 1 Classification of frozen ground due to visible ice content (based on GOST 25100-95)

	Visible ice (part of volume)	
Soil category	Bedrock	Soil
Ice-poor	<0.01	<0.20
Moderately ice-rich	0.01–0.05	0.20–0.40
Ice-rich	>0.05	0.40–0.60
Extremely ice-rich		>0.60

Ground ice

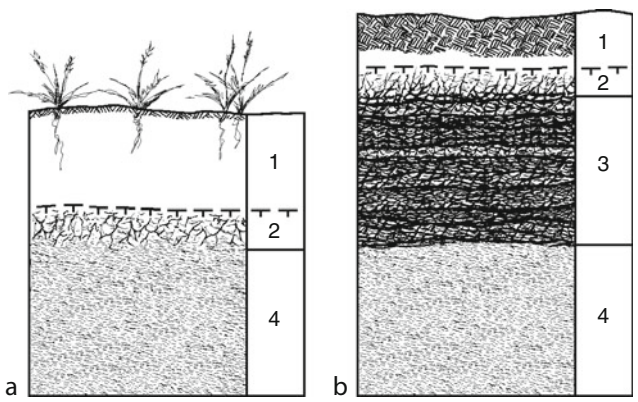
The volume and type of ground ice is important in determining thaw settlement characteristics and the sensitivity of permafrost to disturbance and thawing. Ice-rich permafrost is defined as thaw-sensitive permafrost containing excess ice (van Everdingen, 1998). It means that perennially frozen ground contains ice in excess of the ice volume required to fill pore space in unfrozen state. Thaw sensitivity of permafrost is subjective and site specific. Thaw strain (thaw settlement divided by initial thickness of a soil in frozen state) as much as 2% is not sufficient to affect structural integrity, while thaw strain of 3% or more can cause settlement damaging to most structures, but practically negligible for most of natural processes. The circumpolar map of permafrost and ground ice (Brown et al., 1997) classifies content of visible segregated ice (percent of its volume in the upper 10 m of permafrost) >20% as high; 10–20% as medium, and <10% as low (for areas with thick overburden cover). For areas of generally thin overburden cover, only two classes of ground ice are mapped, medium to high (>10%) and low (<10%). Russian frozen ground engineering defines four categories of frozen soil on the basis of visible ice content (Table 1). Visible ice content can be evaluated by measurement of thickness of ice inclusions in field or from photographs. The approach can be misleading for syngenetic permafrost, however, because abundant, very thin ice lenses are nearly invisible and often overlooked. The other approach is to define frozen soil by its thaw strain.

Ground ice can be highly variable with many distinctive forms that affect both ice volume and stability of permafrost.

Permafrost aggradation

Permafrost aggradation is a naturally or human-caused increase in the thickness and/or areal extent of permafrost (van Everdingen, 1998). Permafrost aggradation is a synonym to permafrost formation. It can be driven by climate or by change in local conditions (Shur and Jorgenson, 2007). Increase in the permafrost thickness occurs as a downward advance in epigenetic permafrost (forms after sediments have been deposited) and an upward advance in syngenetic permafrost (forms at the same time that sediments are deposited).

A special type of permafrost aggradation is associated with thinning of the active layer during ecosystem development due to changes in vegetation and accumulation of organic matter with low thermal conductivity on the soil surface. This process is widespread in continuous and discontinuous permafrost zones. It leads to a decrease in the thickness of the active layer and formation of a special layer of upper permafrost termed the "*intermediate layer*" (Shur, 1988) (Figure 6). Formation of the intermediate layer is "*quasi-syngenetic*" because permafrost is growing upward, similar to syngenetic permafrost formation, but without accumulation of new sediment on the soil surface. Transformation of the lower part of the active layer into the extremely ice-rich intermediate layer is accompanied by accumulation of aggradational ice (Mackay, 1972; Shur, 1988). Its formation is accompanied by perennial frost heave that can raise the ground surface by as much as 2 m. Formation of the intermediate layer is important to the formation of frost boils and earth hummocks (Shur et al., 2008). Accumulation of aggradational ice near the soil surface makes permafrost vulnerable to thaw subsidence on flat surfaces and to slumping on sloping terrain. Thawing of the intermediate layer is usually associated with an increase in active-layer depth, which can be caused by wildfire, stripping vegetation, or construction works. Relic intermediate layers, which initially formed during periods of decreasing sedimentation and temporal stabilization of the soil surface, can be evident at depth in syngenetic Pleistocene permafrost (Kanevskiy, 2003).



