Encyclopedia of Earth Sciences Series

ENCYCLOPEDIA OF SNOW, ICE AND GLACIERS

Volume Editors

Vijay P. Singh holds the Caroline and W. N. Lehrer Distinguished Chair in Water Engineering, and is also Professor of Biological and Agricultural Engineering, and Civil and Environmental Engineering at Texas A & M University. He has authored 16 text and reference books, edited 49 books, authored 72 book chapters, and published more than 550 refereed journal articles, 320 conference proceedings papers and 70 technical reports. He is Editor-in-Chief of the Water Science and Technology Book Series of Springer, the ASCE Journal of Hydrologic Engineering, and Water Science and Engineering. He has received more than 60 national and international awards and numerous honors, including the ASCE's Arid Lands Hydraulic Engineering Award; Distinguished Research Master Award from Louisiana State University; ASCE's Ven Te Chow Award; AIH's Ray K. Linsley Award; Hon. Ph.D. from University of Basilicata, Italy; and Hon. Diplomate from American Academy of Water Resources Engineers. He is a fellow of ASCE, AWRA, IE, IAH, ISAE, and IWRS. He is a member/fellow of 10 international science and engineering academies. His research interests include surface and groundwater hydrology, hydraulic engineering, irrigation engineering, and mathematical and stochastic modeling.

Pratap Singh has over 30 years experience in snow and glacier hydrology with an emphasis on modeling of snow and glacier melt runoff. He developed a snow melt model (SNOWMOD), which has been applied for streamflow simulation for snow- and glacier-fed rivers. He has published over 100 technical papers in international/national journals and co-authored with Professor V.P. Singh a book on *Snow and Glacier Hydrology*, published by *Kluwer Academic Publishers*, The Netherlands. He is Associate Editor for the Hydrological Sciences Journal, Wallingford, UK.

Umesh K. Haritashya is a faculty member in the Department of Geology at the University of Dayton, where he teaches courses in glacial geology, geomorphology and remote sensing. He has extensive experience of working on many mountain regions around the world. His research interests include debris cover glacier characterization, glacier dynamics, contribution of glaciers to sea level rise, impact of climate change on mountain glaciers, and glacier hydrology. He is also associated with NASA's GLIMS project and is an editorial board member of the Journal of Hydrologic Engineering, the Open Hydrology Journal, and Himalayan Geology.

Editorial Board

Aims of the Series

The *Encyclopedia of Earth Sciences Series* provides comprehensive and authoritative coverage of all the main areas in the Earth Sciences. Each volume comprises a focused and carefully chosen collection of contributions from leading names in the subject, with copious illustrations and reference lists.

These books represent one of the world's leading resources for the Earth Sciences community. Previous volumes are being updated and new works published so that the volumes will continue to be essential reading for all professional earth scientists, geologists, geophysicists, climatologists, and oceanographers as well as for teachers and students. See the dustjacket of this volume for a current list of titles in the *Encyclopedia of Earth Sciences Series*. Go to http://www.springerlink.com/reference-works/ to visit the "Earth Sciences Series" online.

About the Series Editor

Professor Charles W. Finkl has edited and/or contributed to more than eight volumes in the Encyclopedia of Earth Sciences Series. For the past 25 years he has been the Executive Director of the Coastal Education & Research Foundation and Editor-in-Chief of the international *Journal of Coastal Research*. In addition to these duties, he is Research Professor at Florida Atlantic University in Boca Raton, Florida, USA. He is a graduate of the University of Western Australia (Perth) and previously worked for a wholly owned Australian subsidiary of the International Nickel Company of Canada (INCO). During his career, he acquired field experience in Australia; the Caribbean; South America; SW Pacific islands; southern Africa; Western Europe; and the Pacific Northwest, Midwest, and Southeast USA.

Founding Series Editor

Professor Rhodes W. Fairbridge (deceased) has edited more than 24 Encyclopedias in the Earth Sciences Series. During his career he has worked as a petroleum geologist in the Middle East, been a WW II intelligence officer in the SW Pacific and led expeditions to the Sahara, Arctic Canada, Arctic Scandinavia, Brazil and New Guinea. He was Emeritus Professor of Geology at Columbia University and was affiliated with the Goddard Institute for Space Studies.

Preface

Snow, ice and glaciers (SIG) are the components constituting what is called cryosphere. They exist at all latitudes and contain the majority of the earth's fresh water. Due to their dominant prevalence, they influence weather, climate, ecosystems, vegetation, and life and human activities in a variety of ways. Indeed they shape human civilization. Owing to looming climate change and global warming, temperature changes now seem inevitable and are changing the landscape of snow, ice and glaciers, or even the existence thereof. In fact, the changes occurring in SIG can be construed as major indicators of climate change. The nature of cryosphere is highly interdisciplinary and calls for an updated interdisciplinary account of its dynamics. Recent decades have witnessed increasing attention to SIG and scientific communities have started working collectively to develop the basic foundation upon which the broad understanding of cryosphere rests. However, there is still a long way to go.

Discussions on climate change and global warming now seem to be occupying the center stage in public debates, professional forums, news media, and political dialog. As a result, the general public has become much more aware of what is happening to our climate. Since both climate change and climate variability have been found to be closely linked with the cryosphere, it is important for scientists and professionals in the field of earth, environmental, oceanic and atmospheric sciences to develop a better understanding of this sphere from conceptual, theoretical, technical and applied viewpoints. This is especially important for snow, ice and glacier covered areas, since they are rarely stable and are continuously changing in their thickness, areal extent, and flow speeds. Recent advances in field-based studies and quantitative and numerical modeling have provided answers to several key questions but have also highlighted the urgent need for cryospheric studies in many areas, for example, contribution of snow, ice and glacier melt to the sea level rise; importance of snow and glacier to water resources; and so on.

The objective of this Encyclopedia is to present the current state of scientific understanding of various aspects of earth's cryosphere – snow, glaciers, ice caps, ice sheets, ice shelves, sea ice, river and lake ice, and permafrost – and their related interdisciplinary connections under one umbrella. Therefore, every effort has been made to provide a comprehensive coverage of cryosphere by including a broad array of topics, such as the atmospheric processes responsible for snow formation; snowfall observations; snow cover and snow surveys; transformation of snow to ice and changes in their properties; classification of ice and glaciers and their worldwide distribution; glaciation and ice ages; glacier dynamics; glacier surface and subsurface characteristics; geomorphic processes and landscape formation; hydrology and sedimentary systems; hydrochemical and isotopic properties; permafrost modeling; hazards caused by cryospheric changes; trends of glacier retreat on a global scale along with the impact of climate change; and many more quantitative estimates of various glacier parameters, such as degree-day, mass balance, extent and volume, and downwasting. Also included are articles on GPS application, and satellite image application in glaciology; GPR analysis; and sea level rise.

For purposes of the Encyclopedia 463 articles were selected. Literature on snow, ice and glaciers has grown too large to be fully treated in a single volume; therefore, the selection of articles included some subjectivity but was reviewed by many experts who have long been at the forefront of research in the field of cryosphere. We truly understand that given the scope of this subject it is almost impossible to include each and every topic in this type of reference book, but we have tried our best to avoid any glaring omissions or miss something which could significantly hamper the quality of the Encyclopedia. Therefore, we have made the contents of the Encyclopedia exhaustive, but we understand that we might have missed certain topics. We are also aware of some partial omissions. As it frequently happens, willing contributors

cannot unfortunately be always found for all the suggested topics. It may be noted that if the reader does not see an entry for the particular topic that interests him or her, then he or she should look in the index because that topic may have been covered under a different heading and perhaps in more than one article. In making the list exhaustive, it is possible that there might be a little bit of repetition here and there, but we do not want readers to read two articles to understand one.

The material presented in the articles consists of established information on a particular topic and represents easily accessible digested knowledge. The level of material is such that a graduate student can benefit from the presentation which is not necessarily from his or her area of expertise. An effort has been made such that each article stands on its own, without an assumption that a reader will be seeing any other portion of the Encyclopedia. Although entries are presented in alphabetical order, they have been organized under major compilation headings which should become particularly obvious when the reader uses the cross-references with each entry. This is not an exhaustive list but hopefully it gives a structure to the Encyclopedia's contents. Of equal value are the many references given with the entries.

This *Encyclopedia of Snow, Ice and Glaciers* is supposed to provide clear explanations of current topics, and is not structured as a student textbook, but it is rather for quick access to particular terms and concepts in self-contained entries. We hope that this volume will also tempt the casual reader to browse through and become curious about the different facets and foci of cryosphere.

The contributors represent varying backgrounds and many of them represent WHO'S WHO in the cryosphere. It is hoped that the Encyclopedia will serve as a reference to scholars and students. The Encyclopedia will also be a valuable resource for geologists, geographers, climatologists, hydrologists, and water resources engineers; as well as to those who are engaged in the practice of agricultural and civil engineering, earth sciences, environmental sciences and engineering, ecosystems management, and other relevant fields.

The encyclopedia is comprised of articles under three categories: A, B, and C. Tables 1, 2 and 3 provide a list of major headings of articles included in the encyclopedia for a quick reference (see List of Articles, pages 1233–1237). 64 articles in category A represent major divisions and review topics. These also serve to coordinate the widely scattered entries of categories B and C. 182 Category B articles constitute building block items, inspired by textbook subheads, but also the cookbook items. 217 articles in category C are mini-entries dealing with materials, fancy terms, or outdated concepts. All these categorical entries on different topics are compiled in an alphabetical order, with their length being related to their relative importance.

Acknowledgments

This Encyclopedia is a result of the collective contributions of the authors who were gracious, generous and willing to write different articles. These authors, representing five continents, have synthesized the body of knowledge in their particular area, and therefore the quality of the Encyclopedia is a reflection of the quality of their efforts. We are grateful to these authors. Any drawbacks are editors', not authors'. The preparation of this Encyclopedia was greatly aided by the assistance we received from our International Advisory Board members:

Richard Armstrong, NSIDC, Boulder, Colorado, USA;
Michael P. Bishop, University of Nebraska-Omaha, USA;
Helgi Björnsson, Institute of Earth Sciences, Iceland;
Wilfried Haeberli, WGMS, University of Zurich, Iceland;
Johannes Oerlemans, University of Utrecht, Netherlands;
John F. Shroder, University of Nebraska-Omaha, USA;
Martyn Tranter, University of Bristol, UK;

We wish to express our deep gratitude to them for their invaluable support and encouragement.

All category A articles and major category B articles were peer reviewed. Reviewers of these articles are gratefully acknowledged for their constructive reviews. Their efforts have greatly enhanced the quality of contributions contained in the Encyclopedia. Special thanks goes to Tom Allen, Andrew Bush, Etienne Berthier, Poul Christoffersen, Graham Cogley, Luke Copland, Moritz Dick, Thomas Grenfell, William Harrison, Robert Hellstrom, Kenneth Jezek, Richard Lindzen, Frederick Nelson, Mauri Pelto, Donald Rapp, and Cornelis Vanderveen.

We would also like to acknowledge the constant support and help we received from Petra van Steenbergen, Senior Publishing Editor, Earth Sciences and Geography, Dr. Sylvia Blago, Associate Editor MRW and Simone Giesler, Editorial Assistant, Springer.

Our families (V.P. Singh: wife Anita, son Vinay, daughter-in-law Sonali, and daughter Arti; P. Singh: wife Anju, sons Arpit and Aman; and U.K. Haritashya: wife Namrata and daughter Vanshika) allowed us to work during holidays, weekends and in night away from them. They provided support and help whenever we needed. Without their patience and love, this volume might not have been completed, and we are much grateful to them.

Guide to the Reader

For the beginners, it is good to start with a general article, then track the list of cross-references provided at the end of the article to locate similar or relevant articles. For example, if one wants to learn about hydrological aspects of snow and glaciers, then one should go to Glacier Hydrology and Snow Hydrology, then Melt Runoff Modeling, then Impacts of Snow and Glaciers on Runoff, then Hydrochemical Characteristics of Snow, Ice and Glaciers, then Hydropower: Hydroelectric Power Generation from Alpine Glacier Melt, or several other specific Snow or Glacier Hydrology related articles. The list of cross-references provided at the end of the article is not exhaustive, otherwise it would lead to a long listing, rather it is a guide for the reader to find other relevant articles, which are further cross-referenced.

Experts or other readers with background in cryosphere may directly search for specific topics. For example, Ice Age Cycles: Data, Models, and Uncertainties, or Basal Sediment Evacuation by Subglacial Drainage Systems. If one does not find the topic one is looking for, it is possible that it may have been covered under a different heading. Therefore, one should go to the index that would lead to the articles that may cover the topic of interest. If a reader is looking for more explanation than what is already described under any particular topic, then most articles provide important and landmark bibliographic references that relate to both general and research articles. Some articles provide older references which allow readers to find the historical aspect of the topic.

A

ABLATION DEPRESSION

Lasafam Iturrizaga

Synonyms

Ablation valley; Ablation valley complexes; Lateroglacial valley; Randkluft; Valley-side depression

Definition

The ablation depression ("ablation valley") is an element of the lateroglacial landform system. The term refers to a depression in-between the glacier and the adjacent valley flank or the sediment mantling the valley flank. It is mainly formed by solar insolation processes. Its width ranges generally from several meters to some tens of meters. The ablation depression might act as important sediment trap.

Geographical distribution

Ablation depressions may occur along the lateral margins of any glaciers worldwide as long as they are flanked by slopes of bedrock or sediments (Figure 1). Ablation effects by the emission of long-wave radiation occur in all geographical latitudes, but at different extents. The optimal distribution area of ablation valleys is located along glaciers in subtropical latitudes, such as in the Andes (Jordan, 1991) or in High Asia (Kuhle, 1991). They are best developed in the extensively glaciated Karakoram Mountains (Visser, 1938; Röthlisberger, 1986) and attain their highest altitudinal distribution worldwide in this mountain region (Iturrizaga, 2003, 2007) (Figure 2). Low rates of humidity promote a high transparency of the air leading to insolation rates that may almost reach values of the solar constant. Ablation valleys occur from altitudes around the snow line at about 4,800–5,200 m down to 2,900 m (Iturrizaga, 2007; cf. Visser, 1938). However, they are also reported from glaciers in high latitudes, such as along Norwegian glaciers, where they are developed in smaller size (Gresswell, 1958).

Their distribution is influenced by aspect (Visser, 1938). Therefore, they are supposed to show an asymmetric allocation along the glaciers and occur preferentially in South-aspect at W-E running glaciers. However, topographical-controlled factors, such as debris supply by the tributary valleys into the lateroglacial environments, might predominate the aspect-controlled distribution of the ablation depressions.

Formation process

Ablation depressions have been firstly documented as glaciological landforms of heat radiation from the Himalayas (Strachey, 1847). Oestreich (1906) introduced the nongenetic term of "Randtälchen" (*small marginal valleys*) for these lateroglacial depressions. Visser (1938) has investigated the lateroglacial landforms in a more systematic approach and recognized that they are characteristic key forms of subtropical high-mountain areas. He introduced the term "ablation valley" (*Ablationstal*), but it has been subsequently widely confused with the landform of a "lateral moraine valley" (Röthlisberger, 1986; Hewitt, 1993). Because this landform is no true valley, that means it possesses no continuous gradient and is in general only some tens to hundreds of meters long, the term "ablation depression" has been introduced.

The formation of an ablation depression is a direct consequence of solar insolation and reflection effects of the bedrock. Due to the heating of the rock and the subsequent emission of long-wave radiation, the glacier ice is melting back at its margins forming a striking void. Temperature values of the bedrock surface can rise to over 30°C along

the glacier margins, even at altitudes of 5,000 m depending on the color and mineralogical composition of the geological parent material (Visser, 1938; Iturrizaga, 2007). Ablation processes include the melting and runoff or evaporation and sublimation of the glacier ice, which results in wasting of the ice and mass loss. Sublimation processes play a major role in the dry air in the formation of the ablation depressions.

In principle, ablation depressions can occur at clean ice, debris-covered glaciers, advancing glaciers, and also along avalanche cones at the base of south-exposed valley flanks in the form of ablation crevasses. They can be mixed up with valley-side depressions as a result of general ice shrinkage and the backwasting of the glacier at its marginal sides.

The formation of ablation depressions may be enforced by lateroglacial rivers, which widen the gap between glacier and valley flank. Once an ablation depression has been built up, dumping processes of supraglacial moraine material at the glacier margins may cover the clean ice surfaces and protecting the glacier ice to a certain extent from further melting processes. The ablation depressions can

act subsequently, as well as sediment traps forming lateral moraine valleys.

Summary

To conclude, ablation depressions are rather short-lived lateroglacial landforms. They might be easily mistaken as indicators of glacier shrinkage. After the formation of an ablation valley, the steep glacier marginal cliffs may be covered by a lateral moraine and transformed into a more stable and long-lasting lateral moraine valley.

Definition

An ablatometer is an instrument used for measuring the rate of surface ablation of exposed ice or snow. The sensing element may be a potentiometer linked to a movable metal tube, supported between two poles that are drilled at least 2 m into the surface to minimize subsidence of the supports, as in the Lewkowicz (1985) ablatometer. The sensing tube has a foot constructed of wood for ice and plastic for snow, which rest on the surface, thus following it down as ablation occurs. The ablatometer operates by converting an extension of the slide into a change in the electrical resistance of the potentiometer. The later is wired into a micro-logger for continuous recording of ablation.

The star ablatometer, as explained by Muller and Keeler (1969), consists of a 1 m long six-arm metal star mounted on a stake. Thirty-six points are measured by the lowering of a thin rod through the six sleeved holes in each arm. The rod contacts a variety of surface points, including both peaks and depressions of the microrelief, and penetrates the larger cryoconite holes and some of the spaces between loose crystals. Thus, the star ablatometer provides some information on the changes within the weathering crust in the surface lowering value and therefore yields a more accurate measure of ablation than the straightedge method. The instrument is removed between measurements, thus obviating the interference that additional stakes would cause.

ACIDITY OF GLACIER ICE

Cunde Xiao
State Key Laboratory of Cryospheric Sciences, Cold and Arid Regions Environmental and Engineering Research Institute, Chinese Academy of Sciences, Lanzhou, Gansu, China

Synonyms

Acidity of snow; Alkalinity of glacier ice

Definition

The acidity of glacier ice is the degree of acidity (content of $[H^+]$) of glacier ice, reflecting the dissolved anionic contents among the grain boundaries of glacier ice.

Acidity of glacier ice

The acidity of glacial ice is determined by the anionic contents of aerosols captured by snow and ice. When no extra

ions are in input, then ionic balance in current polar snow/ice can be represented as:

$$\Delta C = [Na^+] + [NH_4^+] + [K^+] + [H^+] + [Ca^{2+}] + [Mg^{2+}] - [F^-] - [Cl^-] - [NO_3^-] - [SO_4^{2-}] - [CH_3SO_3^-] - [HCOO^-] - [CH_3COO^-]$$

Usually there are very low concentrations of Ca^{2+}, Mg^{2+}, and Cl^- in the polar ice sheets. Therefore the acidity is mainly determined by Cl^-, NO_3^-, and SO_4^-. Therefore, the above equation can be reduced as:

$$[H^+] = [Cl^-] + [NO_3^-] + [SO_4^{2-}].$$

While in extra-polar regions, HCO_3^- and CO_3^{2-} are important anions due to larger areas of bare rock/soil surface. It can be represented as:

$$[H^+] = [Cl^-] + [NO_3^-] + [SO_4^{2-}] + [HCO_3^-] + [CO_3^{2-}]$$

Acidity of glacial ice is always reflected by electrical properties of solid ice. Ice conductance is often measured using electrical conductivity method (ECM) or dielectric profiling (DEP), which rapidly detects impurity ions incorporated into the ice lattice and at grain boundaries. High ECM or DEP reflects high acidity. When detecting ECM and DEP along ice cores, high signals reveal past volcanic events that characterized by high SO_4^{2-} concentrations in ice layers.

In mountainous glaciers in the mid-latitudes, it is found that electric conductivity (EC) of glacial melt water is a useful proxy for the total concentrations of dissolved ions. Therefore, alkalinity (OH^-) of glacial ice has positive relationship with major cations such as Ca^{2+}, Mg^{2+}, Na^+, and K^+, which derives mainly from dust aerosols. Therefore, higher dust loading of glacier ice corresponds to lower acidity.

Summary or conclusions

Acidity of glacier ice is a useful proxy for the past climatic and environmental changes. Volcanic events recorded in ice cores were detected using this proxy. Anthropogenic pollution can also be reflected by high degree of acidity in the ice. Loadings of alkaline dust can reduce the acidity of glacier ice.

ACTIVE ICE WEDGE

Pratima Pandey
Centre of Studies in Resources Engineering, Indian Institute of Technology, Bombay, Mumbai, Maharashtra, India

Definition

An *ice wedge* is defined as a crack in the frozen ground. It may have an opening at the ground surface of the order of few meters which reduces with depth. Ice-wedge is abundantly found along the Arctic coast and in many permafrost areas of the world. The formation and growing of ice wedges have been backed by the thermal contraction theory. In general, the melting of snow and its refreezing in thermal contraction cracks are accepted as the main reason for recent ice wedge formation. Due to thermal contraction, cracks open in winter and filled in with water in summer and form ice veins. The wedges which are still evolving and growing because of repeated but not necessarily annual winter cracking are defined as active ice wedges. Permafrost is the region where most ice wedges remain active. Ice wedge cracking is sensitive to climatic factors, particularly the winter snowfall. The long-term monitoring of ice wedge cracks can play an important role in climatic change–related studies.

ADFREEZE

Pratima Pandey
Centre of Studies in Resources Engineering,
Indian Institute of Technology, Bombay, Mumbai,
Maharashtra, India

Definition

Adfreezing is the process by which two objects are bonded together by ice formed between them and that anchors piles or buried foundations in permafrost, so that they can be unaffected by frost heave occurring in the active layer. Adfreeze (adfreeze strength) is the shear or tensile strength that has to be overcome to separate two objects that are bonded together by ice. The shear stress required to separate an object from the frozen ground is frequently referred to as the "tangential adfreeze strength."

AERIAL PHOTOGRAMMETRY FOR GLACIAL MONITORING

Martin Kappas
GIS and Remote Sensing Section, Institute of Geography, Georg-August University Göttingen, Göttingen, Germany

Definition

Before starting with the main text, some photogrammetry terms and some standard technical terms of photogrammetry are introduced. As defined after the fifth edition of the Manual of Photogrammetry: "Photogrammetry is the art, science and technology of obtaining reliable information about physical images and patterns of electromagnetic radiant energy and other phenomena." In short it is the "science of measuring in photos." It belongs to the broader field of remote sensing. The principle of *stereoscopic viewing* is used to derive three-dimensional information in photogrammetry.

Photo: The original photo on film
Image: The photo in digital representation – scanned or directly digitally captured by a digital camera
Stereo model: Two neighboring images within a flight strip that have an area with stereoscopic overlap
Strip: All overlapping images within a flight line
Block: All images of all strips
Base: Distance between the projection centers of two neighboring photos
Oriented image: A digital image that has both the interior and exterior orientations known
Rectified image: A digital image, in which the pixels have been corrected to a vertical projection and errors resulting from the non-verticality of the camera have been removed
Orthophoto: A digital image in which the pixels have been corrected to an orthogonal projection, removing errors due to tilt and terrain displacement
Monitoring: To observe or measure an object from time to time

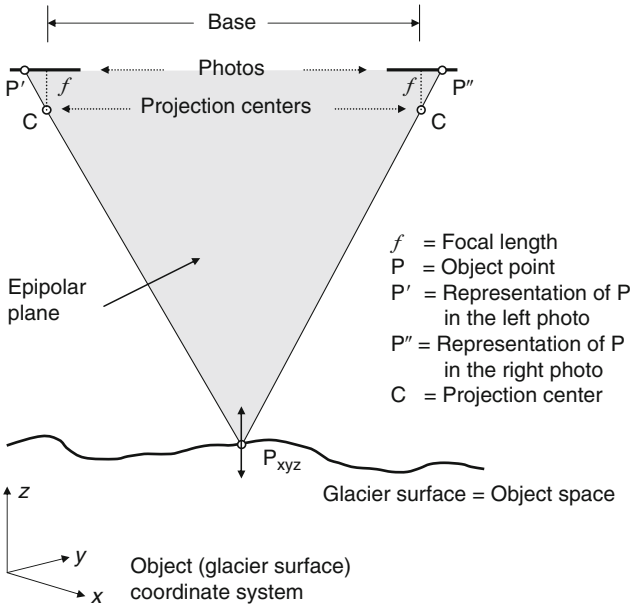
Introduction

Glaciers are three-dimensional objects, which change their shape in length, width, and height. The monitoring of these changes is one major field of airborne-based or satellite-based (e.g., ASTER) photogrammetry. To measure three-dimensional coordinates, a method is needed to get the third dimension. In photogrammetry, the so-called stereoscopic viewing is used to get three-dimensional information: If two or more photos from the same object (glacier) are taken from different positions, the three-dimensional coordinates (x, y, z) of any point that is represented in both or more photos can be easily calculated. In general, for any object point represented in at least two photos, three-dimensional object (terrain- or surface-) coordinates can be calculated. If the height in point P (on the glacier surface) is changing, the corresponding points P′ and P″ are linearly moved along their epipolar lines. Figure 1 illustrates the geometry in an oriented stereo model. Each point on the glacier surface (object point) is detectable in at least two photos. If all geometric parameters of the situation during photo shooting are known, the three-dimensional coordinates (x, y, z) of the point P on the glacier surface can be calculated by setting up the equations for the rays (P′ → P) and (P″ → P).

Measurement in photos means also to measure points on the object without a physical contact to the object. Therefore, photogrammetry is useful for glaciers or for situations in which the object cannot easily be reached (often the case for glaciers).