Permafrost, Figure 6 Structure of the upper permafrost before (**a**) and after (**b**) intermediate layer formation. Ice is black. Decrease in the active-layer thickness is related to accumulation of organic matter at the surface. 1 – active layer; 2 – transient layer; 3 – intermediate layer with aggradational ice; 4 –permafrost sequence before formation of the intermediate layer (Based upon Shur, 1988; French and Shur, 2010).

Permafrost landforms

A great variety of periglacial landforms can develop on permafrost terrain in response to the aggradation and degradation of permafrost. Some prominent features associated with ground ice aggradation include low-centered polygons, palsas, and pingos. In contrast, features associated with collapse of ice-rich terrain include thermokarst lakes, thaw slumps, collapse-scar bogs, and high-centered polygons (Jorgenson and Osterkamp, 2005). These landforms are useful in mapping permafrost distribution and in assessing the amount and type of ground ice present.

Palsa

Palsas are peat and peat-mineral soil mounds formed by frost heave due to accumulation of segregated ice. They rise above unfrozen bogs in the discontinuous and sporadic permafrost zones and usually form isolated patches of permafrost. Palsas occur separately or in clusters as rounded mounds and ridges. In some areas, they form large fields of tightly neighboring mounds.

The height of separate palsas varies from dozens of centimeters to 10 m, and they occupy area from a few to thousands of square meters. Palsa is the best example of the ecosystem-driven permafrost (Shur and Jorgenson, 2007). It is also the most sophisticated permafrost feature. It forms in wide range of climatic conditions of the discontinuous and sporadic permafrost zones. Both climate and vegetation succession participate in their formation. Palsas develop in the conditions most unfavorable to permafrost formation in the permafrost region. Accumulation of organic matter including sphagnum moss and peat are essential to palsa formation (Seppälä, 1986). Palsa formation cannot be explained only by an impact of physical factors such as temperature and snow depth.

Development of palsas includes pre-permafrost and permafrost stages. At the pre-permafrost stage, ecological succession prepares conditions favorable to perennial soil freezing. In the discontinuous and sporadic permafrost zones, bogs with water on the surface are free of permafrost. To be susceptible to perennially freezing, vegetation succession and accumulation of peat in bogs should reach the stage at which the surface of the bog rises above the water level. In West Siberia, for example, this stage is presented by a dwarf shrub-sphagnum association. Accumulation of sphagnum and a rise of bog ridges and hummocks create conditions in which the difference between thermal properties of peat in frozen and unfrozen state becomes an important modifier of soil climate that can be compared with increase in the winter freezing index and decrease in summer thawing index. The thickness of snow on the locally elevated surface is smaller than on

surrounding terrain, which is also a factor stimulating perennial freezing of soil in palsas (Seppälä, 1990). Initial formation creates a positive feedback to further permafrost aggradation because of natural snow removal by wind from the elevated surfaces surrounded by lower flat terrain.

Palsas are typical features of a poorly drained terrain in discontinuous and sporadic permafrost zones. They widely occur in Fennoscandia, Russian European North, West Siberia, Russian Far East, and Kamchatka. West Siberia is the greatest region of palsa development where the area of their occurrence is about 500 km by 1,000 km. Its southern boundary coincides with the southern boundary of the permafrost area and its northern boundary is the southern boundary of the continuous permafrost zone. The range of mean annual air temperature in this area varies from about −1°C to −7°C. Although palsas are mostly features of discontinuous and sporadic permafrost zones, small palsas can be observed sometimes in the continuous permafrost zone where they develop as a result of expansion of aquatic marsh vegetation in lakes and ponds.