A brief history of photogrammetry

From a historical view, photos are the first "remotely sensed" data of the earth surface. Therefore, photos about glaciers offer an important historical data archive about the glaciers state and development over time, which can be used for monitoring purposes. The history of



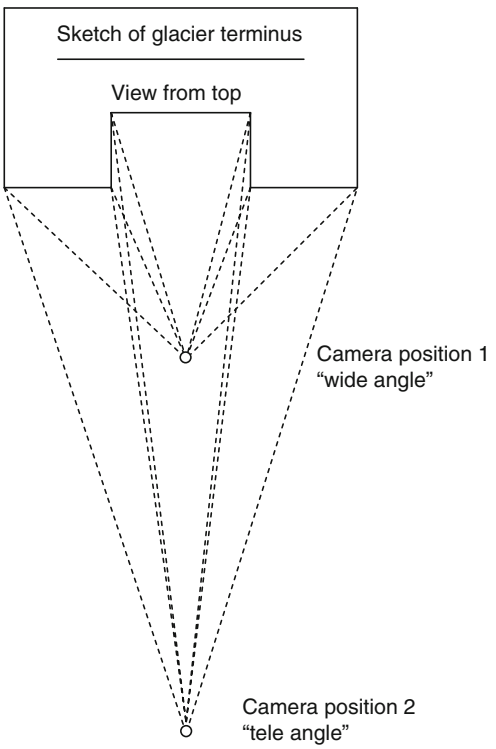
Aerial Photogrammetry for Glacial Monitoring,
Figure 1 Geometry in an oriented stereo model (modified after Linder, 2006).

photogrammetry and in particular the history of photogrammetry for glacier monitoring is covered here in terms of time periods corresponding to the emergence of specific photogrammetric technologies. In brief, three different era's can be highlighted: During the first era, the *Analogue Era*, photogrammetry developed into an advanced and coherent technology with the evolution of aviation and the development of optical-mechanical devices that replicated perspective image geometries and offered the first opportunity for precise spatial measurements from stereo imagery. It can be said that aerial photography made its first serious debut in 1912, and since then it has been subject to constant development in both technology and application. The second period, the *Analytical Era*, started with the advent of electronic computing clearing the way for photogrammetric exploitation of imagery by replacing analogue instruments with mathematical modeling. With the advent of computers, the main idea was to no more reconstruct the orientation analogue but algorithmic – via algorithms and their coefficients. This work was still done with real (analogue) photos and needed a high precision mechanical and optical piece of equipment, the so-called analytical plotter. According to that, this time period was called "Analytical Photogrammetry". The last era is the *Digital Era*, which developed with the accelerated progress of the age of electronics. At present, appliances are provided to acquire, store, and exploit images in digital form. At the beginning of the twenty-first century, imagery is captured and exploited in all digital environments, offering vast opportunities for rapid, accurate, and economical measurements of glaciers. Today, our conventional (large format 23 cm²) air cameras have been

subject to considerable change – mainly a reflection of new modern technology. Forward-motion image compensation (FMC) is today an accepted standard in all well-known air cameras, such as the Wild (RC 30) or Zeiss (RMK TOP and LMK 2000) cameras with additional image stability reinforced by stabilized mounts. Further GPS navigation (INS) is integrated with computer terminals such as flight planning, navigation, camera operation, and even post-flight analysis that can be retraced by survey flight management systems.

Geometric principles for monitoring glaciers by photogrammetry

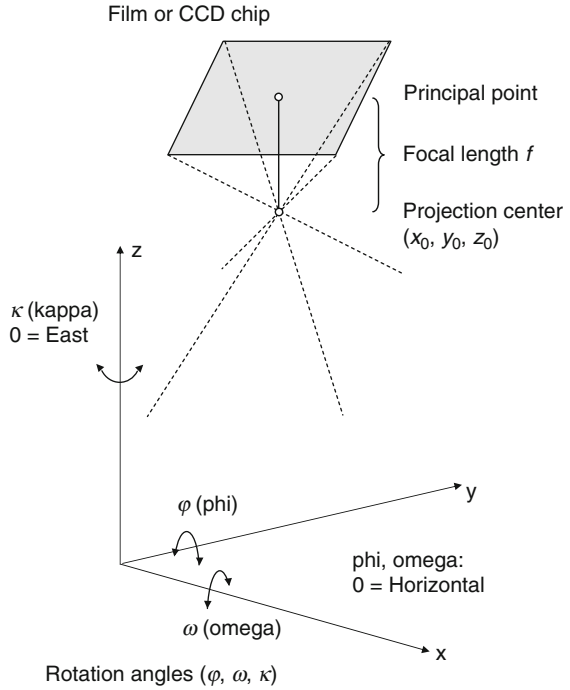
The distance between camera position and object (in our case flight height above glacier for vertical air-photos or distance to the glacier terminus for oblique-air-photos) affects the quality of the air-photos. The smaller the distance between camera position and object and the wider the lens angle, the greater are the displacements considering the central perspective. Vice versa: The greater the distance between camera position and object and the smaller the lens angle (tele-view), the smaller are the displacements. Figure 2 summarizes the effect of different camera positions and lens angles in relation to displacements inside the photos. If we would like to transform a single air-photo about a glacier to a given map projection, it would be best to take the photo from as high as possible to reduce the displacements (comparable to satellite images). On the contrary, the displacements (radial-symmetric) are a prerequisite to measure pairs of images stereoscopically. Because an aerial photo is based upon central projection, it is subject to distortion and displacement. Distortion is any shift in the position of an image on a photo that alters the perspective characteristics of the image. Displacement is any shift in the position of an image that does not alter the perspective characteristics. Topographic displacement, or terrain displacement, is a serious concern, because it alters scale inside the image. Areas of higher elevation of the glacier lie closer to the camera and appear bigger than areas lying in lower elevation. Objects on the glacier are also displaced on the photo by the camera on the aircraft, which is not perfectly horizontal at the moment of the exposure. This phenomenon is known as tilt. Tilt is a basic characteristic of all aerial photos and it is used to classify photos as either vertical or oblique.



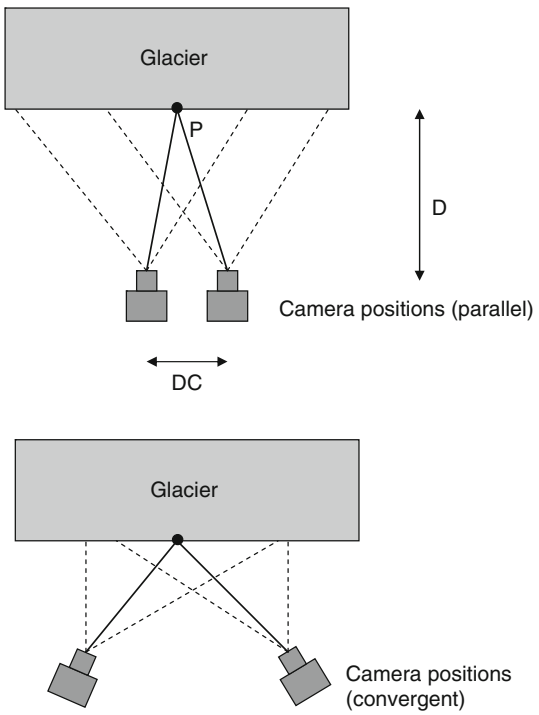
Aerial Photogrammetry for Glacial Monitoring, Figure 2 Different camera positions and lens angles.

The first step in using aerial photos about glaciers will be the reconstruction of the orientation of each photo (image). This means that first the exact position of all photos, which are to be used inside the object (glacier-terrain) coordinate system, should be defined. In general, three image orientation steps can be distinguished: interior, exterior, and absolute orientation. The interior orientation consists of the camera's focal length, photo's principal point x location, and photo's principal point y location. The exterior orientation is made up of three positions (or translations) X, Y, Z and three tilts (or rotations): φ (phi) = nose of the airplane up or down; ω (omega) = wing of the airplane up or down; κ (kappa) = swing, crab, or yaw. At large, there are nine orientation elements of an aerial photo. There are six elements associated with the camera position in space, which include the three positions of the camera relative toward the ground (X, Y, Z) and three rotations of the camera (φ, ω, κ). The values of φ and ω will normally be near zero. In the case of being exactly zero, the photo is called *nadir photo*. In practice, all air photos show deviations from zero due to wind drift and small motions of the aircraft.

If the coordinates of the projection centre, the three rotation angles (against the x-, y-, z-axis, e.g., Figure 3), and the focal length of the camera are known, the position of the photo in the 3D-space is defined. To get three-dimensional coordinates of objects on a glacier, at least two images from our target are needed, whereas the pictures must be taken from different positions. This is the principle of stereoscopy, which is based on the relative camera positions. The accuracy of height measurements derived from stereo models is a function of the distance of observation (in case of vertical aerial photos = flying height; in case of oblique aerial photos = distance to object) and the distance between points of observation (air base). The air base corresponds to the distance of two camera positions (see Figure 4). Let D be the distance between the glacier and the cameras and DC the distance between both camera positions (base), then



Aerial Photogrammetry for Glacial Monitoring, Figure 3 Focal length, projection center, and rotation angles (modified after Linder, 2006).



Aerial Photogrammetry for Glacial Monitoring, Figure 4 Camera positions for parallel (*above*) and convergent (*below*) situations (modified after Linder, 2006).

the angle between both projection rays (continuous lines) depends on the ratio D/DC. This ratio is called height/base-ratio. Generally spoken, the larger the value of the height/base-ratio, the more accurate the measurement. The accuracy of the calculated coordinates P (x, y, z) can be improved by increasing the base (the distance between two camera positions). If the overlap area (stereo model) gets to small, convergent camera positions can be used. The disadvantage of the convergent case is that additional perspective distortions are produced. Normally, the parallel case is suitable for stereo viewing and automatic surface reconstruction. The convergent or oblique case can often lead to a higher precision particularly in z direction. Another geometric consideration is that the height/base-ratio is equal to the focal length/aerial base-ratio. For precise height measurements, the photos are preferably taken with a short focal length camera in order to get a large base/height-ratio.

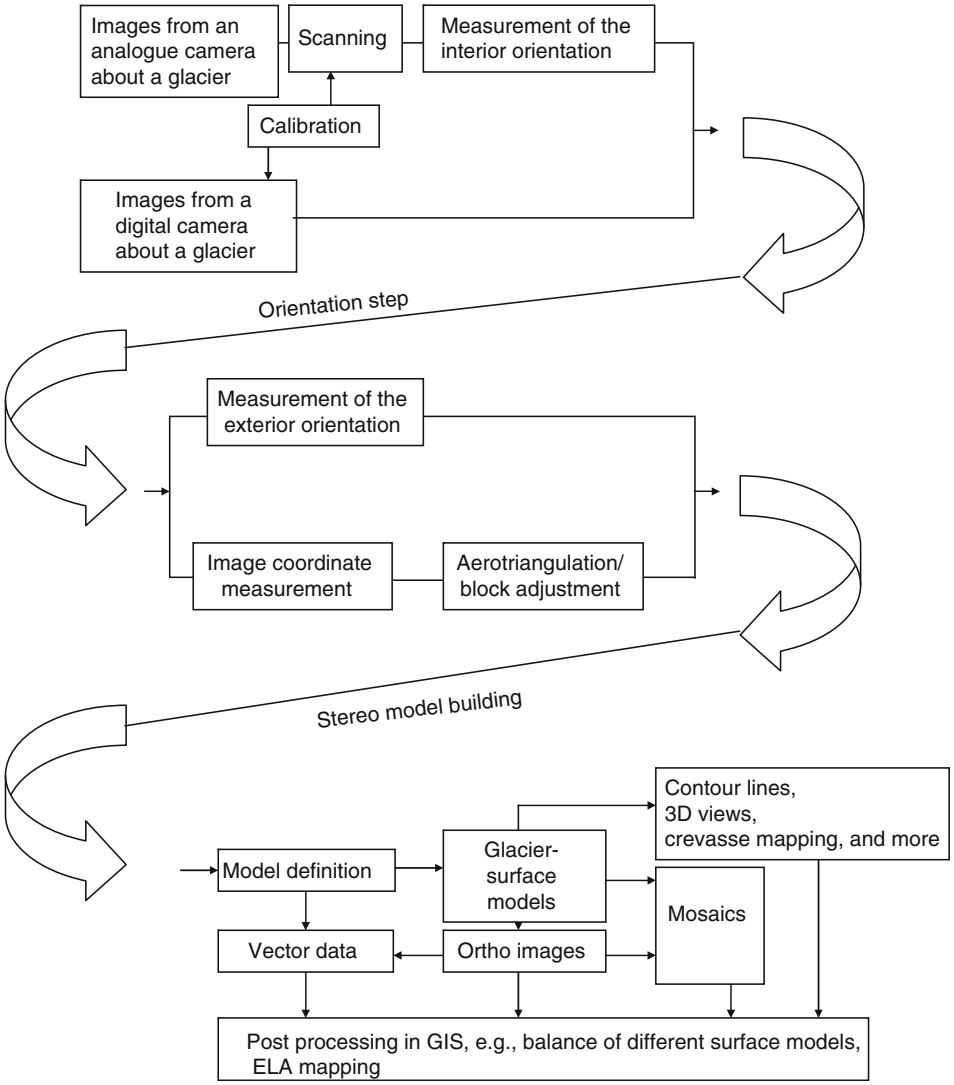
Summary of the geometry of a single photo

- A map has one scale – a photo has many.
- A map is based upon orthographic projection – a photo upon central projection.
- Displacement of images on the photo is caused by tilt and ground terrain (also height of objects).
- Camera coordinate axes are expressed in lower-case letters (x, y, z), where x is parallel with the flight direction and y is perpendicular.
- A photo has three centers:
  - Principal point, where principal axis intersects the film plane. The principal point is defined by the intersection of lines coming from the diagonally opposing corners (mostly fiducial marks).
  - Nadir, is the point vertically beneath the camera.
  - Isocenter is the point, which falls on a line halfway between the principal point and the Nadir (for small angles).
- There are nine elements for a complete orientation.
- Focal length and flying height affect scale and ground coverage.
- Scale = focal length/flying height.

A typical workflow for using photogrammetry for glacier monitoring is summarized in Figure 5. Starting with the capturing of the photo or images, the orientation parameters of all images that will be used in the analysis will be calculated. After completion of the different orientation steps, object coordinates inside the model can be measured and various products like surface models or orthophotos can be derived.

Analogue and digital cameras for glacier monitoring

The evolution of photogrammetry is closely connected with the development of aviation and photography. For more than over 100 years, photos have been taken on glass plates or film material (negative or positive). In general, specific photogrammetry cameras (also called metric



Aerial Photogrammetry for Glacial Monitoring, Figure 5 Typical workflow for monitoring glaciers with photogrammetry (modified after Linder, 2006).

cameras) work in the same way as amateur cameras do. The differences arise from the high-quality demands. Besides high precision mechanics and optics, aerial cameras also use a large film format. Amateur cameras normally use the size of 24 by 36 mm. Aerial cameras use a size of 230 by 230 mm (9 by 9 in.). This is essential for a good ground resolution inside the photos. As a result of the large format, the focal lengths ("wide angle," "normal angle," "tele angle") differ from those normally known. The frequently used wide angle aerial camera has a typical focal length of about 153 mm. The normal angle has a focal length of about 305 mm. Furthermore, the lens system of aerial cameras is constructed as a unit within the camera. There is no "zoom" or lens change possible in order to provide high stability and good lens correction. Today, digital aerial cameras dominate the photogrammetry market. For the close-range domain, the transition from film to digital cameras can be characterized in the way that existing film cameras are still used, but if a camera is replaced, the new one will be a digital camera system. Small and medium format cameras like those from Rollei (D7 metric, D30 metric, or the AIC) are well suitable for the aerial domain. There are two main construction strategies: One strategy is to maintain the central perspective principle which is well-known from existing film cameras. This strategy offers the advantage that existing software for data processing can be used. For this strategy, an area sensor is required (frame camera). The problem for this solution is that a high-resolution area sensor providing the same information as 230 by 230 mm photos captured on film would be very expensive. One solution for this problem is for instance to use four

overlapping smaller sensors and to match these four images together (like Digital Mapping Camera, DMC from Intergraph). Another strategy is to use a line sensor across the flight direction. This technique is comparable to sensors on satellites or from hyper-spectral scanners (e.g., Leica's ADS 40).

Urgent suggestions for using a digital camera for glacier monitoring:

- *Manually parameter setting*: In general, it should be possible to choose and set the parameters as focal length, exposure time, focus, and *f*-number manually.
- *Focus* or *distance setting*: It should be possible to deactivate the auto focus system.
- Evaluating the *Focal length range*: The optical range is decisive and not the digital (interpolated) range.
- *Number of pixels* or *resolution*: The physical or real resolution, and not the interpolated resolution, is important. Resolution increases with the number of pixels.
- *Exposure time* and *f-number*: The maximum f-number or lens opening should not be less than 1:2.8. The exposure time should have a range of at least 1–1/1,000 s.
- *Image storage*: In general, images are stored in a format like JPEG or TIFF. The image compression rate should be selectable or the image compression itself should be able to be switched off.

Essential concepts and applications in glacier monitoring

Today, photogrammetry is the leading concept in monitoring glaciers. Digital photogrammetry offers a high amount of automation in the generation of glacier surface models. At the same time, light detection and ranging (LIDAR) and interferometric synthetic aperture radar (IFSAR) systems are increasingly used to collect and produce high quality elevation data about glaciers.

LIDAR systems primarily produce elevation data but can also produce intensity images. A LIDAR system is an active sensor that employs a high performance inertial measuring system combined with GPS to measure the sensors' attitude and position. During the aircraft flight, position, attitude, and range to the ground and glacier surface are measured. Typical LIDAR systems scan the surface with laser pulses. Regarding the wavelengths used, they often cannot penetrate clouds or heavy moisture compared to passive optical photogrammetry, but unlike optical photogrammetry, LIDAR systems work well at night. LIDAR systems also record the returned intensity for each laser pulse. The main result is an intensity image at the same density as the elevation points. The intensity images can be used to check the quality of the elevation data. The high accuracy of the LIDAR products (5–30 cm) gives them many advantages over other methodologies such as photogrammetry. The quality of the LIDAR elevation products for a glacier depends on many factors such as:

- Position and attitude measurement quality
- System calibration quality
- Point density
- Flying height and speed
- Amount and density of objects

LIDAR outputs include grid formats and/or irregular formats. They often produce 10,000–80,000 data points per second and this produces very large datasets of dense elevation data. Typical elevation models range from 0.5 m horizontal spacing to 5 m horizontal spacing on the ground. Vertical accuracies typically vary from 5 to 30 cm range.

Interferometric synthetic aperture radar (IFSAR) is another concept to derive information about the glacier surface. IFSAR systems produce raw elevation data and intensity images that can be processed into elevation and orthophoto products. Comparable to LIDAR system, IFSAR systems use active sensors which measure the aircraft's position and attitude while also measuring the range and received intensity of the radar pulse from the ground. IFSAR systems use two antennae and measure the phase difference of the received signals. Typical IFSAR products are elevation data in form of grids or TIN's and image products such as orthophotos and mosaics. IFSAR systems produce high quality elevation and image data at faster data rates than LIDAR systems. Typical IFSAR systems use short wave lengths such as X or C bands, which gain high resolution data. A typical format of IFSAR data is grid based and owns a resolution between 2 and 10 m. IFSAR elevation products typically have accuracies of 0.5–2 m. Accuracies depend on many factors such as:

- System calibration
- Position and attitude measuring system quality
- The base length between the two IFSAR antennae
- Flying height and speed

A well-known example of IFSAR data products is the elevation coverage from the shuttle radar topography mission (SRTM). The SRTM-mission collected elevation data of nearly 80% of the earth's landmass at a resolution of approximately 30 m. Much of these data is today available in grid formats with an accuracy of 20 m horizontally and 16 m vertically. In many cases, these data are too coarse for glacier monitoring.

A future trend in monitoring glaciers will be the combination of data derived from stereo photogrammetry, LIDAR, and IFSAR. The elevation data produced from LIDAR and IFSAR systems can be edited or checked using photogrammetric means.

A further concept to monitor glaciers is to derive orthophotos to map and monitor the glaciers' elongation. Orthophotos are comparable to topographic maps and use the same projection as topographic maps. Today, most orthophotographs are produced by digital image processing methods utilizing aerial photographs as input, which have been converted into a digital form using a photogrammetric film scanner. Mostly, the differential rectification technique is applied through a suitably

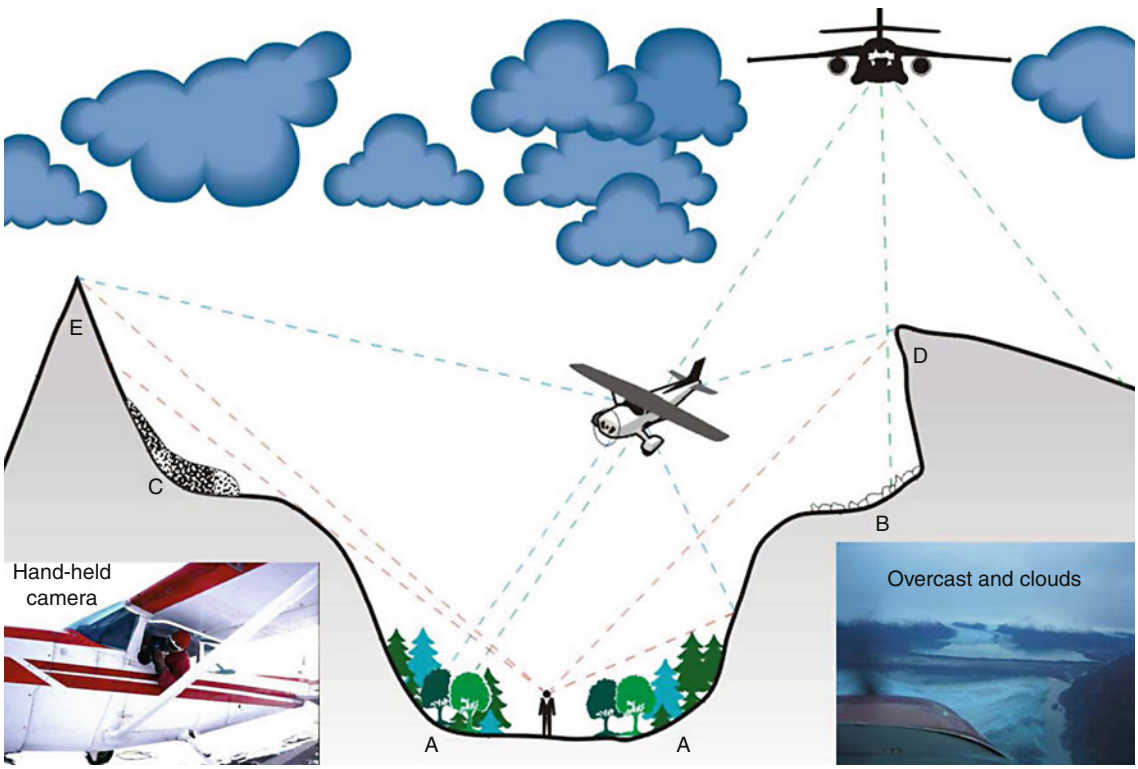
designed software package on the basis of existing DEM (digital elevation model), which may be generated using any one the methods listed below:

- Through the automatic correlation of stereopairs of photographs in digital photogrammetric workstations (DPW);
- Directly from airborne laser scanning or interferrometric SAR (InSAR) data;
- Interpolation of digitized contours from an existing map.

Current investigations also use oblique photogrammetry to gather information about glaciers. The rationale behind this is based on frequently bad weather conditions over glaciers that prevent the monitoring of the glaciers by means of vertical photogrammetry or satellite images. Contrary to the standard aerial survey methods, oblique aerial photography from relatively low altitudes can often be accomplished when weather conditions preclude traditional vertical aerial stereo-photography (Figure 6) (Gleitsmann and Kappas, 2005).

Hence, close range digital multiple-image-photogrammetry (convergent or multi-image-photogrammetry with 100% image overlap) method can be used for aerial surveys even when weather would anticipate standard survey flights. The combination of a German survey camera and Dutch photogrammetric software facilitates the measurement of changes in the ice volume of glacier ablation zones and other geomorphic features of mountain areas. A small single engine airplane with far less operational costs than the normal aerial survey airplane is ideally suited for this. A current project of the University of Göttingen analyzes ice volume changes on several glaciers in south-central Alaska. Recently, most glaciers of the region showed a significant retreat and loss of substance, which is being documented in this project with the help of oblique photogrammetry. A modern digital multiple-image-photogrammetry system is used to process the imagery. Similar to stereo-vertical imagery, automated surface measurements are possible. However, photogrammetric analysis of a surface is limited in the same way as traditional stereo-photo analysis is limited by a lack of identifiable features on the target. Naturally, fresh unbroken snow surfaces in the accumulation areas of glaciers cannot be measured by photogrammetry.

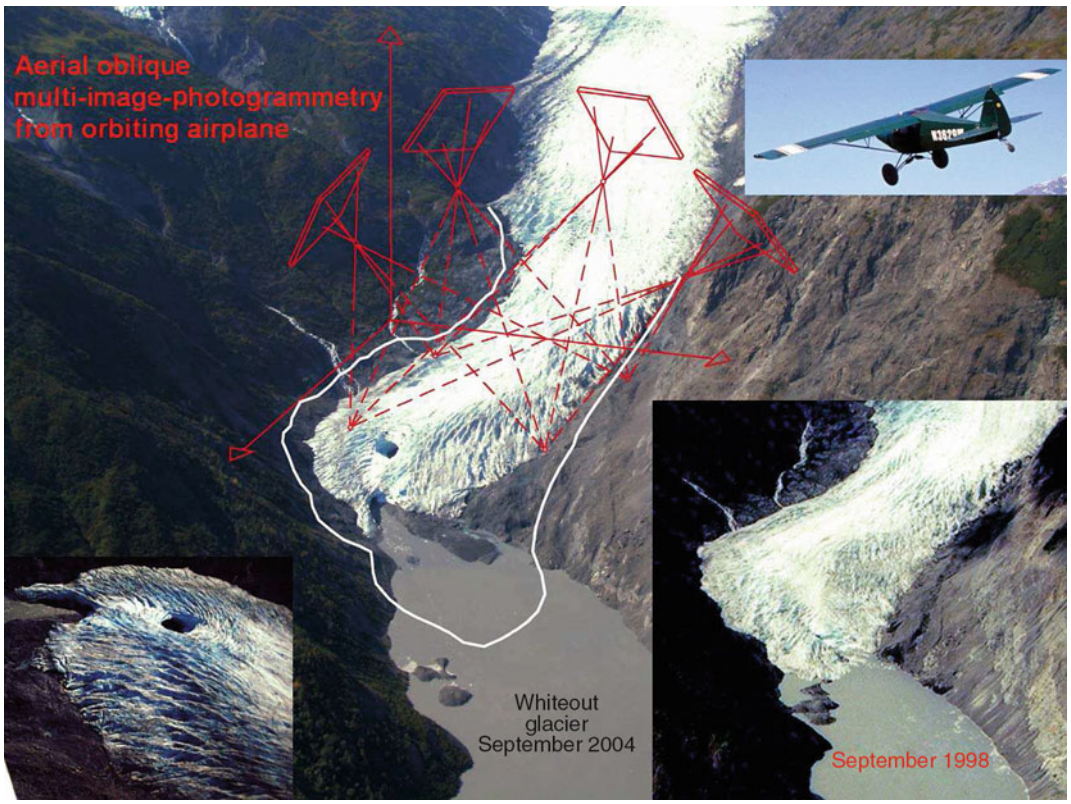
Weather conditions are a limiting factor for aerial survey flights over glaciers, and waiting for favorable weather can cost too much time and money in some circumstances, especially in survey areas that are often



Aerial Photogrammetry for Glacial Monitoring, Figure 6 Considerable advantages exist with oblique aerial photography, instead of stereo-vertical imagery in high mountain environments with adverse weather conditions. *Image*: Schematic of a high mountain valley, with a cirque glacier (C) and a rare overhang (D) with debris talus (B) on a shoulder of a U-shaped glacially formed valley. In Alaska's oceanic influenced areas, the cloud base would be typically under the elevation of the mountain peaks (E); in a Himalayan scenario the clouds would be present within the valley in monsoon-influenced times of the year.

cloudy. In most cases, the optical sensors of satellites have the very same problem, since any cloud cover, even if very high based, does affect them. In the case of this study of the Göttingen University over south central Alaska's glaciers, located in the coastal mountain ranges under an oceanic climate regime, an innovative aerial survey method that can deal with adverse conditions regarding weather and terrain was applied. Conditions in this climate regime often prevent vertical stereo-image survey flights, flown from a high altitude above the ridges and peaks of the terrain, because of cloud cover and turbulence. Modern camera mounts have improved the situation with wind and turbulence somewhat, but not to an extent that makes a difference in this operational scenario. The glaciers and ablation areas studied here are separate targets with limited surface areas, so they can be surveyed with not too many multiple image clusters. Additionally, it is comparatively cheap regarding the equipment requirements and extraordinarily cheap regarding the "platform," a small single engine airplane. Thus, a real world alternative system was developed and tested for survey flights with limited financial resources that focus on smaller target areas under cloud cover (Gleitsmann and Trabant, 2005).

Due to the nature of this study with oblique photogrammetry, a comparison to other methods in use in this field of remote sensing and glacier and snow surface measurements appears appropriate. In the last years, this field of work has seen the introduction of several new survey techniques, and this method should be put in context with them, especially from the financial and practical point of view. The use of the SAR and InSAR satellite data in this field of work, with the high mountain environment, seems to be related to many inherent problems. Radar penetration into a snow surface is difficult to quantify, because it depends on moisture content, and results in the imaging of a measured surface below the real snow surface. With both these methods, large areas can be densely sampled with very high relative accuracy at relatively low cost, after high initial costs of the equipment (Bäumker et al., 2004). Changes in snow-moisture content, melting, fresh snowfall, and snow creep can all lead to loss of interferometric coherence, while steep terrain produces radar shadow, image distortion, and layover resulting in lost data. This is also limiting the availability of useful ground control points. Therefore, the control of the survey often consists entirely on DGPS/INS (Figure 7). The initial



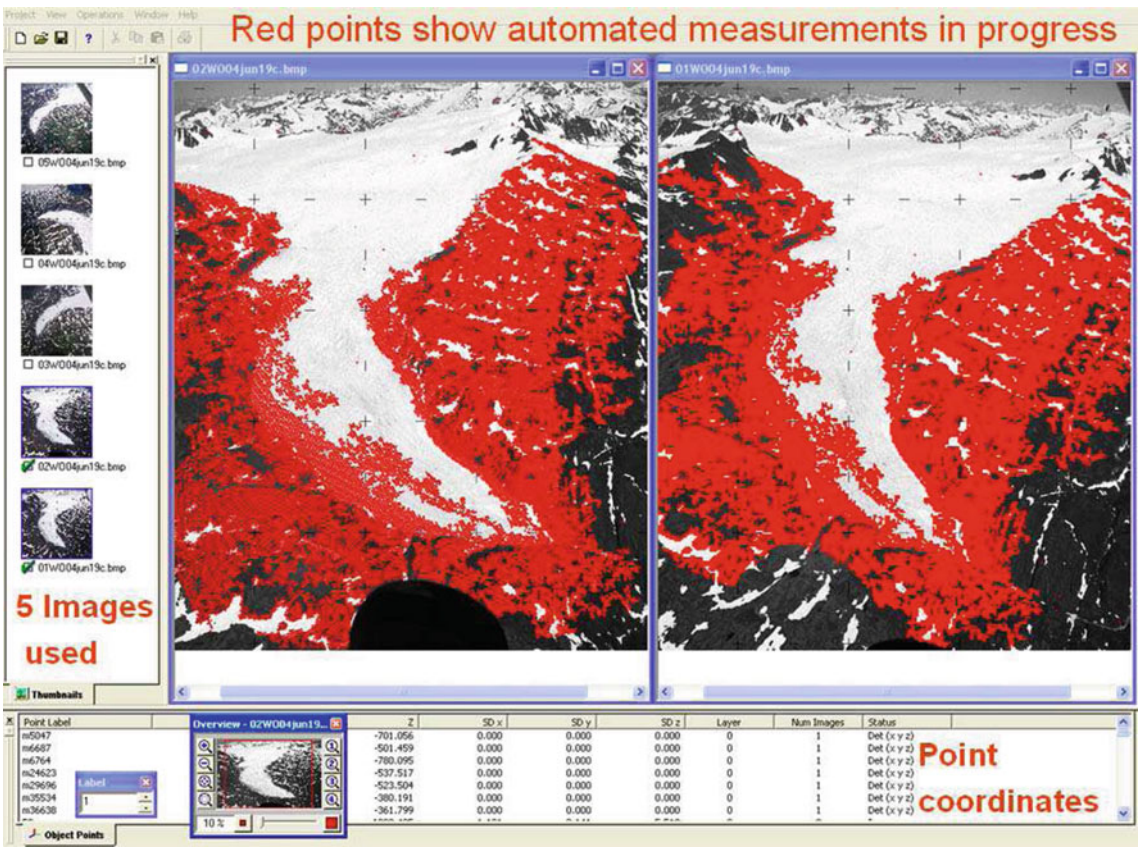
Aerial Photogrammetry for Glacial Monitoring, Figure 7 Aerial Picture of Whiteout Glacier, Alaska; taken on August 24, 2004. *White line* shows extent of Glacier terminus, as documented in September 1998. Graphics in *red* illustrate the concept of multiple-image-photogrammetry, with four image planes of the oblique aerial photography, and a coordinate system based on four ground control points. The points are DGPS measured and are located on bedrock surfaces, not on the glacier surface. Small single engine airplanes are ideal to reach the necessary camera-positions, like in this example, depicted as four red focal-planes. Note the completely different habitus and glacier snout of the receding terminus compared to 1998.

expense of about 50,000 USD for the complete multiple-image-photogrammetry system compares with much higher initial costs for a LIDAR system (Kääb and Volmer, 2000). The expense and the low availability of airborne laser scanning LIDAR (laser-induced direction and range) systems, combined with operational technical (platform) problems to employ them, often prevents a widespread use. Also, the systems seem to be extremely intolerant toward the usual aircraft landing forces, since they have to be reset and serviced after most landings, which is expensive and time consuming. With the LIDAR systems, the content of moisture in the air seems to be a very limiting factor, since even moisture content below the visible level, or any haze, will prevent gathering of LIDAR data. Also, with laser technology, wet ice, which is a widespread phenomenon on coastal glaciers, tends to create a heavy backscatter and rough signal. But, specific limitations apply to any photogrammetric topographic mapping of snow-covered glaciers within steep mountain terrain (Houghton et al., 2001).

Example of glacier-monitoring in South Central Alaska using oblique-convergent aerial photogrammetry as the survey method

Study area

Funded by the German Science Foundation (DFG), the Project of the Remote Sensing Department of the Institute of Geography of the University of Goettingen, Germany, has studied the surface changes of several glaciers in south central Alaska, mainly in the Knik glacier area, 90 km east-north-east of Anchorage. The glaciers under investigation are the USGS benchmark Wolverine Glacier (Figure 8) (Mayo et al., 2004), the Knik (Trabant and Mayo, 1979), Lake George, and Colony Glacier. All of them are located in the Chugiak Mountains of south central Alaska, the last three in the Knik area northeast of Anchorage, while the Wolverine Glacier is located in the eastern Kenai peninsula, which has an even more oceanic climate with extremely high winter precipitation. The Knik glacier got infamous in the past due to its



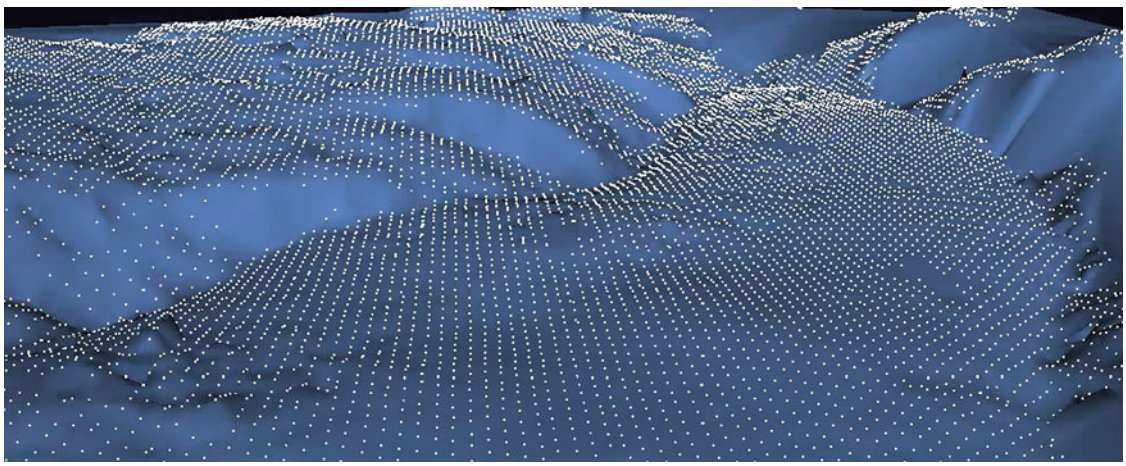
Aerial Photogrammetry for Glacial Monitoring, Figure 8 Images of Wolverine Glacier in June 2004, shown in "Polarphox" software while automated matching process is underway; if completed, all surfaces of the target with identifiable features would be depicted with red measurement points. The fresh snow patches on the areas around the glacier are not covered, since they are only white and featureless.

responsibility for creating one of the largest ice dammed lakes in Alaska (Hulsing, 1981) and regularly triggering dangerous GLOF's (glacier lake outburst floods), which destroyed the railroad and road connections to Anchorage, Alaska's largest city.

Methods

The project investigates the areas under the snow line of several Alaskan glaciers. Aerial survey pictures of the studied glaciers are taken twice a year, in the spring, after the snowmelt, and in the autumn, before the first snowfall. At the same time, fieldwork on the ground is done to create GCPs (ground-control-points) in order to be able to set positions, level, altitude, and scale to the digital models using the photogrammetric measurements. The GCPs are either recognizable features on rock outcrops or painted markers on rock surfaces or aluminum foil coated rocks set together on tundra surfaces. They are identifiable in the imagery, and are surveyed with DGPS, tachymeter and triangulation, and laser distance measurement equipment. The GCPs used at the Wolverine Glacier are the most accurately surveyed points in the project, and are ideal to evaluate the accuracy of the aerial oblique multiple-image-photogrammetry system that is employed here (see Figure 9). In general terms, the aerial multiple-image-photogrammetry survey of a target object works as follows:

Ideally, starting out from a high position vertically above the object (if weather/cloud base permits), the light aircraft that is used as the camera platform performs a gradual downward spiral, orbiting the object. All the time, pictures are taken of the object with a hand-held medium format specialized survey camera out of the open window of the aircraft. A large number of pictures, from any direction, including vertical, if desired, is thus created. This allows for the certain possibility to select the best geometric configuration of images for the multiple-image swathe of the target. The lattice model of photogrammetric measurements gets to be especially accurate due to the higher number of images used for every measurement (Wester-Ebbinghaus, 1990). Depending on the shape of the target, images from all sides are not even always necessary, if the target structure is simple enough, only four pictures from two sides of it may be enough for accurate measurements, provided every piece of surface can be seen in at least three pictures and the angles of the pictures aiming at the target are about 30° apart from each other. Therefore, this method is less affected by weather and low cloud base. If any vertical pictures cannot be taken due to weather, the multiple-image-photogrammetry still works. The camera is a 6 × 6 cm medium format with a réseau plate that creates a grid on commonly available film. The software "réseau-transforms" the digitally scanned photograph ensuring that the digital image is restored to the exact proportions it had when the photographic exposure was made. This digital rectifying produces a more precise rendering of features on the image than the traditional vacuum-plate flattening of film in large format survey cameras. Obviously, the réseau grid cannot be removed from the image. During the processing, common natural points (tie points), which can be identified with high accuracy on the target surface, are used for tying the multi-image composition together. With the points marked, the multiple-image-orientation is the next step. Then, the camera positions are known relative to each other. With the knowledge of the position of at least three points on the target surface, the systems-orientation is done; this produces the scale and the level, as well as the geographical coordinates to every measurement. Then the camera positions can also be identified with very good approximate positions. Following these work steps, every optically identifiable point visible in three pictures of the



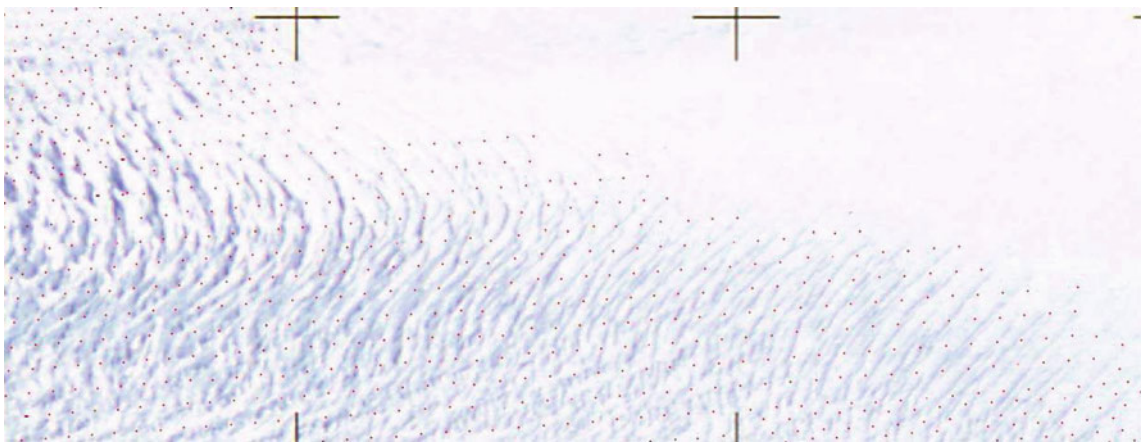
Aerial Photogrammetry for Glacial Monitoring, Figure 9 Uncorrected DEM of the Wolverine Glacier surface, with point measurements shown. The réseau-crosses reappear on the glacier surface, because they have to be masked out on the images for the automated grayscale-differences matching process. Apart from that, the depiction of the surface itself is very realistic.

multiple image composition can be measured with three-dimensional accuracy. The software used in this study is able to automatically generate surfaces from a minimum of three oblique images and can measure the position of points equivalently to a stereo-photogrammetry system (see Figure 8).

The comparison of the resulting surface models of different dates in order to quantify the volume and surface changes of the studied glacier termini is the main method of this study based on oblique photogrammetry. Successful automated surface measurements with the multiple-image-photogrammetry software "Polarphox" were so far conducted for five different surveys (multitemporal) of the Wolverine Glacier and one of the Colony glacier (Figure 10). In general, the measurements worked satisfactory, covering the whole ablation area of the targeted glaciers. The results were found to depend distinctively on the quality of the scans being used, and on the selection of the right patch size for the matching process, depending on the natural size and scale depiction of the surface features to be measured on the glacier surface. Naturally, areas with insufficient surface features, like fresh snowdrifts on the glacier terminus, cannot be measured. But the findings show that the measurements extend to the outermost perimeter of recognizable features, which is very satisfactory (see Figure 9). Cloud shadows going over the glacier in high winds still pose a problem, similar dark shadows of mountains on the ice. Most of those problems can be countered by the use of enough pictures to get the ideal perspectives and by selecting the right time of the day. Very few glaciers are so smooth on their surface below the firn line that points are difficult to measure. The higher the rate of debris coverage is, the easier the measurements are, because the debris provides identifiable features. This makes the Wolverine Glacier the most difficult target, since it has no medial or upper moraine or debris coverage whatsoever, and its surfaces of the terminus are characterized by the runoff of surface water due to its steepness. This creates line features in contrast to the easier to measure point features, which are more prominent on the other glaciers.

Today, photogrammetry can work and automatically measure points despite unknown camera positions and convergent oblique aerial photos, without straight flightlines, using near 100% image overlap, and ideal convergence angles. This technological change makes the use of small (or medium) format survey cameras for mapping of limited sized areas, a competitive option that was impossible until recently. The inherent problem of photogrammetry cannot be countered, of course; if there are no surface features because of fresh, white snow, no measurements are possible. Especially with glaciers as the target of the study, this factor is very significant. Due to this, it seems a combination approach of LIDAR data for the dry and snowy areas above firn line, combined with photogrammetry at the wet terminus of the glacier, would yield the ideal results. In the area around the equilibrium line (ELA) of the glacier where both systems start to encounter their difficulties, the combination of the data would allow for both cross-evaluation of the methods and more dense measurements.

The recent results clearly show the possibility of an aerial application of digital multiple-image-photogrammetry with automated surface measurements, which are based on matching algorithm and grayscale-differences in a search patch. With the use of a medium format camera for aerial surveys, the highest available scan quality with low image noise is necessary. Consumer product type scanners have proven unsatisfactory. The general reasoning for use of oblique imagery for detailed evaluations in high mountain terrain appears as a valid method, especially with the possible use despite adverse weather. The remaining question is,



Aerial Photogrammetry for Glacial Monitoring, Figure 10 A fraction of the surface of Wolverine Glacier in the "Polarphox" photogrammetry software, after automated surface point measurements. The extent of the red measurement points shows the satisfactory use of available surface features and the inherent problem with fresh snow cover.

if the automated surface measurements can produce an accurate surface model over the full extent of the whole target area under these special conditions. For many earth science studies in remote or unsurveyed areas, this approach should open up new possibilities of making use of otherwise unattractive aerial surveys. The low cost and enhanced adverse weather ability should be significant enough to get access to data that would be not attainable otherwise. Adding positioning data from a differential global positioning receiver and mounting an inertial navigation system to the survey camera may eliminate the need for establishing ground control points in the target area in the near Future.

Summary

The last decades have shown a significant retreat of glaciers and seasonal sea ice boundaries, along with changes to permafrost and vegetation zones. Still, there are some glaciers that are advancing (Echelmeyer et al., 2003). The complexity of those observed changes may very well be related to those phenomena known as "global climate change." Many scientific studies have focused on this in recent years, employing a large variety of methods (Mayo et al., 2004). Since climatic change produces changes of the glaciers and also geomorphologic changes and effects, especially in high mountain terrain and in the arctic and sub-arctic latitudes, these areas get more into focus. Many previously uninhabited high mountain areas all over the world are under use now. In these areas, the changes are often observed as an increasing occurrence of natural hazards. Thus, there is a great motivation to study the geomorphology of those areas, and due to the idiosyncrasies of nature in these areas, a need for innovative survey techniques exists. Today, analogue and digital photogrammetry are powerful and adopted techniques to monitor glaciers. In the future, the combination of aerial photogrammetry with new techniques as LIDAR and SAR will be a powerful tool to monitor glaciers. But for historical studies of glaciers, the traditional photos are the only source of knowledge.

ALASKAN GLACIERS

Bruce F. Molnia
U.S. Geological Survey, Reston, VA, USA

Definition

All glaciers located in the Alaska, USA, in North America.

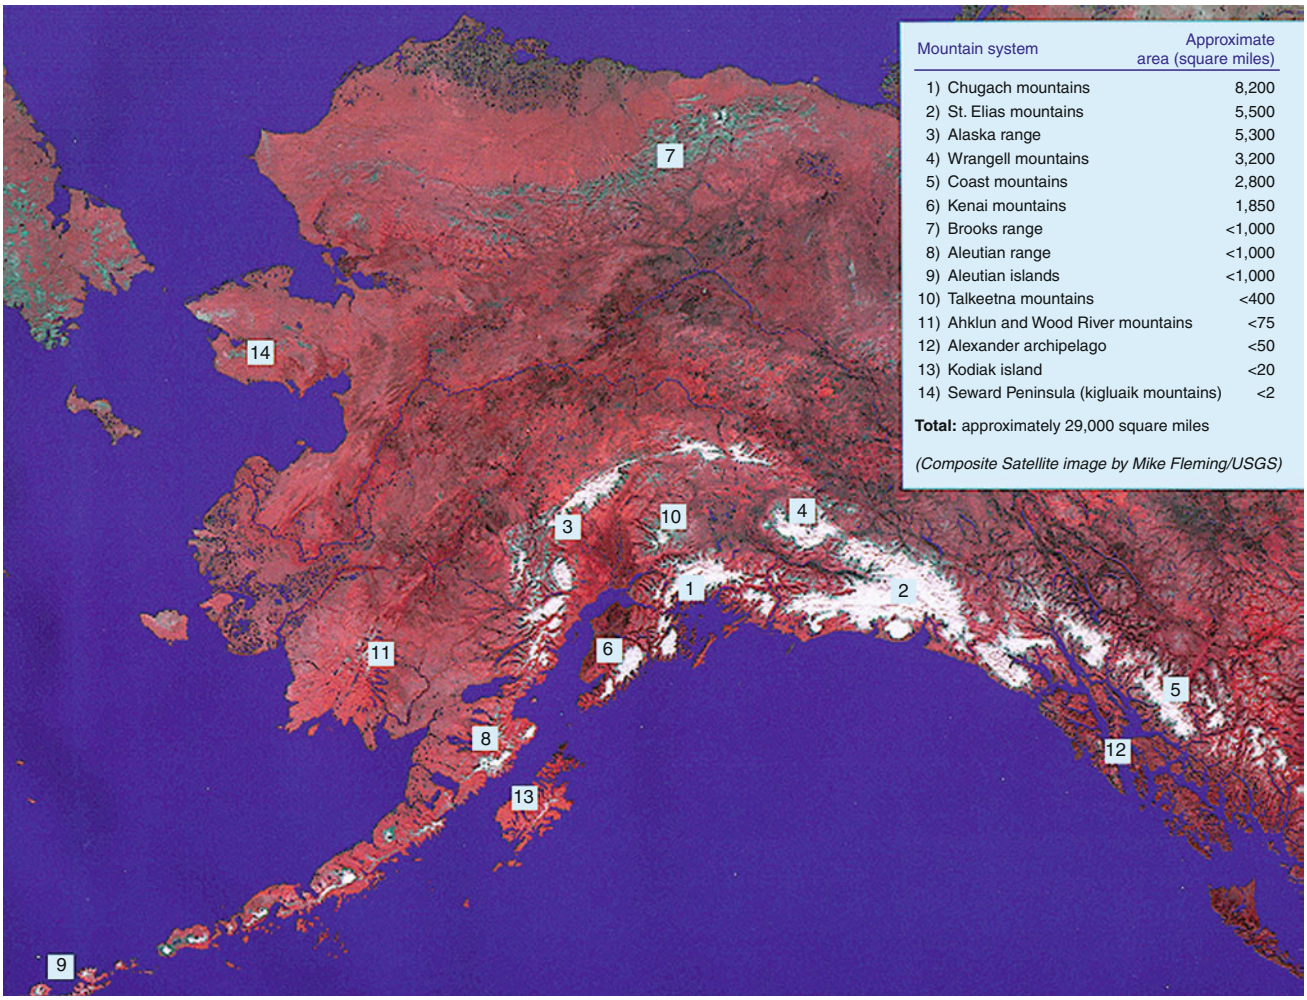
Background

In spite of Alaska's remoteness, its glaciers have been studied for more than 150 years. More than 1,000 journal articles, books, and U.S. Geological Survey publications present details about individual glaciers or glacierized regions. Today, most Alaskan glaciers at lower elevations are retreating. However, about a dozen large valley glaciers, including Hubbard, Harvard, Meares, Taku, and Lituya Glaciers (all tidewater or former tidewater glaciers), are currently thickening and advancing. At higher elevations glaciers are thickening or exhibit no change.

Introduction

Glaciers cover about 75,000 km^2 of Alaska (Post and Meier, 1980), about 5% of the State. As shown in Figure 1, the glaciers are situated on 11 mountain ranges (Alaska Range, Aleutian Range, Brooks Range, Chugach Mountains, Coast Mountains, Kenai Mountains, Kigluaik Mountains, St. Elias Mountains, Talkeetna Mountains, Wood River Mountains, and the Wrangell Mountains), one large island (Kodiak), an island chain (the Aleutian Islands), and one archipelago (the Alexander Archipelago).

Alaskan glaciers range in elevation from above 6,000 m to below sea level. Alaska's glaciers extend geographically from the far southeast at latitude 55°19′N., longitude 130°05′W., about 100 km east of Ketchikan; to the far



Alaskan Glaciers, Figure 1 Location map, showing the location of Alaska's 14 glacier hosting regions.

southwest at Kiska Island at latitude 52°05′N., longitude 177°35′E., in the Aleutian Islands; and as far north as latitude 69°20′N., longitude 143°45′W., in the Brooks Range. Nearly all mountain glaciers in Alaska are temperate. As the glaciers of Alaska melt, their meltwaters flow into the Gulf of Alaska and into the Bering, Chukchi, and Beaufort Seas, contributing to global (eustatic) sea-level rise.

During the Little Ice Age, Alaska's glaciers expanded significantly. Since then, the total area and volume of glaciers in Alaska has decreased. In some areas this retreat began during the eighteenth century (Lawrence, 1950). In others, it only started during the twentieth century (Molnia, 2007, 2008).

Of the 153 1:250,000-scale topographic maps that cover the State of Alaska, 63 sheets depict the presence of glaciers. Although the number of extant glaciers has never been systematically counted and is thus unknown, the total probably is greater than 100,000. Only about 600 glaciers (about 1%) have been officially named by the U.S. Board on Geographic Names (Molnia, 2008). There are about 50 active tidewater glaciers in Alaska (Viens, 1995). Within the glacierized mountain ranges of southeastern Alaska and western Canada, 205 glaciers (75% in Alaska) have a history of surging (Post, 1969).

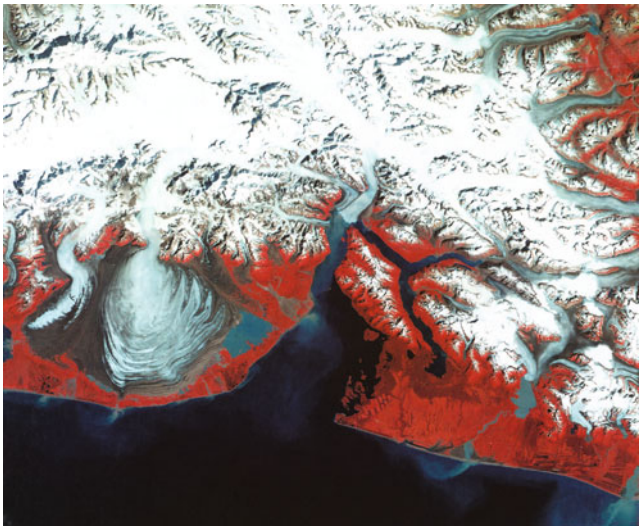
Hundreds of retreating Alaskan glaciers have ice-marginal lakes. Many also form ice-dammed lakes. Post and Mayo (1971) documented that more than 53 present and 7 former large ice-dammed lakes produced jökulhlaups. Ice-capped volcanoes on mainland Alaska and in the Aleutian Islands have a potential for jökulhlaups caused by subglacier volcanic and geothermal activity.

Because of the size of the area covered by glaciers and the lack of large-scale maps of the Alaskan glacierized areas, satellite imagery and other satellite remote-sensing data are the only practical means of monitoring regional changes in the area and volume of Alaska's glaciers in response to short- and long-term changes in the maritime and continental climates of the State.

Distribution and recent behavior of Alaska's glaciers

A review of satellite imagery and historical literature for each of the 14 glacierized areas of Alaska was conducted to determine both the individual and the regional status of Alaskan glaciers and to characterize changes in thickness and terminus position of representative glaciers in each mountain range or island group (Molnia, 2008). In many areas, observations used for determining change date from the late eighteenth or early nineteenth centuries.

For each region, a detailed assessment of Landsat Multispectral Imagery (Figure 2) collected between 1972 and 1982 was made. This decade was selected as the baseline from which to assess recent glacier response to changing climate. The analysis determined that every mountain range and island group investigated can be characterized by significant glacier retreat, thinning, and (or) stagnation,



Alaskan Glaciers, Figure 2 A Landsat 2 Multispectral Scanner false-color composite image of the Malaspina Glacier (piedmont outlet glacier), tidewater Hubbard Glacier, and other glaciers in the St. Elias Mountains, Alaska. (Landsat 2 MSS image 21675-19482; 24 August 1979; Path 67, Row 18 from the EROS Data Center, Sioux Falls, SD). Hubbard Glacier has been thickening and advancing since the later part of the nineteenth century, while the Malaspina Glacier has been thinning and retreating for more than a century. The numerous folded moraines visible on the Malaspina's surface are evidence of its complex surge behavior.

especially those glaciers that end at lower elevations. At some locations, glaciers completely disappeared during the twentieth century. In other areas, retreat that started as early as the early eighteenth century has continued into the twenty-first century. Ironically, in several areas, retreat is resulting in an increase in the total number of glaciers; even though individual glaciers are separating, the volume and area of ice continue to decrease.

Temperature records at all Alaskan meteorological recording stations document a twentieth and early twenty-first century warming trend. Therefore, characterizing the response of Alaska's glaciers to changing climate helps to quantify potential sea-level rise from past, present, and future melting of glacier ice (Shulski and Wendler, 2007).

During the Little Ice Age, the total glacier-covered area and the number of mountain ranges and islands having glacier cover were significantly larger than they were during the "baseline" period. Since the end of the Little Ice Age, there has been a decrease in the glacier area and the thickness of most of the Earth's glacierized areas in the middle and low latitudes, along with advances of individual glaciers in some areas including about a dozen in Alaska. However, the timing, magnitude, and complexity of this post-Little Ice Age glacier change have been different in each of Alaska's 14 glacierized areas. Although thinning of lower elevation glaciers and retreat of glacier

termini are ubiquitous throughout Alaska, the current status of Alaska's glaciers varies significantly from area to area and with elevation.

Although most Alaskan glaciers at lower elevations are retreating, not all are doing so. At elevations below about 1,500 m, about a dozen glaciers, including Hubbard, Harvard, Meares, Taku, and Lituya Glaciers (all tidewater or former tidewater glaciers), are currently thickening and advancing. Many glaciers at higher elevations are thickening or exhibit no change. Several volcanoes, including Redoubt Volcano, had twentieth century eruptions that melted summit glaciers, but these events were followed by the formation of new glaciers in their craters.

The following region-by-region summary details the observed changes in glaciers described by Molnia (2008).

Coast Mountains – The glacierized area of the Coast Mountains is approximately 10,500 km^2. From south to north, the largest glaciers in the southern Coast Mountains are: Chickamin Glacier, with an length of 26 km and an area of about 140 km^2 (26 km, 140 km^2); Le Conte Glacier, the southernmost tidewater in Alaska (36 km, 472 km^2); Baird Glacier (50 km, 784 km^2); Dawes Glacier (37 km, 653 km^2); Sawyer Glacier (37 km, 399 km^2); and South Sawyer Glacier (50 km, 683 km^2). With the exception of Chickamin Glacier, all are outlet glaciers of the Stikine Icefield. To the north, the advancing Taku Glacier (60 km, 831 km^2) is the largest outlet glacier of the 1,955 km^2 Juneau Icefield. Taku's recent behavior was summarized by Motyka et al. (2001). In the 1970s, Taku, Hole-in-the-Wall, and Mead Glaciers were advancing. All other valley and outlet glaciers in the Coast Mountains were thinning and retreating. At the end of the twentieth century and early in the twenty-first century, Taku Glacier's advance continued, while Hole-in-the-Wall Glacier was stable. All other valley and outlet glaciers in the Coast Mountains continued to thin and retreat.

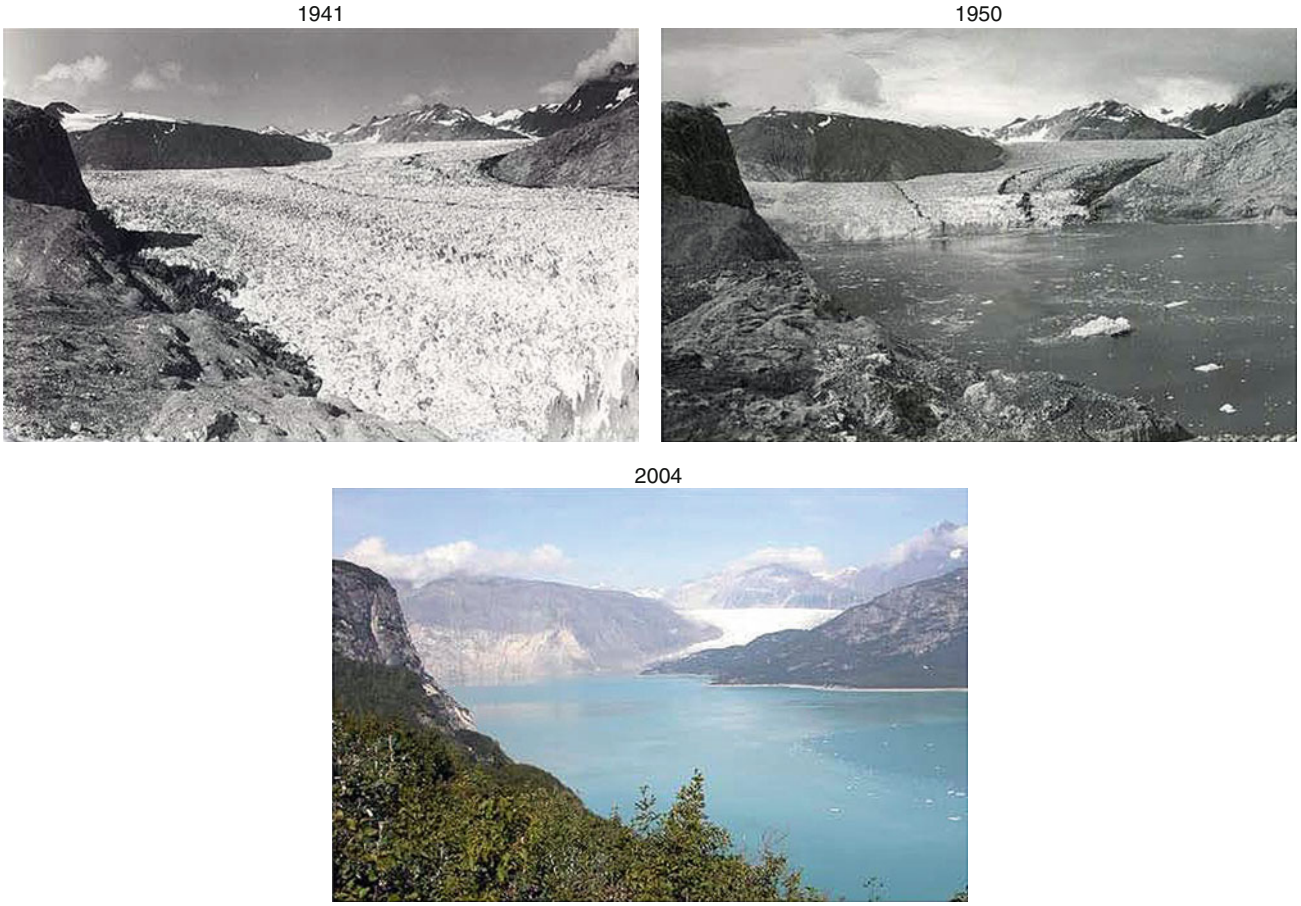
The longest field mass balance measurement in Alaska is from the Juneau Icefield. There studies of Taku and Lemon Creek Glaciers (Miller and Pelto, 1999) have documented significant annual variability and long-term volume loss.

Alexander Archipelago – On mid-twentieth century USGS 1:250,000-scale topographic maps, several hundred small unnamed mountain glaciers were mapped in the mountainous areas of six of the islands in the Alexander Archipelago: Revillagigedo, Prince of Wales, Kupreanof, Baranof, Chichagof, and Admiralty Islands. In the 1970s, the Alexander Archipelago had a glacierized area of less than 150 km^2. The largest of these was an unnamed glacier on Baranof Island that extended for about 5 km on a ridge between 1,100-m-high Mount Furuhelm and an unnamed 1,624-m peak. Since then, due to their small size, low elevation, and southerly latitude, all have thinned and retreated, and some have melted completely and no longer exist.

St. Elias Mountains – The glacierized area of the Alaskan St. Elias Mountains is approximately 11,800 km^2. Included are parts of the three largest temperate glaciers in North America. Two, Bering and Malaspina Glaciers, are piedmont outlet glaciers, each with areas greater than 5,000 km^2; and the third, Hubbard Glacier, is a tidewater glacier (114 km, 3,900 km^2). More than 50 glaciers in the St. Elias Mountains have lengths greater than 8 km. East of Glacier Bay, the largest glacier is Davidson Glacier (20 km, 115 km^2), located in the Chilkat Range. In the Glacier Bay area, about a dozen glaciers have lengths exceeding 15 km, the longest and largest is Grand Pacific Glacier (60 km, 650 km^2), which originates in Alaska, flows through British Columbia, and terminates in Alaska. Brady and Carroll Glaciers also have areas that exceed 500 km^2. Glacier Bay has a length of more than 100 km. About 250 years ago, Glacier Bay did not exist. Its basin was filled by a single large ice mass that reached into Icy Strait. Larsen et al. (2005, 2007) calculated that the ice volume that was lost during post-Little Ice Age retreat was about 3,700 km^3, about 3,450 km^3 was lost above sea level and 250 km^3 below sea level. Figure 3 presents three images that document the rapid retreat of Muir Glacier, the dominant glacier in the East Arm of Glacier Bay between 1941 and 2004. Most of the twentieth century ice loss from Glacier Bay occurred in East Arm.

During the 1970s, Johns Hopkins, Grand Pacific, Margerie, Brady, North Crillon, Lituya, Hubbard, and Turner Glaciers were advancing. La Perouse and South Crillon Glacier were stable, although the positions of their termini fluctuated from year to year. All other valley and outlet glaciers in the St. Elias Mountains were thinning and retreating. At the beginning of the twenty-first century, North Crillon, Lituya, Hubbard, and Turner Glaciers were advancing. Johns Hopkins, La Perouse, and South Crillon Glacier were stable, although the positions of their termini also fluctuated from year to year. All other observed valley and outlet glaciers in the St. Elias Mountains were thinning and retreating.

Chugach Mountains – The glacierized area of the Chugach Mountains is approximately 21,600 km^2. Included are most of Bering Glacier, which surged at least five times during the twentieth century (Molnia and Post, 1995), and more than 20 valley and tidewater glaciers with areas greater than 100 km^2. These include Martin River Glacier, (48 km, 290 km^2), Miles Glacier (52 km, 225 km^2); Bremner Glacier, which has three distinct outlets: Middle Fork Lobe, North Fork Lobe, and Tana Lobe (44 km, 150 km^2); Tana Glacier (68 km, 100 km^2); the western Jefferies Glacier (55 km, 300 km^2), a complex glacier with many outlet glaciers that is contiguous with the Tana Glacier; Sheridan Glacier (24 km, 101 km^2); Scott Glacier (24 km, 160 km^2); Woodworth Glacier (23 km, 185 km^2); Schwan Glacier (23 km, 131 km^2); Allen Glacier (31 km, 230 km^2); Childs Glacier (19 km, 100 km^2); Valdez Glacier (34 km, 158 km^2); Shoup Glacier (30 km, 146 km^2); Columbia Glacier (59.5 km, 1,121 km^2); Meares Glacier (25 km, 142 km^2); Yale Glacier (32 km, 194 km^2); Harvard Glacier (39 km, 524 km^2); Matanuska Glacier (46 km, 324 km^2); Nelchina



Alaskan Glaciers, Figure 3 Three northeast-looking photographs taken in Muir Inlet, Glacier Bay National Park and Preserve, Alaska, document changes that have occurred to Muir Glacier during the 63 years between August 13, 1941 and August 31, 2004. The 1941 photograph shows the lower reaches of Muir Glacier, then a large, tidewater calving valley glacier and its tributary Riggs Glacier. The ice thickness in the center of the photographs is more than 0.7 km. For nearly two centuries prior to 1941, Muir Glacier had been retreating. Maximum retreat exceeded 50 km. In places, more than a 1.0 km thickness of ice had been lost. Note the absence of any identifiable vegetation and the numerous bare bedrock faces present on both sides of the glacier (W. O. Field, # 41–64, courtesy of the National Snow and Ice Data). The August 4, 1950 photograph documents the significant changes that have occurred during the 9 years between it and the 1941 photograph. Muir Glacier has retreated more than 3 km, exposing more of Muir Inlet, and thinned 100 m or more. However, it still is connected with tributary Riggs Glacier. White Thunder Ridge continues to be devoid of vegetation. (W. O. Field, # F50-R29, courtesy of the Glacier Bay National Park and Preserve Archive). The August 31, 2004 photograph documents the significant changes that have occurred during the 63 years between the first and third photographs and during the 54 years between the second and third photographs. Muir Glacier has retreated out of the field of view and is now located more than 7 km to the northwest. Riggs Glacier has retreated as much as 0.6 km and thinned by more than 250 m. Note the dense vegetation, dominated by *Alnus,* that has developed on the till cover of White Thunder Ridge. Also note the correlation between Muir Glacier's 1941 thickness and the trimline on the left side of the 2004 photograph. (USGS Photograph by Bruce F. Molnia.)

Glacier (39 km, 328 km^2); Tazlina Glacier (47 km, 398 km^2); Knik Glacier (49 km, 380 km^2); and Colony Glacier (29 km, 237 km^2). With the exception of the advancing Harvard and Meares Glaciers, all of these glaciers are currently retreating and thinning. Since the early 1980s, Columbia Glacier has been catastrophically retreating (Krimmel, 2001; Pfeffer et al., 2000; Pfeffer, 2007).

Kenai Mountains – The glacierized area of the Kenai Mountains is approximately 4,600 km^2. The region contains several hundred glaciers. Seven have lengths of about 20 km, and 2 exceed 30 km. Most of the glaciers in the Kenai Mountains originate from two large ice fields, the Sargent and the Harding Icefields, and two smaller unnamed ice fields, one north of the Sargent Icefield between Kings Bay and Portage and the other southwest of the Harding Icefield. With the exception of Aialik and McCarty Glaciers, both of which advanced more than 500 m during the second half of the twentieth century, all of the valley and tidewater glaciers in the Kenai

Mountains continued to stagnate, thin, and (or) retreat. Wolverine Glacier, a USGS Benchmark Glacier, has a mass balance record that exceeds 30 years (Josberger et al., 2007).

Kodiak Island – During the 1970s, the glacierized area of Kodiak Island was less than 15 km^2, significantly reduced from the island's Little Ice Age glacier extent. Here, all glaciers are small and poorly studied. Their small size, low elevation, and location on an island that has undergone a temperature increase and is surrounded by temperate ocean water suggest that these glaciers are continuing to thin and retreat.

Aleutian Range –The glacierized area of the Aleutian Range is approximately 1,250 km^2. The range contains more than 30 glaciers having lengths of 8 km or more. The largest, Blockade Glacier, is 44 km long and has an area of about 250 km^2. Large, non-surge-type valley glaciers in the Aleutian Range are generally stagnant, thinning, and (or) retreating. Several glaciers surged during the 1970s, but no termini advances were reported. At the end of the twentieth century and into the early twenty-first century, all of the valley and outlet glaciers in the Aleutian Range continued to thin, stagnate, and retreat. Several small glaciers in the Glacier Fork drainage were reported to be advancing during the 1990s. When Tuxedni Glacier was observed in 2000, it showed some evidence of a recent terminus advance. However, trimlines and abandoned moraines document a long-term history of retreat and thinning. The 1912 eruption of Mount Katmai melted and beheaded a number of summit and flank glaciers (Griggs, 1922). Following the eruption, two small glaciers formed on the talus beneath the crater rim. They continue to exist. Similarly, following the 1989–1990 eruption of Mount Redoubt, snow and glacier ice accumulating in the crater have replaced snow and ice melted during the eruption.

Aleutian Islands – During the 1970s, the glacierized area of the Aleutian Islands was approximately 960 km^2, with glaciers present on at least ten islands in the eastern and central part of the Aleutian Islands. From east to west, islands where glaciers have been reported are Unimak, Akutan, Unalaska, Umnak, Herbert, Atka, Great Sitkin, Tanaga, Gareloi, and Kiska Islands. All of the mapped glaciers of the Aleutian Islands descend from the summits of active or dormant volcanoes, extending into either calderas or down their flanks. All head at elevations greater than 1,200 m. Very little information exists about the status of Aleutian Islands glaciers, either historically or today.

Wrangell Mountains – The glacierized area of the Wrangell Mountains is approximately 8,300 km^2. Many of its glaciers are surge-type. About 50 outlet glaciers have lengths of 8 km or more. The largest, Nabesna Glacier, is 87 km long, and has an area of 819 km^2. It is the largest inland glacier in North America. With the exception of Athna Glacier and South and Center Mackeith Glaciers (Sturm et al., 1991) which were advancing, apparently in response to heat-flow-related non-climatic forcing, all of the valley and outlet glaciers in the Wrangell Mountains appear to be retreating, thinning, or stagnant.

Talkeetna Mountains – During the 1970s, the glacierized area of the Talkeetna Mountains was approximately 800 km^2. Several hundred glaciers were present including seven with lengths of more than 8 km. The longest, an unnamed glacier located above the headwaters of the northwest-flowing Sheep River, had a length of 17.7 km, and an area of 77 km^2. Chickaloon Glacier (14.5 km, 33 km^2) and Talkeetna Glacier (11.6 km, 25 km^2) are the largest named glaciers. Collins (1975) analyzed the comparative sizes and numbers of glaciers shown on topographic maps made from 1948 to 1952 aerial photography with later photography. The result was clear evidence that all of the glaciers of the Talkeetna Mountains were thinning, retreating, and (or) stagnant. Every glacier observed from the air in 2000 and 2007 by the author showed continuing evidence of thinning and retreat, and that many smaller glaciers had completely disappeared.

Alaska Range – The glacierized area of the Alaska Range is approximately 13,900 km^2. The Alaska Range consists of a number of adjacent and discrete mountain ranges that extend in an arc more than 750 km long. The Alaska Range supports thousands of glaciers which range in size from tiny unnamed cirque glaciers with areas of less than 1 km^2 to very large valley glaciers with lengths up to 76 km and areas of greater than 500 km^2. From east to west, the largest include: Johnson Glacier (33 km, 183 km^2); an unnamed glacier (24 km, 108 km^2), which forms the headwaters of the West Fork of Robertson River; Gerstle Glacier (24 km, 80 km^2), which forms the headwaters of the Gerstle River; Gakona Glacier (32 km, 112 km^2); Canwell Glacier (24 km, 89 km^2); Trident Glacier (28 km, 222 km^2); Gillam Glacier (25 km, 144 km^2); Yanert Glacier (35 km, 183 km^2), which advanced about 5 km in a 1942 surge, stagnated for more than 57 years, and surged again in 2000 and 2001; West Fork Glacier (41 km, 311 km^2); Susitna Glacier (36 km, 323 km^2), which surged about 5 km in 1952 or 1953; Black Rapids Glacier (40 km, 341 km^2); Muldrow Glacier (61 km, 516 km^2); Yentna Glacier (51 km, 487 km^2); Kahiltna Glacier (76 km, 580 km^2); Tokositna Glacier (44 km, 240 km^2); Ruth Glacier (63 km, 449 km^2); Eldridge Glacier (48 km, 485 km^2); Peters Glacier (27 km, 123 km^2), which surged in 1986; Straightaway Glacier (22 km, 71 km^2); Foraker Glacier (25 km, 74 km^2); Herron Glacier (25 km, 79 km^2); and Chedotlothna Glacier (27 km, 97 km^2). Non-surge-type valley glaciers in the Alaska Range are stagnant, thinning, and (or) retreating.

Gulkana Glacier, a USGS Benchmark Glacier, has a mass balance record that exceeds 30 years (Josberger et al., 2007). West Gulkana Glacier, a 4-km-long valley glacier was mapped in 1957 (AGS, 1960) and again in 1987 (Thompson and Smith, 1988). A comparison of the maps shows that the glacier retreated about 520 m and thinned and narrowed in the 30 years between surveys.

Wood River Mountains – A GIS analysis of USGS 1:63,360-scale topographic maps of the Wood River Mountains by Manley (1999) determined that 106 glaciers exist in the Wood River Mountains. The analysis quantified 32 different parameters of these 106 glaciers and determined that the total glacier-covered area was approximately 60 km^2 and that individual glaciers ranged in area from 0.05 to 6.4 km^2 (median area 0.26 km^2). They ranged in average elevation from 581 to 1,176 m (median elevation 937 m), in length from 0.25 to 4.38 km (median length 0.61 km), in width from 0.17 to 2.97 km (median width 0.72 km), and in perimeter from 1.0 to 23.8 km (median perimeter 2.6 km). The ELAs ranged from 545 to 1,155 m (average 929 m) and displayed high local variability. The largest glacier, Chikuminuk Glacier, was mapped in 1957 and 1958 during the IGY (AGS, 1960). Since then, its terminus region has thinned and retreated. However, at elevations above 1,000 m, it has thickened by an average of about 10 m.

Kigluaik Mountains – As recently 1986, three very small valley glaciers, Grand Union, Thrush, and Phalarope Glaciers, which have a collective glacierized area of less than 3 km^2, existed in the Kigluaik Mountains (Kaufman and Calkin, 1988). Their field investigations confirmed that other glaciers that existed during the early twentieth century had completely disappeared. They also documented that the remaining three Kigluaik Mountain glaciers were continuing to decrease in area and length. Given the rate at which these three glaciers were retreating and thinning, it is possible that one or more of them may have subsequently disappeared.

Brooks Range – The Brooks Range is the northernmost mountain group in Alaska, containing about a dozen named generally east–west-trending contiguous mountain ranges. Here, polythermal glaciers cover an area of 723 km^2 (C. Suzanne Brown, oral communication, 1992). The largest glaciers are located in the Romanzof Mountains. There, at least 188 glaciers with a combined area of 260 km^2 existed during the 1970s (Denton, 1975). Four had lengths of 5 km or more, including 8.3-km-long Okpilak Glacier and 7.6-km-long McCall Glacier. Details of mass loss at McCall Glacier have been presented by Nolan et al. (2005). All Brooks Range glaciers are retreating.

The general thinning and retreat of lower elevation temperate glaciers is one of the most visible manifestations of the post-Little Ice Age response of Alaska's glaciers to changing regional climate. As the regional summaries of the status of Alaska's glaciers clearly show, most Alaskan mountain glaciers at lower elevations are stagnant and (or) retreating and thinning in response to a post-Little Ice Age regional warming. In fact, more than 98% are currently thinning, retreating, or stagnant. As has also been shown, local and regional variability has given every glacier in Alaska its own complex and unique history of change. For example, many glaciers in southeastern Alaska – such as most of the glaciers of the Glacier Bay and the Lynn Canal areas – began to retreat as early as the mid-eighteenth century. Today while most of Alaska's glaciers continue to retreat, others, like the tidewater Harvard and Hubbard Glaciers, have been advancing for more than a century.

Airborne and spaceborne measurements of changes in Alaskan glaciers

Numerous airborne and spaceborne geophysical missions have provided insight into elevation and volume change of many glacier-covered regions and individual glaciers. For instance, Arendt et al. (2002) synthesized the result of more than a decade of geodetic airborne laser profiling of 67 glaciers in Alaska and adjacent Canada, representing about 20% of the glacierized area of Alaska and adjacent Canada. They concluded that the total annual volume change of Alaska glaciers, expressed as water equivalent, to be -52 ± 15 km^3/year for the period from the 1950s to the early 1990s and -96 ± 35 km^3/year for the period from the middle 1990s to the late 1990s. These volumes are equivalent to a rise in sea level of 0.14 ± 0.04 mm a-1 during the early period and 0.27 ± 0.10 mm a-1 during the more recent period.

More recently, Arendt et al. (2006, 2009), Berthier et al. (2010), and VanLooy et al. (2006) used spaceborne sensors to make measurement of glacier elevation changes in Alaska that confirm and expand the earlier airborne studies. Numerous studies, such as Arendt et al. (2008), Chen et al. (2006), Luthcke et al. (2008), and Tamisiea et al. (2005), have used the Gravity Recovery and Climate Experiment (GRACE) satellite mission to document mass changes in Alaskan glaciers. For example, Chen and his colleagues determined that monthly gravity data, spanning April 2002–November 2005, showed a prominent glacial melting trend in the mountain regions around the Gulf of Alaska equal to 101 ± 22 km^3/year.

Summary

This entry presents a summary of the distribution, size, behavior, and characteristics of the glaciers of Alaska. It has documented that today, most of Alaska's approximately 2,000 valley glaciers are retreating, thinning, and/or stagnating. Additionally, many lower elevation mountain and cirque glaciers have disappeared in post-Little Ice Age time. In spite of the regional trend of significant ice loss, about a dozen large valley glaciers are currently thickening and advancing. All of these are near the Pacific Ocean and generally possess significant higher elevation accumulation areas. At higher elevations, generally above 2,000 m, glaciers are thickening or exhibit no change.

Several volcanoes, including Redoubt Volcano, had twentieth century eruptions that melted summit glaciers. Post-eruption conditions resulted in the formation of new glaciers in their craters. Recently, space-based investigations have confirmed the role of melting Alaskan glaciers in global sea-level rise and documented the acceleration of the rate of melting and retreat at many locations.

ALBEDO

Thomas C. Grenfell
Department of Atmospheric Sciences, University of Washington, Seattle, WA, USA

Definition

Albedo: The fraction of incident solar radiative energy flux, or irradiance, reflected and scattered upward from a surface integrated over the solar spectrum from 300 to approximately 3,000 nm.
Spectral Albedo. The ratio of upwelling to incident irradiance versus the wavelegth of the radiation.

Introduction

Heat exchange over snow and ice is strongly affected by the interaction of solar radiation with the surface. A quantitative understanding of this interaction is critical in treating a wide variety of problems involving both the state and evolution of the surface, the subsurface layers, and the overlying atmosphere. The concept of surface albedo has been introduced as an essential tool for specifying the *surface energy balance*. The albedos of surfaces across the Arctic and Antarctic as well as snow-covered and glaciated areas at lower latitudes have been an ongoing topic of observations and modeling for many years. Pioneering work has been carried out by Dunkle and Bevans (1956), and Langleben (1971). Albedo values have been obtained with progressively increasing accuracy and with a variety of modern instruments. Developments in radiative transfer theory make it possible to examine the physical principles involved in great detail. Many of the principles given here apply to terrestrial surfaces in general, but the present discussion will be limited to surfaces consisting of various forms of snow and ice. For these media, the albedo is typically dominated by volume scattering and absorption of light that penetrates below the surface, while surface scattering or reflection is usually a secondary effect.

In winter, with a thick snow cover on the surface, the albedo is spatially quite uniform, for example, over the large continental ice sheets and some areas of the Arctic. In general, however, the albedo of a given region can be quite complex due to spatial inhomogeneities in the surface such as undulations, crevasses, or windswept zones giving rise to areas where the snow is shallow. Vegetation both in and extending above the snow generally lowers the albedo. These considerations are particularly important in the spring and summer during the melt season that occurs near sea level at almost all latitudes as well as over a significant fraction of the Greenland ice sheet and around the margins of Antarctica. As the snow becomes thinner and finally melts away, patches of the underlying surface are exposed or meltwater accumulates on or percolates below the surface. Underlying ice surfaces such as sea ice and glacier ice continue to melt throughout the summer producing further spatiotemporal variations. In these cases, changes in albedo can affect both vertical and lateral melting rates, which in turn can modify the local and regional albedo producing a decrease that accelerates the melting. In recent climate modeling studies, these effects are referred to as "snow-albedo or ice-albedo feedback" and they act to accelerate the changes in the properties of the surface, in the albedo, and in the total energy balance of the area in question. An understanding of how the albedo varies in response to changes in the state of the surface is a central component in understanding the climate of ice-covered regions and the climate in general.

Definition of surface albedo

To understand the physical principles determining the albedo, we consider the radiative energy flux or irradiance, integrated over the upward (F_{up}) or downward (F_o) hemisphere, which is commonly expressed in units of watts per square meter. The albedo, denoted by α, is expressed simply as the ratio

$$\alpha = F_{up}/F_o. \tag{1}$$

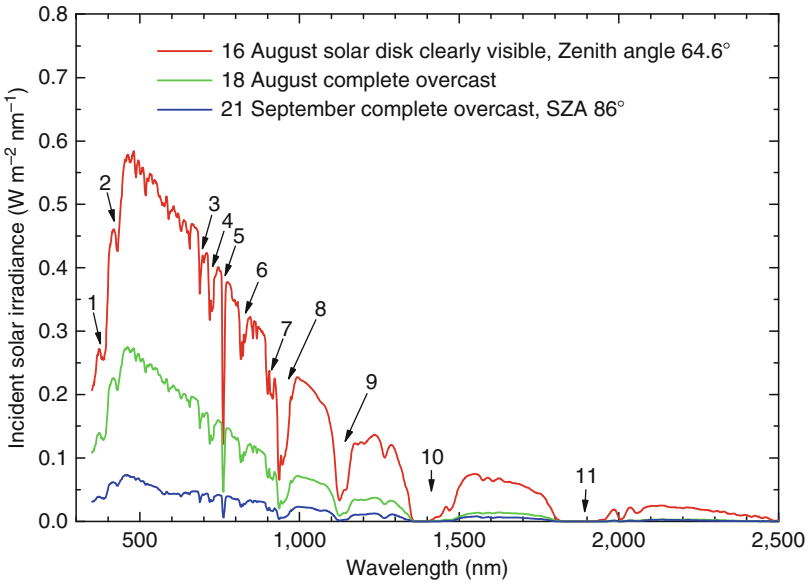
The downwelling irradiance at the surface, F_o, consists of total direct plus scattered solar radiation over the wavelength range from about 350 to 3,000 nm. This is often referred to as "shortwave radiation" in contrast to thermal infrared radiation emitted by terrestrial surfaces and by the atmosphere. F_{up} is the total shortwave irradiance redirected upward as a result of scattering and reflection by the near-surface layers. On clear days, F_o consists primarily of direct solar radiation with a secondary diffuse component due to Rayleigh and aerosol scattering by the atmosphere. On days with uniform overcast skies, F_o is diffuse and nearly isotropic. The incident radiation is attenuated in its passage through the atmosphere more strongly in the infrared than at visible and UV wavelengths due primarily to water vapor absorption. Representative examples of F_o for the Arctic are shown in Figure 1. F_o has a strong dependence on wavelength, λ, consisting of a blackbody spectrum with a maximum near 500 nm and superposed spectral absorption bands. Because the absorption properties of ice and snow also have a strong wavelength dependence, it is important to define the concept of spectral irradiance $F(\lambda)$ and the corresponding spectral albedo, α_λ, where

$$\alpha_\lambda = F_{up}(\lambda)/F_o(\lambda). \tag{2}$$

The total albedo is given by:

$$\begin{aligned}\alpha &= \int_{SW} \alpha_\lambda \cdot F_o(\lambda)\, d\lambda \Big/ \int_{SW} F_o(\lambda)\, d\lambda \\ &= \int_{SW} \alpha_\lambda \cdot F_o(\lambda)\, d\lambda \Big/ F_o,\end{aligned} \tag{3}$$

where SW denotes the shortwave radiation band.



Albedo, Figure 1 Incident solar radiation spectra over Arctic sea ice with the solar disk clearly visible on 16 August 2005 and for overcast skies on 18 August and 21 September 2005 (Grenfell and Perovich, 2008). The following atomic and molecular absorption features are present: **1**. Ca II H/K, 393–396 nm; **2**. Fe/Ca, 431 nm; **3**. O_2 B, 686–688 nm; **4**. H_2O, 718–729 nm; **5**. O_2, 759–765 nm; **6.** H_2O, 820 nm; **7.** H_2O, 910 nm; **8.** H_2O, 933–946 nm, **9.** H_2O, 1,118–1,144 nm, **10.** H_2O, 1,350–1,480 nm; **11.** H_2O, 1,810–1,950 nm.

It is important to realize that the albedo is an *apparent* optical property. This means that it depends on the angular distribution and spectral composition of the ambient radiation field as well as on the *inherent* optical properties, which depend only on the structural and optical properties of the medium. This is evident from Equation 3 but also depends on the transfer of radiation within the medium. Spectral albedo depends in general on the solar elevation and cloud cover and thus is also an apparent optical property, but it is insensitive to many natural variations in the ambient radiation field related to the spectral distribution of the radiation. Because α_λ depends strongly on wavelength for all snow and ice surfaces as does $F_o(\lambda)$ in general, an understanding the physical principles governing the albedo require detailed understanding of the spectral albedo. In order to categorize α_λ for comparison purposes, it is most convenient to specify its values under conditions of diffuse illumination encountered beneath a uniform cloud cover, avoiding complications due to daily and seasonal variations in $F_o(\lambda)$. Conveniently, heavy cloud cover is common over large areas of melting snow and ice. The techniques discussed in Radiative Transfer Modeling can then be used to calculate corresponding values of α_λ appropriate for the full range of solar elevations and a wide variety of cloud conditions. Note that the α_λ under diffuse illumination for snow and ice is equal to the value for clear skies for a solar zenith angle of approximately 50° (Wiscombe and Warren, 1980). Because clouds absorb preferentially in the solar infrared leaving more radiation in the visible where α_λ is greater, it can be seen from Equation 3 that cloudy conditions modify the value of α, producing an increase in α for solar zenith angles near 50° for example.

Underlying principles

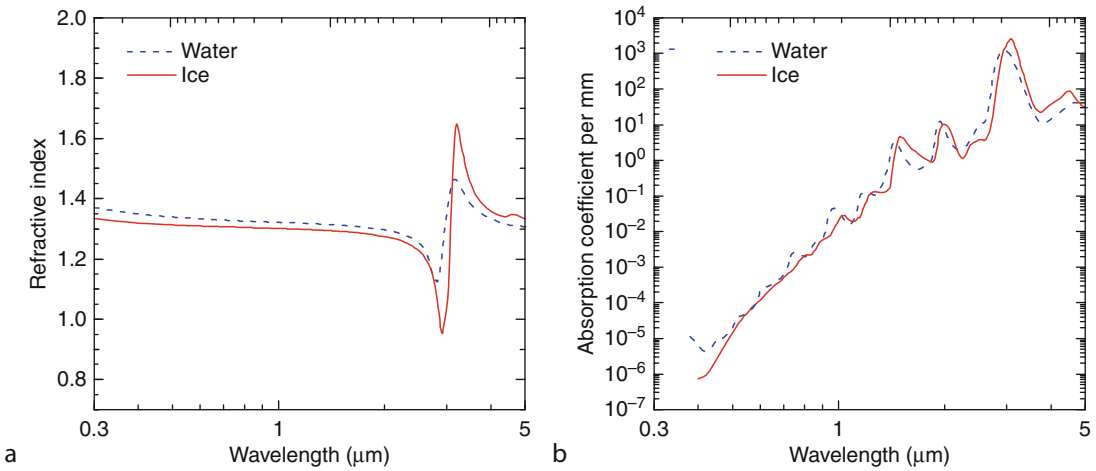
To model the albedo of a snow or ice medium in terms of its physical properties, it is necessary to take into account the layer structure, grain and bubble size distributions, and impurity contents as appropriate. In the following it is assumed unless stated otherwise that the total snow or ice layer in question is locally plane parallel and "optically thick," i.e., sufficiently thick that the albedo would not increase if the thickness were increased. In this case, the albedo is not influenced by the properties of the underlying medium. In practical terms this applies to a snow layer of at least 5–10 cm in thickness while other more transparent surface types such as bare sea ice or lake ice would need to be at least ten times thicker. Also required are the inherent optical properties of ice and water as functions of wavelength, including the refractive indices and absorption coefficients, together with the scattering coefficients for ice grains, bubbles, and other inhomogeneities. The scattering coefficients depend, in general, on the size distribution function, $n(r)$, and shapes of the particles as well as on the optical constants of ice and of any foreign inclusions. In modeling albedo, when we refer to "grain size" we mean effective grain radius derived from the actual size distribution, $n(r)$, by an expression such as the equation

$$r_{eff} = \int r^3 \cdot n(r) \cdot dr \Big/ \int r^2 \cdot n(r) \cdot dr \qquad (4)$$

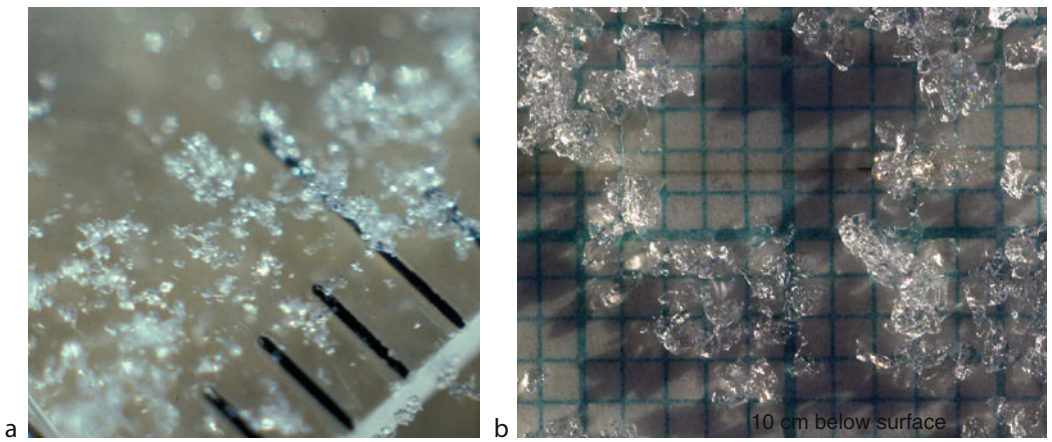
introduced by Hansen and Travis (1974).

The most recent compilation of values for absorption coefficient and refractive index for ice (Warren and Brandt, 2008) is shown in Figure 2a and b. Corresponding values for pure water (Segelstein, 1981) are also needed for wet or melting snow and ice. To model the volume scattering, the size distribution and shapes of the scattering particles are needed. Although falling snow grains are usually hexagonal, the shape of the grains in the upper layers of the snow on the surface quickly become rounded even under polar conditions (Figure 3) and can often be well approximated as spheres or more generally by the method of equivalent spheres (Grenfell and Warren, 1999) for which Mie scattering theory provides a rigorous solution. For other cases such as snow in the atmosphere or very new snow, the grains can be hexagonal or irregular with very complex shapes such as multibranched dendrites, and ridged, ruffled, or rimed surfaces. Considerable progress has been made in recent years in modeling the scattering functions of many of these types of nonspherical particles, but specifying the actual shapes and size distributions of such particles in a given situation is very complex and is a topic of current research.

The modeling study by Wiscombe and Warren (1980) clarified the dependence of albedo on the structure of snow. For a thick snowpack, the albedo is sensitive primarily to the size of the snow grains in the sense that as the snow grain radius increases the albedo decreases. The decrease is greater in the infrared because the absorption coefficient of ice is greater at longer wavelengths. This can be understood in physical terms by noting that

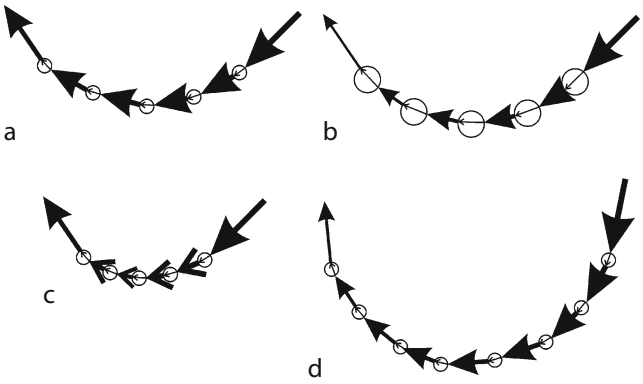


Albedo, Figure 2 Index of refraction (**a**) and absorption coefficient (**b**) for ice and water from 0.2 to 5 μm. Ice data from Warren and Brandt (2008). Water data from Segelstein (1981) and Pope and Fry (1997). Values in the ultraviolet between 0.3 and 0.4 μm are very low for both ice and water and are presently uncertain.



Albedo, Figure 3 Rounded and eroded snow grains from (**a**) the surface layer near South Pole Station; and (**b**) from 10 cm below the surface near Dome C Station. The spacing between the black lines in (**a**) and between the thinner blue lines in (**b**) is 1 mm.

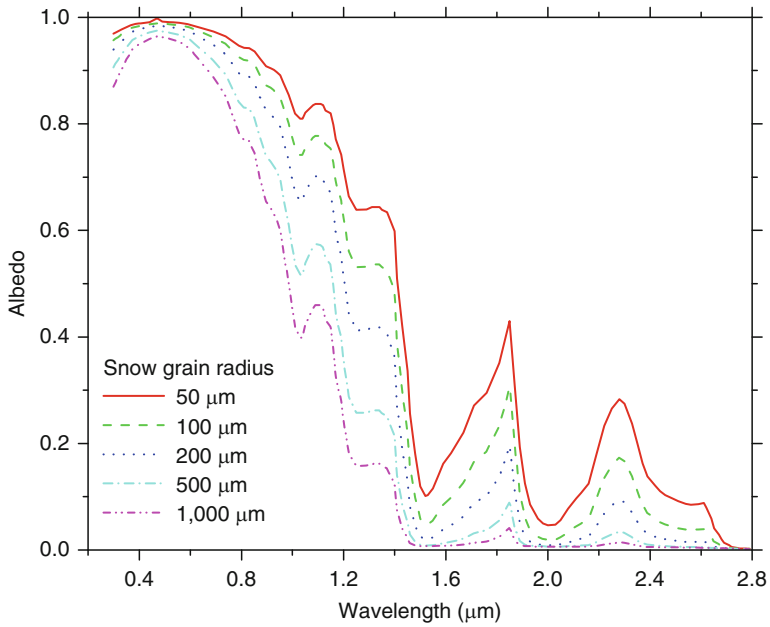
snow grains scatter radiation predominantly in forward directions so that downward propagating rays must be scattered by many grains before they reemerge at the surface. Further since the grains are very large compared with the wavelength of the light, about the same number of scattering events is needed to redirect an incident ray back out of the snow regardless of grain size. Then from Figure 4 cases A and B we see why a homogenous snowpack with larger grains will have a lower albedo than one with smaller grains. The total absorption path length for a ray emerging from the snow is the distance traveled through ice grains and the path length through ice is greater for larger grains. If the grains are compacted to increase the density (case C), the number of scattering events for a ray to emerge will remain about the same so the absorption path length will be the same as for case A. Hence the albedo will remain the same even though the penetration depth varies. From case D, it is can be seen that emergent rays that have entered the snow closer to the vertical have experienced a larger number of scattering events and hence greater absorption, thus the albedo under clear skies will decrease as the solar elevation increases for constant snow-pack structure. The grain size dependence of α_λ is illustrated by the model results shown in Figure 5.



Albedo, Figure 4 Schematic diagram showing the influence of grain size, density, and solar elevation on albedo. Width of arrows external to the grains indicates the relative intensity. Case (**a**). Small grains, low absorption, high albedo; Case (**b**). Larger grains, greater absorption path length through ice, lower albedo than Case (**a**); Case (**c**). Small grains, greater snow density, absorption path length and albedo equal to case (**a**). Case (**d**). Small grains, higher sun angle, more scattering events, greater absorption path length and lower albedo than case (**a**).

Radiative transfer theory has been shown to model accurately the spectral and total albedo of thick snow on the Antarctic Plateau (Grenfell et al., 1994). This is an ideal test location where the snow is extremely pure and snow conditions are very stable. For snow in other areas, extra absorption usually arises from inclusions of foreign material such as soot, dust, and biological organisms. For other ice types including sea-ice and glacier ice, brine inclusions and vapor bubbles play a central role, and foreign materials are also usually present. Modeling of albedo in these cases requires an investigation of the size and shapes and optical properties of all inclusions.

Since bubbles and other air inclusions are also strongly forward scattering, analogous considerations apply for lake ice (Mullen and Warren, 1988), continental ice sheets, and glacier ice. A greater number density of bubbles gives



Albedo, Figure 5 Radiative transfer model results of spectral albedo of pure snow for different effective snow grain radii for a solar zenith angle of 60° from Wiscombe and Warren (1980), transcribed.

more volume scattering and thus a higher albedo while larger bubbles for a given number density imply lower albedo (Grenfell, 1983). The bulk structure in these cases typically includes additional complexity such as cracks, variable surface topography, and thickness variations due to deformation events. The determination of $n(r)$ is in general complex and can be quite sensitive to the number very small bubbles, which are at or near practical limits of resolution and can exhibit considerable spatial variability.

Other factors that can be significant in determining the albedo, depending on the ice type in questions, are the presence of subsurface ice layers, surface roughness (e.g., sastrugi), and inhomogeneities such as cracks on varying scales from microscale to crevasses. In addition, these quantities typically show spatial variations particularly over meter and larger scales as well as temporal variations especially associated with melting and refreezing events in the spring and fall. For these cases, modeling is much more complex and considerable work remains to obtain a quantitative understanding the intricacies involved.

Instruments and techniques

To understand how to measure albedo, it is useful to consider the following expansion of Equation 2:

$$\alpha_\lambda = \int_{\text{upper hemisph.}} I_{up}(\lambda,\mu,\varphi)\,\mu\,d\mu\,d\varphi \Big/ \int_{\text{lower hemisph.}} I_{dn}(\lambda,\mu,\varphi)\,\mu\,d\mu\,d\varphi, \tag{5}$$

where μ is the cosine of the angle of incidence (zenith or nadir as appropriate), φ is the azimuth angle, the subscript "up" or "dn" denotes upwelling or downwelling radiation, which is integrated over the appropriate hemisphere. From Equation 4 it follows that an ideal receptor for measuring $F_{\text{up}}(\lambda)$, $F_{\text{o}}(\lambda)$, and spectral albedo should have a hemispherical field of view with a sensitivity that is proportional to μ and independent of φ under uniform illumination by a beam of constant intensity. Such an instrument is said to have an ideal "cosine" response and its output is directly proportional to the irradiance incident upon it regardless of the angular distribution of the radiation field incident upon it. An instrument to measure wavelength integrated values should also have a sensitivity that is independent of wavelength over the shortwave spectral region.

A major development in studying α has been the development of a remarkable class of instruments called pyranometers that closely satisfy the above requirements for radiation incidence angles from 0° to between 70° and 75°. These instruments make use of a thermocouple array or thermopile covered with a nearly ideal black coating that is exposed directly to and heated by the radiation. Pyranometers measure the temperature difference between the thermopile and a reference mass inside the instrument that is shielded from the radiation and kept at ambient air temperature. The thermopile is protected by a pair of hemispherical quartz domes that limit the detected radiation to the shortwave region and provide shielding from the wind while introducing no angular bias in sensitivity. These instruments have a linear response over a large range in light intensity. They are lightweight, compact, easy to deploy, and require no external power source. Units consisting of a matched pair of sensors looking up and downward simultaneously are now available from Kipp and Zonen (www.kippzonen.com). A wide variety of low-power solid-state recorders are also available to record the output, making it feasible to carry out long-term unattended observations. The main challenge is that the outer domes often collect condensation, rime, or frost, which must be removed to obtain accurate results.

Pyranometers are not suitable for high resolution α_λ measurements because their sensitivity is too low. Modern photo-optical sensors, such as photodiode arrays and more recently CCD arrays, have overcome the sensitivity problem, and spectrophotometric instruments that provide measurements over the full shortwave spectrum are now available. One of the major concerns with these instruments is to produce a sensor with a true cosine response at all wavelengths or to correct the measurements for departures from the ideal response.

The first spectrophotometers for field use in the Polar Regions were restricted to the 400–1,100 nm wavelength range. Grenfell and Maykut (1977) reported observations of spectral albedo for sea ice and snow, but extrapolation to longer wavelengths was necessary to determine total albedo, limiting the accuracy of the results. A prototype instrument produced the first set of accurate spectral albedo observations over the full wavelength range for clean snow and ice in the Antarctic (Grenfell et al., 1994). The turret receptors in use had significant deviations from an ideal cosine response, particularly in the infrared, and significant wavelength-dependent corrections had to be applied. Commercial instruments are now available with improved sampling speed, accuracy, sensitivity and spectral resolution, and broad-band cosine receptors whose response is much closer to the ideal cosine dependence.

Calibrations

Observations can be made directly with matched upward and downward-looking instruments or by orienting a single instrument alternately upward and downward and recording the ratio of the signals. In the latter case, it is important to have an external reference instrument with similar response characteristics to monitor changes in the incident radiation field, particularly when clouds are present.

Albedo measurements have also been made with a receptor with a limited field of view looking downward alternately at the surface and then at a diffusely scattering reference plate such as Spectralon® that scatters the incident radiation toward the receptor. In this case, corrections

for the departure of the reference plate from a perfect diffuse scatterer can be applied because its directional reflectance properties are well characterized (Bruegge et al., 2001; Voss and Zhang, 2006). It is necessary to compensate properly for the angular distribution of the upwelling radiance from the surface outside the field of view of the detector.

For either mode of measurement, it is necessary to determine a shadowing correction to account for the obstruction of the ambient radiation fields by the presence of the instrument and other obstructions. Corrections for both α and α_λ range from about 0.005 to 0.04 for typical configurations (Grenfell et al., 1994), but shadowing corrections can be significantly larger if the instruments are mounted on a ship or aircraft or near taller buildings and must be determined on a case-by-case basis (Allison et al., 1993).

Albedo observations have been reported using only a photodiode detector system with a response over the spectral range from about 350 to 1,100 nm. These must be corrected for the effects of solar radiation at longer wavelengths since about half the incident irradiance lies at wavelengths between 700 and 3,000 nm. Approximation by reference to existing tabulations or radiative transfer modeling can be used; however, significant uncertainties remain in the incident infrared portion of the spectrum due to fluctuations in atmospheric water vapor and in the structure of the near surface layers of the snow or ice.

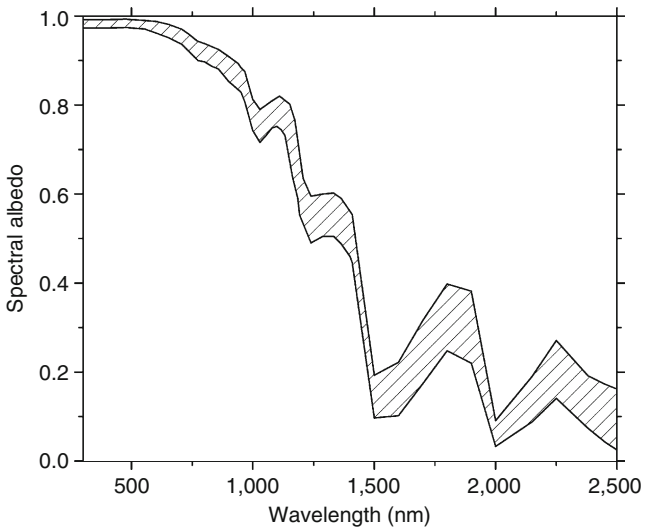
Considerable effort has been devoted to inferring spectral and total surface albedos using satellite observations. These require at least two important additional corrections. First it is necessary to account for attenuation and scattering by the atmosphere, whose properties can vary on time scales as short as a few seconds. Many satellite studies make use of surface-based albedo data as standards to infer optical properties of the atmosphere. Second, satellites view a given surface element with a very narrow field of view and from only a single direction or at most a few different directions; however, to extrapolate the observations over the upward hemisphere requires a knowledge of the hemispherical reflectance distribution function (HRDF). This is closely related to the bidirectional reflectance distribution function (BRDF) that describes the directional dependence of radiation scattered upward from a collimated incident beam. The HRDF describes the distribution of upwelling radiation from actual illumination conditions under clear skies taking into account the diffuse sky component as well as that of the direct solar beam. Values have been reported for broadband use for a selection of reference surfaces including cold snow covers (Taylor and Stowe, 1984; Kato and Loeb, 2005). Spectral values for Antarctic snow have been presented by Hudson et al. (2006) and for glacier ice by Greuell and de Ruyter de Wildt (1999). Accurate HRDF observations are very difficult to carry out under general field conditions due to the need to take a large series of observations rapidly while compensating for changes in ambient lighting. Spatial and temporal variations of surface properties introduce further uncertainties. Automated steering mechanisms for the receptor have been developed that have produced significant improvements providing the capability to measure values of HRDF rapidly (e.g., Painter and Dozier, 2004). Theoretical interpretation of these results is considerably more involved than for α_λ, which is much less sensitive to much of the fine-scale angular dependence of the upwelling radiation field.

Observations of snow and ice surfaces

Observational results from a variety of surfaces from different stages in the seasonal cycle are presented in this section. Almost all the surfaces discussed below undergo an annual cycle consisting of a cold period where the upper layers consist of snow deposited in the current year followed by a melt season where much or all of the snow melts away exposing an ice or ground surface underneath. The surface albedos vary over the annual cycle. Only on the high altitude ice sheets of Antarctica and Greenland are there large areas where summer melting does not occur and the optical properties of the surface layers are much more stable throughout the year (Liljequist, 1956). The magnitude of actual seasonal and interannual variations in reflectance patterns have recently been reported by Jin et al. (2008). These regions are of particular interest as stable reference surfaces for remote sensing measurements.

Snow

Spectral albedos for a thick clean snow cover have been reported from observations on the Antarctic plateau (Figure 6). Volume scattering is very strong and nearly constant across the entire shortwave band. Consequently,



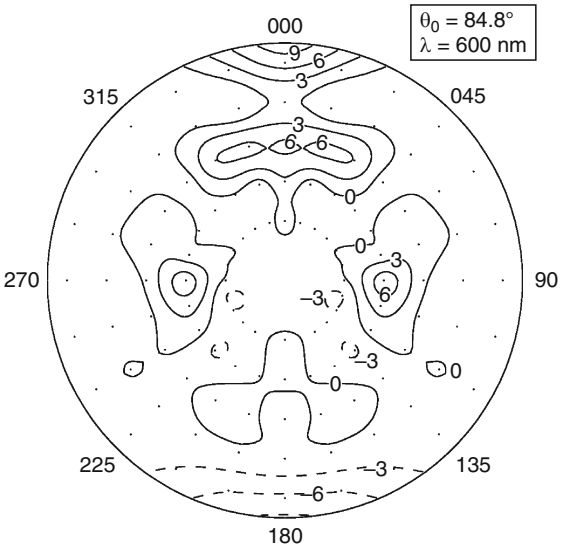
Albedo, Figure 6 Envelope of the observed spectral albedos of snow on the Antarctic Plateau from South Pole, Vostok, and Dome C stations. Data from austral summers of 1985–1986, 1990–1991, and 2004 (Grenfell et al., 1994; Hudson et al., 2006). Mean $\alpha = 0.85$.

α_λ at visible wavelengths where ice is very weakly absorbing closely approaches unity. At longer wavelengths, ice absorption increases by many orders of magnitude (Figure 2b), and α_λ decreases to very low values in the infrared. The corresponding total albedos for diffuse illumination are 0.85 ($\pm$0.02). The results of observations made under uniform cloud cover at different locations and in different years are essentially the same indicating the stability of the albedo of snow on the Antarctic plateau. The observations have been successfully matched by radiative transfer models (Grenfell et al., 1994). Similar studies in other polar regions (Aoki et al., 2000; Grenfell and Perovich, 2004) have also shown good agreement between observation and theory but impurities in the snow influence the results resulting in lower values, particularly at visible wavelengths as discussed below.

Spectral bidirectional reflectance observations of snow on the Antarctic Plateau have been analyzed and parameterized by Hudson et al. (2006) for the full range of local solar zenith angles over the full solar spectrum. The values are characterized in general by a strong enhancement in the direction of the sun with nearly isotropic values at other angles. A representative example is shown in Figure 7. A very similar pattern has been reported for a temperate snowpack (Painter and Dozier, 2004).

Sea ice

Albedos for sea ice have been reported at various locations and times of year since the early 1960s. A summary is given by Grenfell and Maykut (1977). An annual cycle of α for thick multiyear sea ice has been reported from the Surface Heat and Energy Budget of the Arctic (SHEBA) experiment in 1997/1998 as shown in Figure 8.

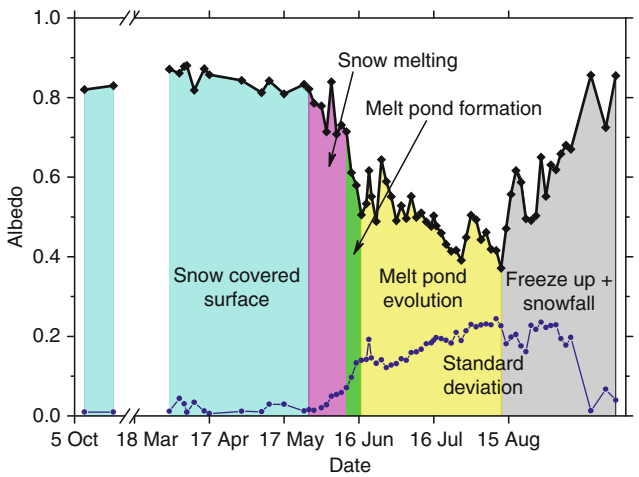


Albedo, Figure 7 Polar contour plot of anisotropic reflectance factor of snow at Dome C Station, Antarctica, for a solar zenith angle of 84.8° and a wavelength of 600 nm (Hudson et al., 2006).

During the cold season from October to late-May, the sea ice was covered with a layer of snow about 30 cm in thickness and the albedo was quite stable. The fluctuations were mainly due to changes in illumination conditions and variations in grain size. Significant changes occurred as soon as the snow began to melt in the Spring, and they continued throughout the melt season and into the fall until the snow cover and cold Winter conditions resumed.

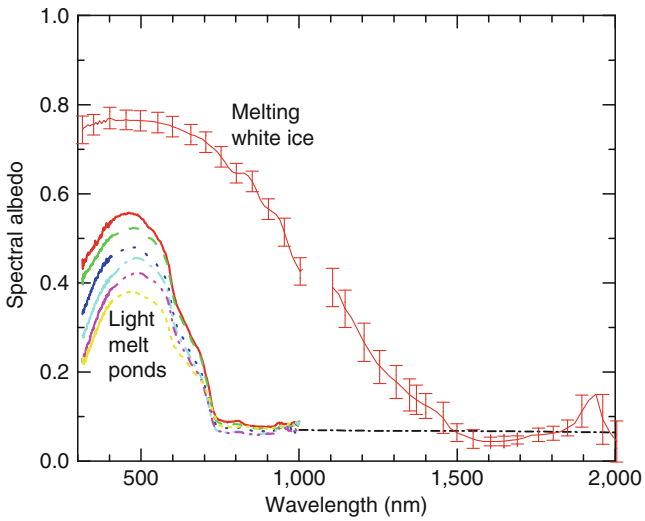
The spectral albedo of thick winter sea ice is quite similar to the pure snow albedos shown in Figure 6. The spectral albedo of growing thin and young ice ranges from a low almost wavelength-independent value near 0.067 increasing with ice thickness and accumulation of surface frost and snow. The development of the albedo of young ice types can be influenced by episodic events such as air temperature variations and snowfall. Representative sequences have been presented for specific situations (Grenfell et al., 1998; Brandt et al., 2005).

The summer ice cover consists of drained white ice and melt ponds. Selected values of α_λ are shown in Figure 9. The spectral albedo of white ice is nearly constant across the visible part of the spectrum decreasing in the infrared. In this case, α_λ is quite stable throughout the summer because of the presence of a drained layer above freeboard level whose thickness and structure are maintained by hydrostatic adjustment as water from the melting surface drains off the floes. Melt ponds occur in local depressions where the melt water can collect. The albedo of melt ponds is primarily determined by the amount of volume scattering in the ice beneath the water while the dependence on water depth in the ponds is relatively weak (Makshtas and Podgorny, 1996). Both light and dark melt ponds occur for cases where the volume scattering is greater or smaller respectively. For dark melt ponds the maximum



Albedo, Figure 8 Time series of wavelength-integrated albedo of sea ice in October 1997 and from 1 April 1998 through 27 September 1998. Values were averaged over a 200-m-long albedo line. The standard deviation of albedo measured along the albedo line for each is plotted as *solid blue circles*. From Perovich et al., 2002 with modifications.

values of α_λ, near 500 nm, are smaller than those shown in Figure 9, but they taper off to the same values in the near-infrared where the water is opaque. Because of the decrease in α_λ from 500 to 750 nm the ponds look blue or greenish blue. The regional albedo of melting sea ice floes is determined primarily by the albedos and areal coverage of the melt ponds, both of which are quite variable.



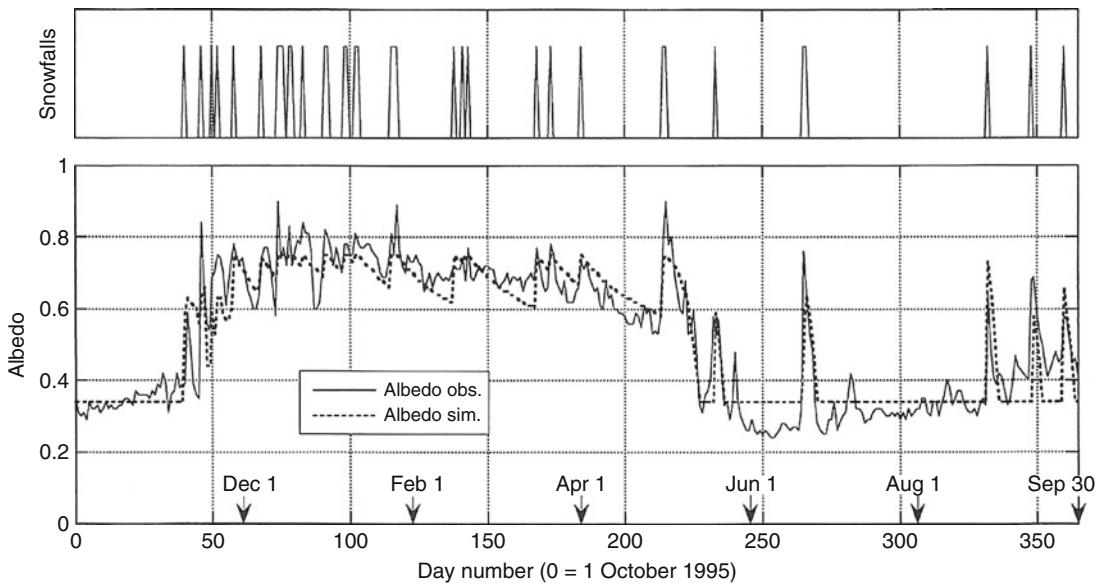
Albedo, Figure 9 Spectral albedos of bare drained sea ice (white ice) during the melt season from 7 July through 14 August 1998 ($\alpha = 0.65$) and light melt ponds over approximately the same interval (Perovich et al., 2002). *Dashed line* is an extrapolation of melt pond albedo based on Fresnel reflection coefficients using the active index values for ice.

Aircraft surveys of the fractional area of pond coverage during SHEBA recorded values as high as 25%. The melt pond coverage is thus very important for the regional shortwave energy balance.

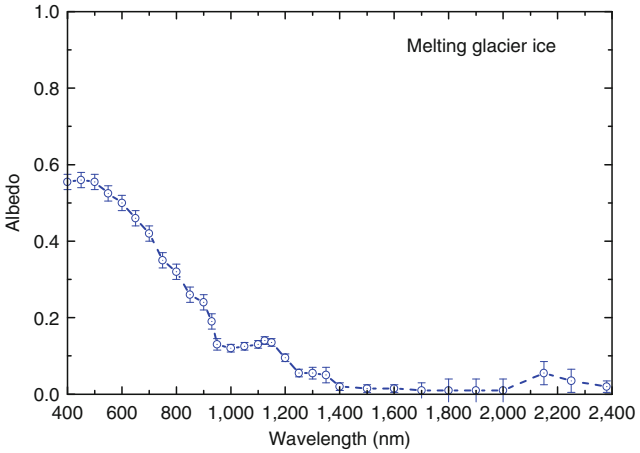
An additional surface type associated with sea ice is open water in leads and polynyas formed by separation of ice floes, exposing the ocean beneath. The spectral albedos are nearly independent of wavelength and are dominated by specular reflection from the upper surface. Plankton and algae in the water can produce some volume scattering resulting in a slight increase across the visible part of the spectrum. Values of $\alpha = 0.066 \pm 0.007$ have been measured for diffuse illumination (Pegau and Paulson, 2001; Brandt et al., 2005). Because of their low albedo, the areal coverage of leads and polynyas are also very important in the seasonal energy balance.

Glaciers

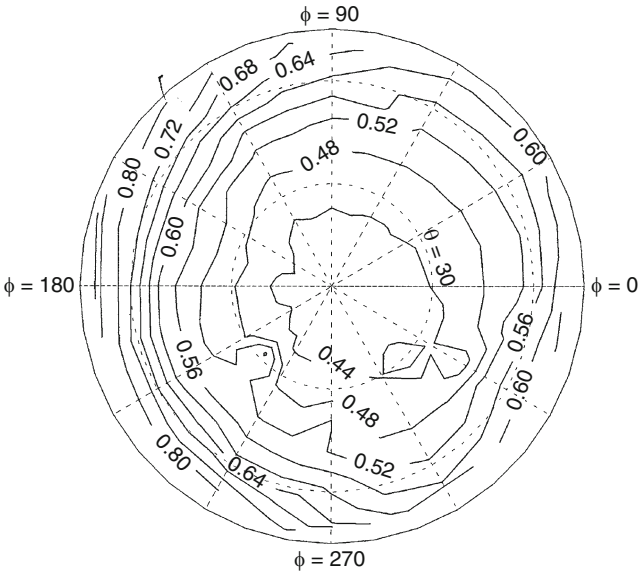
The albedo of glaciers in temperate zones undergoes a strong seasonal cycle where the winter values of uniform surfaces closely resemble those of cold snow, and summer values range from melting coarse grained snow (~0.65) to lower values for exposed melting firn and bare ice. The volume scattering that dominates the albedo is due to snow grains near the surface and vapor inclusions formed as the snow is compressed into impermeable ice at depth, trapping the air between the grains. To illustrate the annual cycle of glacier albedo, a 1-year record of albedo and snowfall events from the ablation zone of the Morteratschgletscher (Oerlemans and Knapp, 1998) is shown in Figure 10. The main variations shown were shown to be due to snowfall events and changes in the thickness of the annual snow cover. An example of α_λ from late



Albedo, Figure 10 A record of albedo (*lower panel*) and snowfall events (*upper panel*) from the ablation zone of the Morteratschgletscher from 1 October 1995 through 30 September 1996 (Oerlemans and Knapp, 1998).



Albedo, Figure 11 Bare melting glacier ice in the ablation zone of Athabasca Glacier 16 September 1981. $\alpha = 0.34$ (GP 84). Variable amounts of dust and debris from neighboring mountains can result in large local and regional variations in glacier albedo.



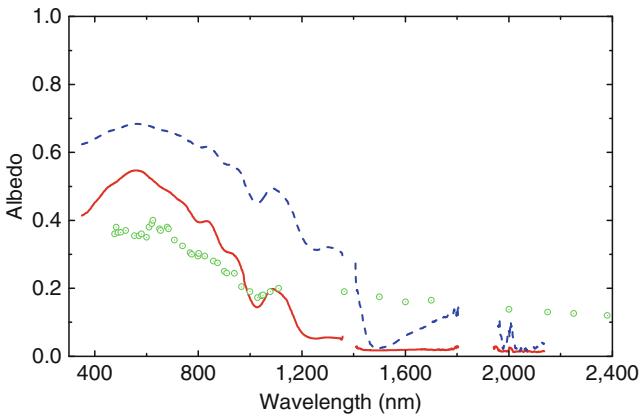
Albedo, Figure 12 Directional reflectance observations of glacier ice in the ablation zone of the Morteratschgletscher for solar zenith angle 74° and wavelength 540 nm (Greuell and de Ruyter de Wildt, 1999).

summer for the ablation zone of the Athabasca glacier is shown in Figure 11 for which the total albedo was 0.34. Since glacier ice almost always accumulates windblown dust from the surrounding mountains, both the surface snow and the underlying ice are not usually clean. The albedo is quite variable and thus difficult to model on both small and regional spatial scales, due not only to varying amounts of dust but to dynamically introduced features such as crevasses, stress cracks, medial moraines, etc. As described below, the apparent albedo can be strongly influenced by the tilt of the surface, a significant consideration for ice in mountainous terrain.

Directional reflectance observations for glacier ice (Figure 12) have been carried out, for example, by Greuell and de Ruyter de Wildt (1999) together with concurrent albedo observations to derive parameterizations relating the HDRF to the albedo for a given viewing geometry in the Landsat TM 2 and 4 bands. The reflectance patterns show a less distinct forward peak than that of Antarctic snow and a greater degree of anisotropy particularly at near nadir viewing angles.

Lake ice

Representative values of spectral albedos from three different stages during the annual cycle are shown in Figure 13. In winter, lake ice can have a thick snow cover with a resulting albedo similar to that of snow in Figure 6; however, if the snow has been removed exposing the bare ice, the spectral albedo is much lower (green circles in Figure 13). For this case, α_λ at visible wavelengths was relatively low but remained at about 0.1 throughout the solar infrared due to the strong specular reflection due to the large solar zenith angle at the time of the experiment ($\sim$70°). During the spring melt season, the ice near the



Albedo, Figure 13 Albedos for snow-free lake ice. Melting ice, Imikpuk Lake, Barrow AK, 13/18 June 2001, overcast, $\alpha = 0.39$ (*solid red curve*), and 20–22 June 2001, overcast, $\alpha = 0.54$ (*dashed blue curve*), (Grenfell and Perovich, 1984, 2004) edited. Cold bare lake ice, Moses Lake WA 17 January 1984 clear sky, solar zenith angles from 68° to 75° (*green circles*) (Mullen and Warren, 1988, transcribed).

lake surface melted preferentially at the contact planes of the ice crystals, establishing an array of anisotropic ice grains (horizontal dimensions $\sim$1 cm, vertical dimensions $\sim$10 cm) above the local water table that gave rise to increased volume scattering and a decrease in specular reflection component. As a result, α_λ at visible wavelengths was higher than for the winter case while in the infrared it decreased to values near 0.01 (red solid curve). As melting progressed the surface granular layer

thickened, the ice grains fell apart decreasing the grain size, and the albedo resembled that of melting sea ice (blue dashed curve). When the ice has melted completely, the albedo depends on the depth and clarity of the water, and for deep lakes values it is similar to those of leads and polynyas discussed above. If the lake is shallow and the water clear, α_λ depends on the optical properties of the material at the bottom of the lake.

Underlying surfaces

Spectral albedos for snow and ice-free surface types are important for interpreting the albedo of areas with thin or patchy snow cover. Values of α_λ measured in the Arctic coastal zone near Barrow AK in late May and early June are shown in Figure 14. Tundra albedo increased across the visible and into the near infrared resulting in a brown surface. The albedos of mud (brownish) and gravel (gray) were also low across the shortwave band with less pronounced increases across the visible. This is opposite to the behavior of α_λ for snow and ice surfaces so these types of surfaces can be distinguished from snow or ice.

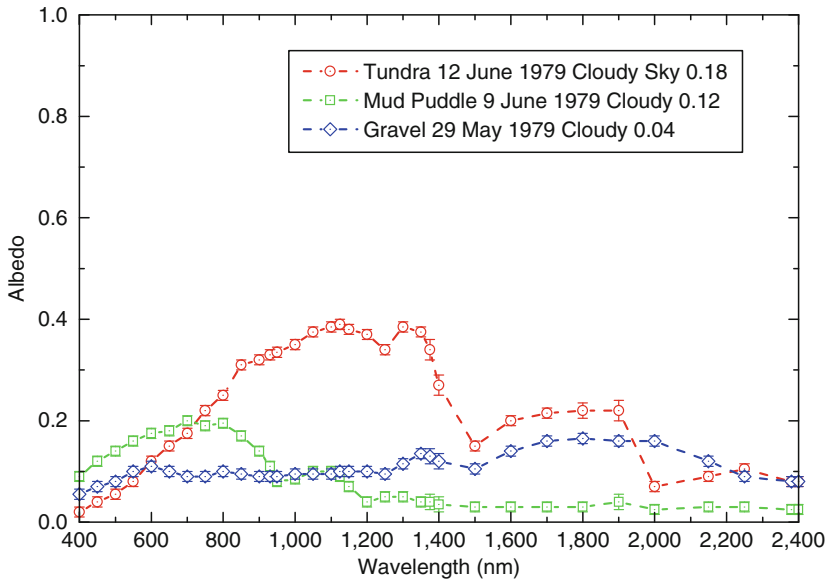
Remote sensing and regional values

Predictions of regional albedo values using the above results in combination with satellite imagery have been carried out in order to identify various features or areas detectable from space and provide important spatial and temporal information on regional albedo and surface type distribution for sea ice and polar land areas. Studies of Antarctic sea ice combining surface-based albedo observations with a determination of the distribution of surface types based on visible estimates from ship traverses in conjunction with total ice fraction provided by the satellite imagery have been reported by Allison et al. (1993) and Brandt et al. (2005). The satellite data do not provide direct albedo values per se and rely at present on the accuracy of the surface-based measurements and parameterizations. Satellite studies provide an immense amount of useful information about the earth's surface, but there are considerable uncertainties still involved in inferring albedos from the imagery. The recently deployed polar orbiting MISR instrument offers the potential to observe the same scene from nine different viewing angles and determine much of the HRDF directly. MISR data were used, for example, to explain how clouds over snow alter the BRDF (Hudson and Warren, 2007).

The spectral dependence of upwelling scattered radiation has been used to infer effective snow grain size by Nolin and Dozier (2000). In conjunction with radiative transfer calculations, this information can be used to reconstruct the albedo over a broad range of illumination conditions avoiding many of the difficulties mentioned above, but the technique relies on the assumption that the snowpack is optically thick and spatially homogeneous over distances of many tens of meters to kilometers depending on the resolution of the satellite in question.

Additional uncertainties

An important potential source of error in albedo measurement under clear skies is the tilt of the surface away from horizontal. Particularly in mountainous regions, surface slope can introduce errors because of the large slope angles. Even small slopes can cause significant error due to the large solar zenith angles. A case study at South Pole station (Grenfell et al., 1994) for a surface slope of 2°



Albedo, Figure 14 Representative albedos for snow-free and ice-free Arctic surfaces early in the melt season 1979: Bare Tundra albedo, Mud, Gravel (Grenfell and Perovich, 1984).

showed deviations above and below the true albedo of up to 10% depending on the solar azimuth. The effect was well matched using a small slope model; however, Dozier and Frew (1990) have presented the following general formulation for any surface slope where the sun remains above the local horizon:

$$\alpha_\lambda(apparent) = \alpha_\lambda(true)\cdot \frac{\cos(\theta_{sun})\cos(\theta_{surf}) + \sin(\theta_{sun})\sin(\theta_{surf})\cdot\cos(\phi_{sun})}{\cos(\theta_{sun})}, \quad (6)$$

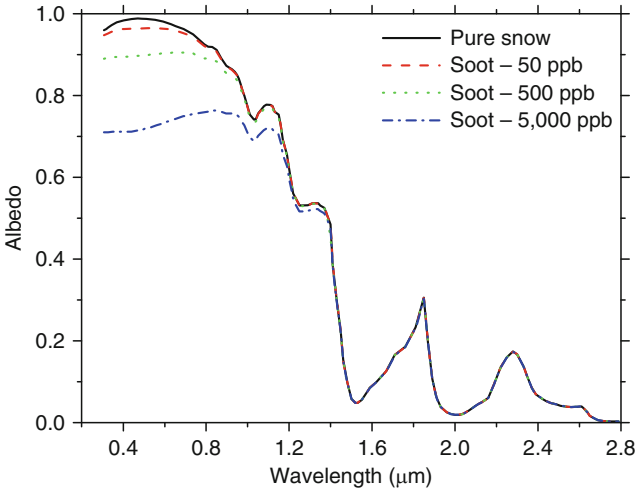
where φ_{sun} is the solar azimuth angle defined as 0° in the downhill direction, and the θ values indicate solar zenith angle (sun) or surface tilt angle (surf). Taking into account the surface tilt is of particular important for glacier ice, where slopes can be large (Klok et al., 2003). Aligning the instrument with its optical axis perpendicular to the local surface rather than vertical is preferred to remove the bias; however, if distant terrain is in the field of view of the upward looking sensor, a shadowing correction should also be taken into account (Grenfell et al., 1994; Grenfell and Perovich, 2008).

A thin snow or ice cover with finite optical thickness over a darker underlying surface such as soil, rock, or ocean water would give a lower combined albedo with the greatest reduction at visible wavelengths. In cases where the snow is optically thin, less than 10 cm or so, the snow cover is frequently patchy exposing the surface below producing a spectral albedo that is flattened out in the visible and mimics the response of a dirty continuous snow cover.

The grain size in a snowpack typically increases with depth due to metamorphism. This can also have a significant effect on the albedo and on the interpretation of its spectral distribution. Because absorption by ice increases into the infrared, there is a corresponding decrease in penetration depth of the radiation. Thus in the infrared near 2,000 nm, for example, α_λ will be influenced by the grains right at the surface while at visible wavelengths the radiation will interact with grains well below the surface whose radius can be much larger. As a result, a multilayer model is needed in general to explain α_λ across the solar spectrum.

Impurities

The presence of soot, dust, sediment, or biological material can modify the albedo of both snow and ice. Soot in particular has been identified as being important for global energy balance (Hansen and Nazarenko, 2004). Warren and Wiscombe (1980) presented demonstrating the effect of varying levels of soot in a thick uniform snowpack. For a particular soot loading, the main effect is that the visible albedo decreases most strongly compared with clean snow while the infrared albedo is less affected. This is because ice absorbs weakly in the visible but very strongly



Albedo, Figure 15 Model results for varying amounts of soot in snow. Snow grain radius 100 μm, snow density 100 kg/m^3, solar zenith angle 60°. (Warren and Wiscombe, 1980). Median background soot levels in the Arctic are presently less than 50 ppb.

in the infrared so that the addition of small amounts of another absorber can have a significant effect in the visible but little effect at longer wavelengths. The effect of soot on α_λ is shown in Figure 15 for soot concentrations up to 5,000 ppb. At three locations on the Antarctic Plateau, background soot levels in the snow have been measured in the range 0.1–1 ppb (Warren and Clarke, 1990; Grenfell et al., 1994). This is sufficiently low that the resulting albedo reduction is not detectable and is not important for climate. In the Arctic, median background soot concentrations in the snow have been reported in the range 1–50 ppb (Clarke and Noone, 1985) for which the resulting decreases in α can be as large as about 0.04 depending on snow grain size (Warren and Wiscombe, 1985). A recent study (Hegg et al., 2009) has shown that most of the soot in the perennial snow cover of the Arctic comes from biomass burning and current median background levels range from 1 to ~30 ppb. Because of the relatively small variations in albedo associated with these levels, soot concentrations are presently below the levels of uncertainty in satellite studies and need to be determined from surface-based observations.

Summary

The physical principles involved in the determination of the albedo of snow and ice covered surfaces as well as the uncertainties in the observational techniques are well understood. Modern instrumentation has significantly improved the accuracy and ease of obtaining surface-based observations, and a wide range of satellite borne sensors now provide the potential to extend monitoring over the full extent of both polar regions. Table 1 presents representative values and uncertainty for the albedos of selected surface types.

Albedo, Table 1 Representative median values of albedo for selected surface types under conditions of diffuse illumination. The uncertainties represent natural variability due to differences in bubble or crystal size distribution or variations in foreign impurities such as dust and soot

Surface	Albedo	Uncertainty
Snow-covered ice on Antarctic Plateau	0.85	0.02
Cold snow-covered arctic sea ice	0.83	0.03
Melting snow-covered arctic sea ice	0.75	0.05
Melting bare multiyear sea ice	0.65	0.02
Cold snow-covered glacier ice	0.8	0.05
Melting glacier ice	0.35	0.1
Melting bare lake ice	0.45	0.1
Melt ponds on arctic sea ice	0.26 to 0.1	0.15
Cold bare lake ice	0.2	0.1
Calm deep water (open water in sea ice and deep lakes)	0.067	0.005
Arctic tundra	0.18	0.04
Dry arctic beach gravel	0.04	0.01

Agreement has been achieved between radiative transfer models and field observations of clean flat snow covers, but natural snowpacks are generally more complex. The approximations of homogeneous flat surfaces or pure snow do not apply in many situations where the surface is rough, tilted, or inhomogeneous complicating our understanding of the albedos of natural surfaces in general. Impurities in snow and ice have been identified in selected areas as being large enough to be important to affect the earth's climate, but large-scale spatial and temporal distributions of these impurities are not yet well quantified. The study of the albedo of snow and ice-covered surfaces thus remains an active area of scientific study.

Definition and introduction: the Alps and alpine climates

Although mountains differ considerably from one region to another, one common feature is the complexity of their topography, which results in some of the sharpest gradients found in continental areas. Related characteristics include rapid and systematic changes in climatic parameters, in particular temperature and precipitation, over very short distances (Beniston, 2003); greatly enhanced direct runoff and erosion; systematic variation of other climatic (e.g., radiation) and environmental factors (e.g., differences in soil types). Mountains in many parts of the world are susceptible to the impacts of a rapidly changing climate, and provide interesting locations for the early detection and study of the signals of climatic change and its impacts on hydrological, ecological, and societal systems. All these features have a bearing on the location, behavior, and evolution of alpine cryospheric systems.

The Alps cover just over 200,000 km^2 and consist of an arc that stretches in a north–south direction from the Mediterranean in France to Switzerland, then curves eastward through Switzerland to finally reach as far as eastern Austria. Alpine climates are governed by four major factors, in increasing order of importance: latitude, continentality, topography, and altitude (Barry, 2008). Altitude is certainly the most distinguishing and fundamental characteristic of mountain climates, because atmospheric density, pressure, and temperature decrease with height in the troposphere. Mountains often serve as elevated heat sources, whereby diurnal temperatures are higher than at similar altitudes in the free atmosphere. Topographic features play a key role in determining local climates, in particular due to the slope, aspect, and exposure of the surface to climatic elements. These factors tend to govern the

redistribution of solar energy as it is intercepted at the surface, as well as precipitation that is highly sensitive to local site characteristics. Precipitation is generally observed to increase with height in the Alps and even modest topographic elements can exert an often disproportionate influence on precipitation amount. These climatic and topographic factors control, to a large extent, the extent and behavior of alpine glaciers that, currently, occupy about 2,900 km^2, and permafrost that is estimated to occupy up to 3–5% of the surface area of the mountain chain (Harris et al., 2001). At the synoptic scale, the Alps are subject to the competing influences of Mediterranean, Atlantic, Continental, and Polar weather regimes.

The importance of the alpine cryosphere for natural and socioeconomic systems

Snow is an essential component of numerous aspects of the alpine environment, and any changes in the amount, duration, and timing of the snowpack can have long-lasting environmental and economic consequences (e.g., Stewart et al., 2004). Snow determines the timing of peak river discharge during the melting of the snowpack in the spring and, in many instances, maintains river flows even during warm and dry summer periods. The timing of snowmelt is also a major determinant for initiating the vegetation cycle of many alpine plant species, and hence its quantification is necessary when assessing the response of vegetation to year-to-year climate variability or long-term climatic change (e.g., Keller and Körner, 2003). Körner (1999) has shown that for many parts of the Alps, the length of the snow season and minimum temperatures are the most important factors for high alpine vegetation because they determine the growth and survival rates of numerous species at high altitudes. Furthermore, in many parts of the French, Italian, Swiss, and Austrian Alps, snow is intimately linked to tourism based on winter sports, on which numerous mountain resorts depend for a substantial part of their income (OECD, 2006).

Changes in the alpine snowpack

A quantification of the amount of snow in the mountains and the changes that occur with shifts in climate is crucial for assessing the amount of water that will ultimately runoff and be routed into the numerous river systems originating in the Alps in the spring and early summer. The Alps in general and Switzerland in particular, have in the past been referred to as "the water tower of Europe" (Mountain Agenda, 1998). Any substantial changes in the mountain snow pack inevitably has a significant impact on the flow of many major river basins, not only because of changes in the amount and timing of runoff, but also because of the potential for enhanced flooding, erosion, and associated natural hazards.

The two principal determinants of snow are temperature and precipitation; as climate changes, subsequently modifying temperature distributions and precipitation patterns, so does snow amount and duration. In mountain regions, an average rise of 1 °C is accompanied by a general rise of about 150 m in the altitude of the snowline (Beniston, 2004). Regional studies of climatic change in Switzerland (e.g., Schär et al., 2004) suggest that alpine temperatures could rise by 3-5 °C by 2100 (for the IPCC SRES A-2 Scenario; Nakicenovic et al., 2000), with possibly increased precipitation in winter but a substantial decrease in summer (e.g., Frei et al., 1998). For the Swiss Alps, a warming of this amplitude would push the snowline upward by at least 500–800 m in winter.

The length of the snow season has tended to decrease at many locations since the early 1970s (Beniston, 2004), although the behavior of the snow cover exhibits high interannual variability. In a climate where winters may experience a rise in average temperatures by 3-5 °C compared to today, and a possible increase in precipitation by 5-20% (e.g., Beniston et al., 2003), there could be more abundant snowfall in the higher reaches of the mountains, but much reduced snow at lower levels where precipitation is more likely to fall in the form of rain. The "crossover" level where snow becomes more abundant under milder conditions is located at around 2,000 m above sea level. The volume of snow, which is a key variable for assessing peak flow from snowmelt in river systems originating in the Alps, may decrease by 50–100% (i.e., an inverse relationship with altitude, roughly 10% reduction per degree of warming at 2,000 m above sea level and 20% reduction per °C at 1,000 m height). The projected increase in precipitation will not be sufficient to compensate for the rise in mean winter temperatures.

Behavior of alpine glaciers

The volume of ice in a mountain glacier, and correspondingly its surface area, thickness, and length, is determined by the balance between inputs (accumulation of snow and ice) and outputs (melting and calving). As climate changes, this balance may be altered, thereby modifying the equilibrium line altitude of the glacier (the altitude at which accumulation and ablation are in approximate balance) and resulting in a change in thickness and the advance or retreat of the glacier (e.g., Zemp et al., 2007). Most of the alpine glaciers with the exception of those at very high altitudes (above 3,500 m above sea level) have surface and internal temperatures very close to the freezing point, so that any small rise in temperatures beyond the 0 °C threshold results in a very sensitive response of the glaciers.

Since 1850, the glaciers of the European Alps have lost about 30–40% of their surface area and about half of their volume (Haeberli and Beniston, 1998), a feature that has been observed in many other mountain glaciers of the world, both in the midlatitudes and in the tropics; this serves to emphasize the global nature of atmospheric temperature increase (Paul et al., 2007). Empirical and

energy-balance models indicate that 30–50% of existing mountain glacier mass could disappear by 2100 according to the rate of warming project by global climate models (Haeberli and Beniston, 1998). The smaller the glacier, the faster it will respond to changes in climate. For most mountain glaciers in the temperate parts of the world, there exists a close linear relationship between the equilibrium line altitude of the glacier and the precipitation and temperature controls on glacier mass. In order to maintain the equilibrium line altitude of a glacier, it is estimated that roughly 300 mm of additional precipitation per degree of warming would be necessary. Projections from regional climate models (e.g., the PRUDENCE Project; Christensen et al., 2002) suggest that warming will be accompanied by an average reduction of annual precipitation, with strong reductions in summer that any local increases in winter will not compensate for. This will result in rapidly waning glaciers until they perhaps find a new equilibrium at much higher elevations, with substantially reduced volume and surface area; some may disappear entirely as the equilibrium line altitude may ultimately end up well above the glacier catchment area (IPCC, 2007).

Shrinking glaciers will lead to changes in the hydrological response of certain regions compared to today; as glaciers melt rapidly, they will provide enhanced runoff, but as the ice mass diminishes, the runoff will wane.

Mountain permafrost

The interpretation of recent changes in the alpine permafrost is much more complex than that of glaciers or the snow pack. This is because the exact extent and depth of permanently frozen soils is not fully known, in part because it can also exist intermittently at altitudes well below those where permafrost would usually be expected to occur. Some limited direct measurements of permafrost have taken place in the Alps through the monitoring of the temperature profile at depth in boreholes. There seems to be a general increase in the temperature at depth over time (e.g., Haeberli, 1990), implying that the signal of climate warming is penetrating deeper into the surface. Modeling studies for a warmer climate suggest that this trend will continue and accelerate into the future (Salzmann et al., 2007), although all of the complexities of heat transfer within the ice-packed soils are not fully understood.

Permafrost degradation has in the past already shown the potential for increasing instability of mountain slopes as a result of the reduced cohesion of mountain soils. With the melting of the present permafrost zones at high elevations, material released by the melting subsurface ice will be available to fuel more frequent and probably more severe rock and mud slides and debris flows. These events in turn will cause problems for high-mountain infrastructure such as buildings and cable-car suspension pylons.

Summary and conclusions

Because the Alps are a key source region for many of Europe's rivers, the impacts of climatic change on hydrology are likely to have significant repercussions not only in the mountains themselves but also in populated lowland regions that depend on rivers like the Rhine, the Rhone, the Po and, indirectly, the Danube for domestic, agricultural, energy, and industrial purposes. Water resources for populated lowland regions are influenced by the alpine climates and cryosphere; meltwater from snow feeds into the hydrological basins and acts as a control on the timing of water runoff in the spring and summer months, supplemented by seasonal thawing of glaciers. Significant shifts in cryosphere regimes in a warming climate will inevitably disrupt the quantity and seasonal distribution of water and its consequent use for a wide range of economic activities.

ALTAI-SAYAN GLACIERS

Vladimir Aizen
College of Science, University of Idaho, Moscow, ID, USA

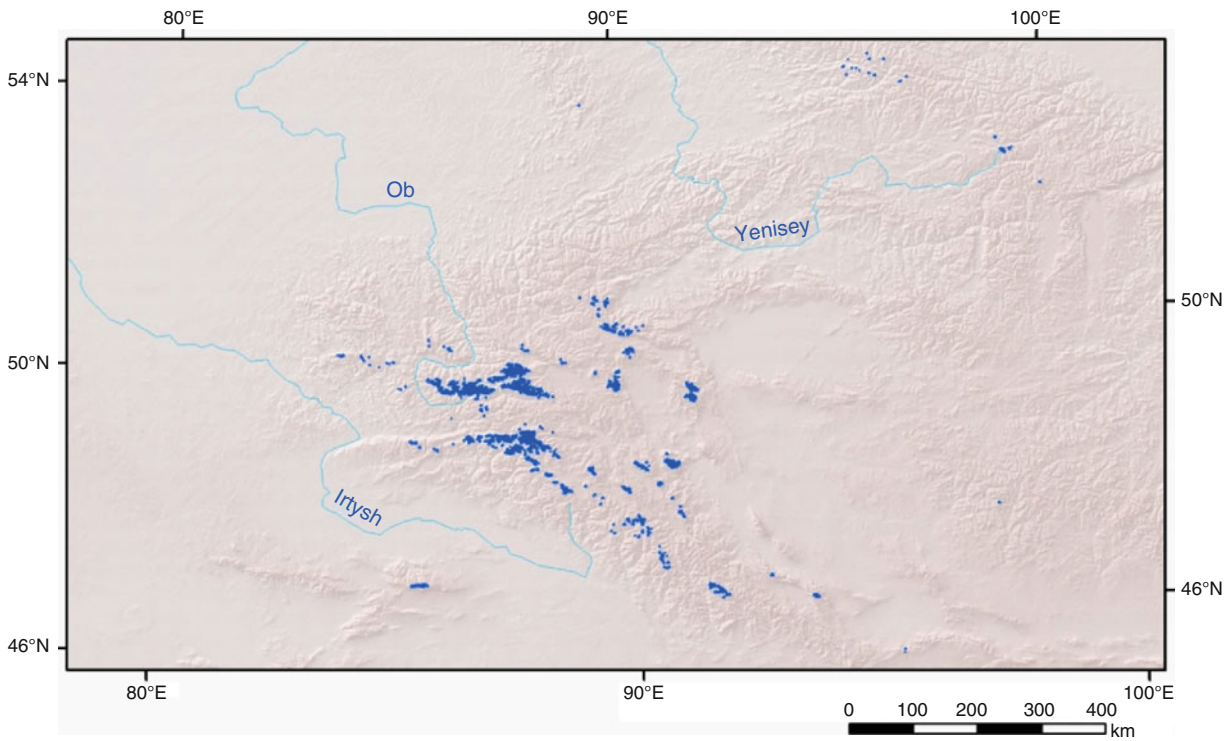
Synonyms

Alpine glaciers; Altai-Sayan; Glaciers of central Asia; Glaciers of mid-latitudes; Glaciers of south Siberia, Russia, Mongolia, China, and Kazakhstan; Glaciers in Ob' and Yenisei river basins

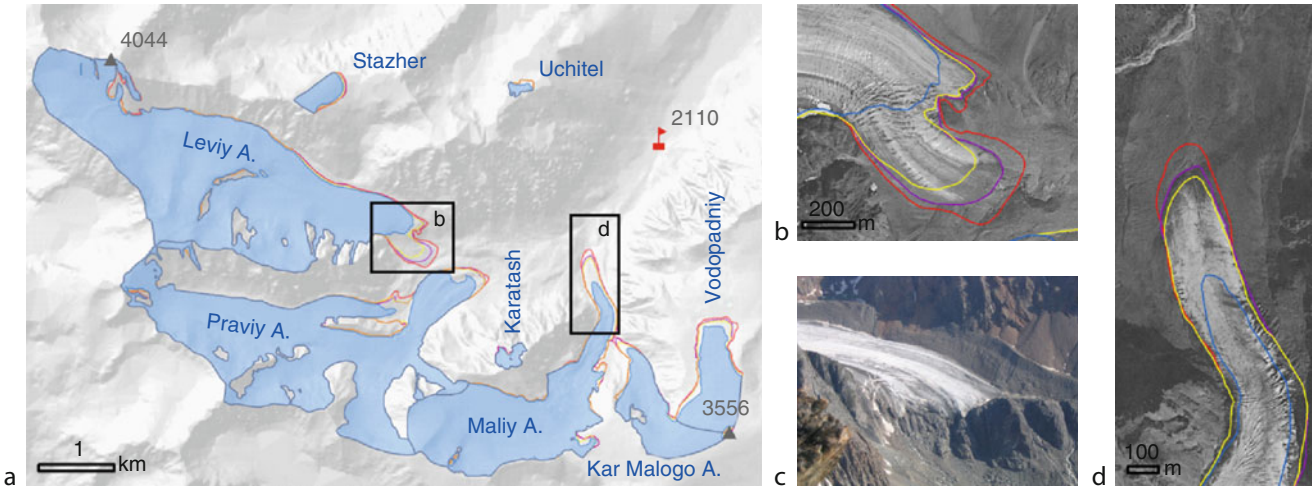
Definition

Altai-Sayan glaciers are the alpine glaciers of the mid-latitudes that are existing in the Altai-Sayan high mountains in south Siberia and north-western Mongolia continental climate.

The Altai-Sayan mountain system stretching between 45°–54°N and 84°–103°E. Glaciers of Altai-Sayan mountains are located in the most northern periphery of the central Asian mountain system and the southern periphery of the Asian Arctic basin (Figures 1 and 2). The highest part of the Altai-Sayan mountains (Katun, South Chuya, and North Chuya ridges) hold 70% of



Altai-Sayan Glaciers, Figure 1 Glaciers of the Altai-Sayan Mountains. The Aktru Glacier basin highlighted by *red* square.



Altai-Sayan Glaciers, Figure 2 (**a**) The Aktru glacier basin in Altai and multitemporal glacier boundaries: 2006 in *blue*, 1975 in *yellow*, 1966 in *violet*, 1952 in *red*. The *red* marker shows location of the Aktru meteorological station. (**b**) The Leviy Aktru glacier terminus position overlaid on the 1966 Corona image. (**c**) A 2006 ground photograph of the Leviy Aktru glacier terminus. (**d**) The Maliy Aktru glacier terminus position overlaid on the 1966 Corona image.

all south Siberian glaciers. The latest investigation in Altai-Sayan mountains based on remote sensing data numbers 2,340 glaciers with total area of 1,562 km^2 (Surazakov et al., 2010). Altai-Sayan glaciers feed the major Siberian Rivers (Ob and Yenisei) in Arctic Basin and the north-western, inner, Mongolia Plateau endorheic basin. Altai-Sayan glaciers distributed between 2,100 and 4,500 m a.s.l. An average glacier equilibrium line elevation (ELA) 2,800 m a.s.l. Average thickness of the Altai-Sayan glaciers is 57 m reaching 328 m in Central Altai (Katun basin glaciers). The total ice volume of Altai-Sayan glacier is 42,565 km^3 estimated by calculation based on passive radar measurements (Nikitin et al., 2010). Taldurinskiy Glacier is the largest Atai-Sayan glacier, which is 7.5 km length and 28.2 km^2 in area (Chagan-Uzun River basin). Between 1950 and 2000, Altai-Sayan glaciers lost 14% area and 10% ice volume on average. The accelerated glacier recession in Altai-Sayan Mountains is mainly the result of increased summer air temperatures by 1.03°C in the last 50 years, which intensify glacier's melt.

Definition

A local wind which blows up a slope heated by sunshine.

Anabatic winds: in relation with snow/glacier basin

An anabatic wind flows upslope of a mountain from lower valleys during daytime (Figure 1). It occurs due to radiational warming of the lower slopes by convection, which allows the warm and less dense air to rise and cold denser air to sink. This type of wind is most common in summer season when slopes are snow free and drier, which allow vertical sun rays to heat the ground faster. In winter, lower slopes are mostly snow covered and do not allow sun radiation to be absorbed and generate convective heating due to high albedo. There appears to have a significant relation between the type of a wind and how it affects snow melting, but theories in this respect have yet to be completely developed. Also, melting is mostly radiation driven, and therefore researchers have mostly focused on developing

Anabatic Winds: In Relation with Snow/Glacier Basin, Figure 1 Anabatic winds flowing upslope during daytime. Chhota Shigri Glacier in the Western Himalaya can be seen on the background. Photo by Umesh Haritashya June 20, 2006.

relations between melting and other meteorological parameters, including wind velocity. In general, anabatic winds are considered to be responsible for producing lower melt rates than the katabatic (downslope) winds (Hannah and McGregor, 1997), and they are also less stronger than katabatic winds. For details see the article entitled *Atmosphere-Snow/Ice Interactions*, and *Katabatic Wind: In Relation with Snow and Glaciers*.

ANCHOR ICE

D. P. Dobhal
Wadia Institute of Himalayan Geology,
Dehradun, Uttarakhand, India

Definition

Anchor ice is formed on ground stones and other objects at the bottom of running water and thus remains attached or anchored to the ground. Ice crystals are formed and may coalesce or adhere to submerged objects like stones, marine organisms, rocks, man-made structures, etc. Anchor ice is most commonly observed in fast-flowing rivers during periods of extreme cold, in the shallow sub or inter-tidal during or after storms when the air temperature is below the freezing point of the water, and in the sub tidal in the Antarctic along ice shelves or near floating glacier tongues. The flow of the rivers having anchor ice is disturbed because it works as a barrier to the flowing water.

Andean glaciers: All glaciers located in the Andes of South America.

Introduction

In all Andean countries of South America, the highest peaks are covered by glaciers. These can be subdivided into tropical glaciers, located in Venezuela, Colombia, Ecuador, Peru, Bolivia and northernmost Chile, and extratropical glaciers, located in central and southern Chile and Argentina. The latter also include the northern and southern Patagonian ice fields (*Patagonia*, qv). While most Andean glaciers outside of Patagonia are

fairly small and contain a limited amount of ice, they are nonetheless very unique and important. The tropical Andes, for example, are home to more than 99% of all tropical glaciers (Kaser, 1999) and they provide very important environmental services, such as freshwater during the dry season to downstream populations. Andean glaciers are also unique with regard to their mass and energy balance and their sensitivity to climate change (*Climate Variability and High Altitude Temperature and Precipitation*, qv), which is very different from glaciers at mid- and high latitudes.

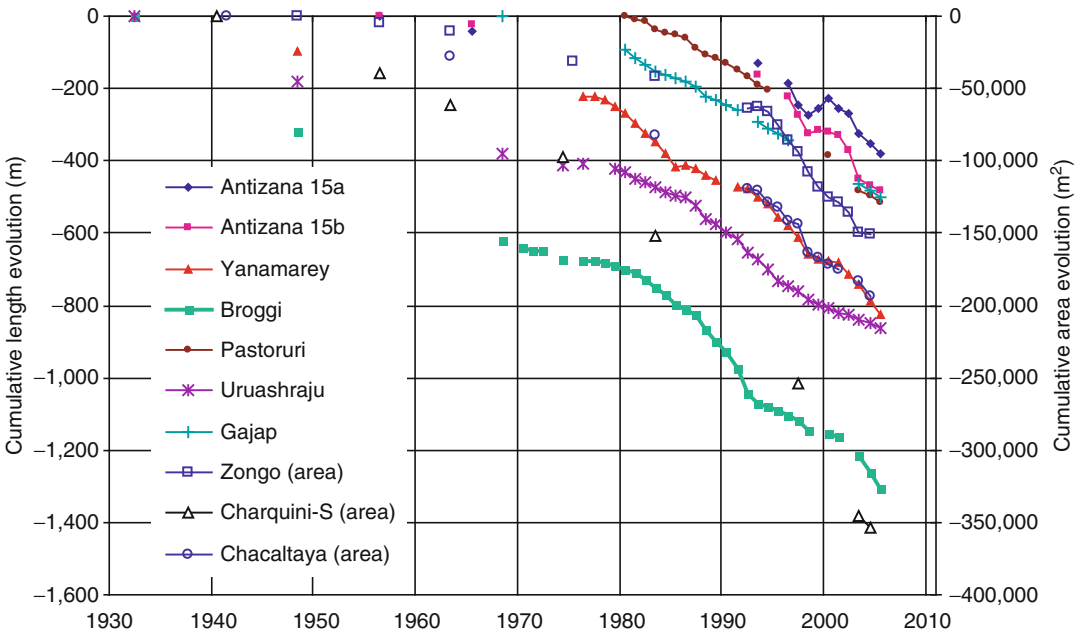
Tropical Andean glaciers

Glacier evolution over the past centuries and current extent

The northernmost tropical glaciers are located in Venezuela, but the country has lost more than 95% of its glacier-covered area since the mid-nineteenth century and the few remaining glaciers total less than 2 km^2 (Vuille et al., 2008a). In Colombia, six different mountain ranges still have some glacier coverage, but glaciers are rapidly retreating there as well. In Ecuador, glaciers are mostly located on volcanoes along the country's two mountain chains, the Cordillera Occidental and the Cordillera Oriental. These glaciers reached a maximum extent during the Little Ice Age (LIA) and have retreated since, interrupted by short periods of advance. Peru contains the largest fraction of all tropical glaciers (~70%) and is home to the world's most extensively glacier-covered tropical mountain range, the Cordillera Blanca. As in all other Andean countries, glaciers reached their maximum extent during the Little Ice Age and have retreated since. In the Cordillera Blanca, for example, the ice coverage decreased from ~850 to 900 km^2 during the LIA to 620 km^2 in 1990. The ice coverage at the end of the twentieth century was slightly less than 600 km^2. Glaciers in Bolivia can be found in two main mountain ranges, the Cordillera Occidental along the western border with Chile and the Cordilleras Apolobamba, Real, Tres Cruces, and Nevado Santa Vera Cruz in the east. The maximum glacier extent in Bolivia was reached during the second half of the seventeenth century (Rabatel et al., 2006). Afterwards glaciers started to retreat, with recession accelerating after 1940 and especially since the 1980s. In many locations of the Cordillera Real glaciers have lost between 60% and 80% of their LIA size and much of the surface and volume loss occurred over the past 30 years (Rabatel et al., 2006). In some instances such as on Chacaltaya, glaciers have disappeared altogether within the past 10 years (Francou et al., 2003). Chile also has a few glaciers along the border with Bolivia that can be considered tropical in the broadest sense (Vuille et al., 2008a). Figure 1 summarizes the retreat of glacier tongues and the reduction of surface area of ten glaciers in the Andes of Peru and Bolivia (from Vuille et al., 2008a).

Tropical Andean glacier mass and energy balance

In tropical locations, temperature stays more or less the same throughout the year but the *Hydrologic Cycle and Snow* (qv) shows a pronounced separation into wet and



Andean Glaciers, Figure 1 Change in length and surface area of ten tropical Andean glaciers from Ecuador (Antizana 15a and 15b), Peru (Yanamarey, Broggi, Pastoruri, Uruashraju, Gajap), and Bolivia (Zongo, Charquini, Chacaltaya) between 1930 and 2005. (Reproduced from Vuille et al., 2008a. With permission from Elsevier.)

dry seasons. Therefore, the mass and *Surface Energy Balance* (qv) of tropical glaciers is fundamentally different from mid- and high-latitude glaciers (Kaser, 2001). While at mid- and high latitudes winter represents the accumulation and summer the ablation season, ablation and accumulation occur at the same time on tropical glaciers. Also, because temperature does not change much throughout the year, ablation occurs predominantly in the ablation zone below the Equilibrium Line Altitude (ELA), and accumulation is restricted to regions above the snow-rain line that remains at a more or less constant altitude throughout the year (Vuille et al., 2008a). Actual mass and energy balance studies on Andean glaciers are fairly limited because they have to be restricted to glaciers that are easily accessible and safe to work. The longest continuous mass balance measurements with stake networks are located on Zongo and Chacaltaya glaciers in Bolivia (Francou et al., 2003). These studies reveal that the largest mass loss and gain occurs during the wet seasons, while mass balance is almost always near equilibrium during the dry and cold months. On interannual timescales, the El Niño-Southern Oscillation phenomenon (ENSO) appears to play a prominent role, dictating mass balance variability, with El Niño years featuring a strongly negative mass balance and La Niña events producing a nearly balanced or even slightly positive mass balance on glaciers in Bolivia (Wagnon et al., 2001; Francou et al., 2003), Peru (Vuille et al., 2008b), and Ecuador (Francou et al., 2004). These results can be explained by the dominant influence of ENSO on climate in the tropical Andes with La Niña years tending to be cold and wet, while warm and dry conditions usually prevail during El Niño years. Energy balance studies on several tropical Andean glaciers indicate a strong sensitivity to changes in atmospheric humidity, which governs sublimation, but also to the timing, amount and phase of *Precipitation* (qv), as this determines the glacier reflectance or albedo, and hence the amount of absorbed shortwave radiation. Net radiation receipts at the glacier surface are further affected by cloudiness, which controls the incoming long-wave radiation. Hence, the sensitive heat flux does not appear to play an equally important role as on mid- and high-latitude glaciers (Wagnon et al., 2001).

Tropical Andean glaciers, climate change, and water resources

The observed glacier retreat in the tropical Andes may soon lead to water shortages in many parts of the tropical Andes, especially in Bolivia and Peru (Vuille et al., 2008a). Studies show that temperature has increased significantly throughout the region (Vuille et al., 2003) and projections of future climate change indicate a significant rise in freezing levels (*Global Warming and its Effect on Snow/Ice/Glaciers*, qv) and hence the Equilibrium Line Altitude over the course of the twenty-first century (Bradley et al., 2006; Urrutia and Vuille, 2009).

This situation is of grave concern as Andean glacier *Discharge/Streamflow* (qv) provides water for human consumption, agriculture, hydropower production, etc., and is also crucial to maintain the integrity of threatened Andean ecosystems. On the Pacific side of Peru, most of the water resources originate from snow and ice in the Andes. Many large cities in the Andes are located above 2,500 m and thus depend almost entirely on high altitude water stocks to complement rainfall during the dry season. In addition, as glaciers retreat and lose mass, they add to a temporary increase in runoff (*Runoff Observations*, qv) to which downstream users quickly adapt, even though this increase is temporary and not sustainable once the glaciers become too small to sustain dry season runoff. Indeed it is estimated that in rivers draining the western side of the Cordillera Blanca 10–20% of the water is from nonrenewed glacier melt and that during the dry season this value jumps up to ∼40% (Mark and Seltzer, 2003). Simulations with a tropical glacier-climate model suggest that glaciers will continue to retreat in the twenty-first century and in some cases (depending on location and climate change scenario considered) completely disappear (Juen et al., 2007). As a result dry season runoff will be significantly reduced, while wet season runoff may actually be higher due to the larger glacier-free areas and the enhanced direct runoff (Juen et al., 2007; Vuille et al., 2008a). Hence, while the overall discharge may not change very much, water availability during the dry season, when it is the most needed, will be significantly reduced.

Extratropical Andean glaciers

South of ∼18°S glaciers are absent along the Andean cordillera due to the extreme aridity, with the snow line reaching above 6,000 m, before they reappear as small ice caps in the central Andes of Chile and Argentina south of the "South American Arid Diagonal" at ∼29°S. Due to the enhanced winter *Precipitation* (qv) and high topography (including the highest elevation in the Southern Hemisphere, Aconcagua at 6,954 m), glaciers to the south of 31°S rapidly increase in size and form true valley glaciers. The total area covered by glaciers south of the arid diagonal but north of 35°S was estimated to be about 2,200 km^2 in 1998 (Lliboutry, 1998). Between ∼35°S and the northernmost limit of the Patagonian ice fields (*Patagonia,* qv) at ∼46°S more than 35 isolated volcanoes, many of them active, have elevations high enough to support glacier ice (Lliboutry, 1998). Glaciers in this region are famous for their penitents, east-west oriented formations of ice in the shape of blades, tilting toward the sun, and created by intense solar radiation and differential ice sublimation rates.

Snow and ice from this part of the Andes helps sustains some of the richest agriculture and large population centers on both sides of the Andes. Despite their importance for regional water supply, little is known about glacier

mass balance in this region. Consistent with the meridional gradient in precipitation both accumulation and ablation values increase southward, with the net balance in the accumulation zone reaching values as low as 30 cm water equivalent (w. eq.) at Cerro Tapado (29°S) to a record value of 1,540 cm w. eq. at glacier Tyndall in Patagonia (Casassa et al., 2006). Mass balance also shows a clear east-west gradient, in particular south of 33°S, due the prevailing westerly circulation, which leads to higher accumulation on the western, windward side of the Andes. On interannual timescales, mass balance is closely related to ENSO events, with dry La Niña years and wet El Niño years (Casassa et al., 2006).

Glacier monitoring on the Chilean side of the central Andes between 32°S and 41°S has revealed a significant tongue retreat, area shrinkage and ice thinning (*Thinning of Glaciers*, qv) over the past decades, with the trend accelerating over the most recent period (Rivera et al., 2006). A glacier inventory (*Inventory of Glaciers*, qv) of nearly 1,600 glaciers with a total ice area of ca. 1,300 km^2 shows a total volume loss due to thinning (*Thinning of Glaciers*, qv) and retreat of 46 $\pm$ 17 km^3 of water equivalent between 1945 and 1996 (Rivera et al., 2006), most likely attributable to a combination of atmospheric warming (*Global Warming and its Effect on Snow/Ice/Glaciers*, qv) and a significant reduction in *Precipitation* (qv) (Bown and Rivera, 2007).

Summary

Glaciers exist in all Andean countries and can be subdivided into tropical glaciers, located in Venezuela, Colombia, Ecuador, Peru, Bolivia, and northernmost Chile and extratropical glaciers, located in central and southern Chile and Argentina. They are mostly fairly small in size and contain a limited amount of ice, but provide important environmental services, such as freshwater during the dry season to downstream populations. Glaciers in the tropical Andes are also unique in terms of their mass and energy balance (*Surface Energy Balance*, qv), which is fundamentally different from mid- and high-latitude glaciers, as accumulation and ablation seasons are not separated into distinct seasons, but occur at the same time. Andean glaciers have been in retreat over the past few decades and many are projected to completely disappear in the twenty-first century.

ANISOTROPIC ICE FLOW

Olivier Gagliardini
Laboratoire de Glaciologie et Géophysique de l'Environnement, CNRS/UJF, Grenoble, France

Definition

Anisotropy. A material is anisotropic if it has a response that differs according to the direction of the loading.
Ice anisotropy. In this article, we focus on the viscous part of the ice deformation. Elastic response of ice is also anisotropic but much less pronounced than its viscous part.

Introduction

The size of an ice crystal varies from few millimeters to few tens of centimeters, whereas the typical size of a glacier or an ice sheet is few kilometers to thousands of kilometers. The strong viscous anisotropy of the ice crystal and the way the crystals are orientated influence the flow of glaciers and ice sheets. This article explains how these very different scales are related and coupled, leading to special features that can only be explained by an anisotropic behavior.

Anisotropy of the ice crystal

Terrestrial ice presents a hexagonal symmetry that induces a strong viscous anisotropic behavior. The principal mechanism responsible for the crystal deformation is the displacement of screw dislocations within the basal planes, perpendicular to the symmetry axis, also called optical-axis or *c*-axis. The ice crystal behaves like a deck of cards: non-basal deformation under a given prescribed strain rate requires stresses 50–60 times larger than for an easy glide-oriented crystal. Owing to this strong anisotropy, a crystal within a polycrystal tends to deform mainly by basal glide and its deformation differs from that of the polycrystal. Satisfaction of the continuity conditions involves a reorientation of the crystal by lattice rotation. This process is responsible for the development of strain-induced fabrics.

Deformation mechanisms

Although strain rates and deviatoric stresses are very low, it is now commonly accepted that deformation processes along polar ice cores are dominated by the viscoplastic mechanism of dislocation, which glide mainly along the basal plane. Diffusional creep, commonly associated with such conditions in many materials, yields a viscosity much higher than that deduced from field data (Lliboutry and Duval, 1985). Deformation by basal glide of dislocations is associated with efficient processes of accommodation such as normal grain growth and dynamic recrystallization.

Strain-induced fabrics and polycrystal anisotropy

An ice polycrystal is composed by hundreds to thousands of crystals, and its viscous behavior depends on its fabric, which describes how all the crystals are oriented. Near an ice-sheet surface, all the grain orientations are, more or less, randomly distributed and the polycrystal response is close to isotropy. At the other extreme, when all the crystals have the same orientation, as observed for height deeps at some places in Antarctica or Greenland, such textured polycrystals are about ten times easier to shear perpendicular to the main orientation than the corresponding isotropic sample. In between these two extremes, the polycrystal anisotropy is entirely determined by its fabric.

On an other hand, the actual fabric can give indications on the strain history undergone by the polycrystal, as far as other recrystallization processes is concerned – grain rotation are not active.

One-maximum fabric or single maximum fabric is characteristic of a uniaxial compression in the direction of the main orientation, whereas a girdle type fabric indicates a uniaxial tension perpendicular to the plane containing the crystal orientations.

Effects of recrystallization processes on fabric

There are three main dynamic recrystallization regimes for polar ice:

1. Normal grain growth that has no direct effect on fabric, except modifying the size of the grains.
2. Rotation or continuous recrystallization (also called polygonization) which, for a vertical compression, is expected to counteract the normal growth of grain and slow down the fabric development.
3. Migration or discontinuous recrystallization that produces grains orientated favorably to the state of stress and has the effect to produce four-maxima fabrics inducing a more or less isotropic behavior.

How anisotropy influences ice flow

The most known effect of anisotropy in ice sheets is the enhancement of the flow induced by the development of one-maximum fabrics vertically oriented. This anisotropy effect induces surface velocities five to ten times larger than the ones expected with an isotropic rheology.

The coupling between the fabric evolution and the anisotropy can conduct heterogeneous deformation of adjacent layers. If two adjacent layers have different initial viscosity, which could be explained by a difference in grain size or in impurities content, then we have a positive feedback: strengthened fabric is easier to shear that again leads to a more strengthened fabric (Paterson, 1991). Such positive feedback can explain a sharp strengthening of fabric in relation to a climatic transition as observed in some ice cores (Paterson, 1991; Durand et al., 2006).

Due to the non-colinearity between deviatoric stress and strain-rate tensors and the presence of rheological inhomogeneities, anisotropy can induce the folding of layers (Thorsteinsson and Waddington, 2002).

Summary

The ice single crystal is one of the most anisotropic natural materials. At the scale of the polycrystal, the viscous behavior is also anisotropic, and it depends on the fabric that evolves from place to place and with depth. Fabric acts, therefore, in controlling the ice flow, but also as a marker of the cumulated deformation. For a single maximum fabric, like those observed below a dome, the flow can be enhanced by a factor up to 10 in comparison to the isotropic case. Moreover, the coupling between fabric evolution and anisotropic behavior can result in the development of heterogeneous flow and layer folding.

For more details, the reader can refer to the two review papers from Placidi et al. (2006) and Gagliardini et al. (2009).

Definition

Antarctica is the southernmost continent on the globe, the fifth largest of the seven continents on the earth. The name originated from "Anti-Arctic," which was used to denote an imaginary landmass, postulated on the opposite pole of the globe with respect to the Arctic (Bernadette Hince, 2000). Much later, in the 1820s, it was first sighted from ship (U.S. Congress, 1989).

Introduction

Today, Antarctica is defined as the entire area of land–ice–water south of the Antarctic Circle (i.e., South of 66° 33 min), where there is at least 1 day of 24-h sun during the polar summer. However, for purposes of the Antarctic Treaty System (ATS), "all areas south of 60° South Latitude" are included in this demarcation (Bastmeijer, 2003).

The Antarctic continent has an area of ~14 million km^2. It is surrounded on all sides by the Southern Ocean. In every winter, the seawater surrounding the continent freezes from ~600 to ~1,000 km from the coast. During peak winter, the area of the surrounding sea ice touches nearly 150% of the size of the continent. As this sea ice remains attached to the main landmass, it nearly doubles the area of the continent. With the arrival of summer season, this sea ice breaks up into floating packs and the area of the continent is reduced back to its original. Since this process of expansion and contraction is repeated every year, Antarctica has also been called "the pulsating continent" (Sharma, 1986).

The floating packs of sea ice during the summer season make navigation difficult in Antarctic waters. This barrier of sea ice sheltered Antarctica from the wooden ships of the past which could not advance much into it. That is the main reason why Antarctica remained undiscovered until the 1800s. Even in the age of modern icebreaker ships, the exploration of Antarctica is still difficult and expensive and Antarctic continues to be the least known part of the globe.

For the past few millions of years, snowfall has accumulated in the interior of the continent, where, due to the extreme cold, there is no melting. The successive deposition of these snow layers has given birth to a thick ice sheet over the continent. On an average, this ice sheet is ~2,500 m thick, while at places its maximum thickness touches ~4,700 m (Kotlyakov, 1966).

In the inner reaches of the continent, the ice makes a high plateau. This has resulted in giving a "flat-bottomed-inverted-bowl-shape" to the continent; where the margins of the landmass are either at or ~50–100 m above the mean sea level (MSL), while the interior of the continent is ~3,000–3,300 m above the MSL. This gives Antarctica the highest average elevation among continents (Stonehouse, 2002).

The total ice volume of Antarctica is ~29 million km^3, which is 90% of all the ice on the globe. It is equivalent of about 65% of all the freshwater on earth. If it melts completely, it could raise the worldwide sea levels by ~60–70 m. Even the annual snow deposition on Antarctica has the capacity to change the global sea levels

by ~5–6 mm if it were to all melt into the ocean (Herzfeld, 2004).

The flow pattern of this huge ice mass is basically domal, starting from the center of the ice sheet on the polar plateau toward the peripheral coasts.

Antarctica is usually divided into East Antarctica and West Antarctica, loosely separated by the Transantarctic Mountain chain. The entire basement is hidden below a thick ice sheet but geophysical soundings have revealed that the East Antarctic Ice Sheet generally rests on bedrock (the Antarctic Shield) above the MSL, while the West Antarctic Ice Sheet rests on bedrock where topographic highs are separated by deep basins below the MSL. If the ice sheet were to melt, western Antarctica would no longer be a single landmass but would become a large group of islands (Michael, 1998; Garrett and Michael, 2002).

The location of the continent at the southern pole of the globe and the presence of a huge ice sheet make Antarctica the coldest place on earth. The usual temperatures in the coastal areas range from +5°C (during summer) to −35°C (during winter). On the Antarctic plateau, the general summer temperatures are about −25°C, while the winter temperatures are around −70°C. The lowest natural temperature ever recorded on earth was recorded at a Russian polar plateau station, "Vostok," in 1983, which was −89.2°C (Greg, 2005).

The large temperature gradient between the interior of the continent and the surrounding sea gives rise to giant low pressure circulatory systems. These systems touch a diameter ranging from 500 to 2,500 km. The rotation of the earth affects the direction of movement of these systems, which always rotate in a clockwise direction around Antarctica. The systems follow each other in rapid succession, making Antarctica the windiest continent, with wind speeds exceeding 300 km/h. Powder-snowdrifts because of these powerful winds, making blizzards common in Antarctica (Riffenburgh, 2007).

Another common meteorological phenomenon is the flow of heavy cold air from the polar plateau toward to the coast, particularly following sunset in the spring and fall. This type of wind is called a "gravity wind" or "katabatic wind," which often reaches speeds of ~60 km/h (McGonigal and Woodworth, 2005).

These peculiarities combine to make Antarctica the highest, coldest, windiest, least vegetated, most isolated, and least explored continent of our globe. It is also the only place on earth which has no native population (Riffenburgh, 2007).

Antarctic ice sheet

The Antarctic Ice Sheet is the largest accumulation of ice on this planet. The ice sheet is flat and wide; but due to the basement/bed topography, it acquires a dome shape. The ice in the sheet flows at a low velocity, generally toward the ice margins.

About 98% of Antarctica is covered by ice and only ~2% of its landmass is exposed on the surface. The outcrops of land protrude through the ice cover like islands inside a sea. When these rocky projections are small and are surrounded by ice, they are called "nunataks" (Figure 5).

Topographic and dating evidence reveal that the area of the Antarctic ice sheet was significantly larger during the Last Glacial Maxima (LGM), that is, about 18,000 years before present (BP); but it has retreated to its present geographic extent since the Last Interglacial Transition, that is, about 8,000 years BP (Riffenburgh, 2007).

The interior of Antarctica has a snowfall of about 5–6 cm of rainfall-equivalent, while the peripheral areas receive about 15–20 cm of rainfall-equivalent snow. When fresh snow falls over the ice sheet, its surface density is ~0.3 gm/cm^3. Old snow metamorphoses and recrystallizes during burial into a denser material termed "firn," with a density of ~0.4 gm/cm^3. The air spaces within the firn are still connected to each other. With further densification of snow, when the air spaces are separated into air bubbles, the firn is said to be converted into "ice," which has a density of ~0.8–0.9 gm/cm^3. With deeper burial, these icy layers are further compacted and ultimately reach a density of ~0.9–0.92 gm/cm^3. This old dense ice may be exposed in zones of ablation, where the top cover is removed, to reveal areas of "blue ice" (Riffenburgh, 2007; McGonigal, 2009).

In the areas of accumulation of snow, various Aeolian snow-forms are carved out by strong winds. The smallest of these are snow-ripples, very similar to the ripples in the sands of the deserts. On a larger scale, a series of undulations (~1–2 m high) is quite common on the polar plateau, these are called "sastrugis." The largest of these structures are dunelike formations made by the winds, these are called "snow barchans" (Kotlyakov, 1966; Riffenburgh, 2007).

The mass balance, an account of the sums of additions and removals of ice mass, of the ice sheet in Antarctica depends on many variables, such as the annual accumulation of snow, drifting of deposited snow, surface evaporation, melting, calving of icebergs, etc. The mass balance in western Antarctica is generally negative, while some parts of eastern Antarctica show a positive mass balance. However, as a whole, there is a general overall tilt toward negative mass balance (Riffenburgh, 2007).

The Antarctic Ice Sheet influences many natural processes of the globe, and there are two important modes of influence on the global climate. The first is through the interactions between the ocean and the continental ice (along with sea ice), while the second is due to the exchanges between the atmosphere and the continental ice along with sea ice (and Ray, 1998; Riffenburgh, 2007).

It is inferred from geological evidence that Antarctica had become an isolated continent ~23 million years BP and tectonically it gradually drifted to its southern location. This location started cooling the continent. About 12 million years BP, ice started covering the entire continent and reflected most of the solar radiation back into the atmosphere. This process accelerated the cooling and

the ice cap thickened. For the past 1 million years, the ice cap has acquired its present thickness (Riffenburgh, 2007; McGonigal, 2009).

Antarctic glaciers

A glacier is a body of ice that moves in a direction dictated by gravity. As the ice sheet moves over the mountains and valleys, it gets divided into a number of glaciers and ice streams, which have variable rates of flow, starting from a meter per annum to a few kilometers per annum (Tulacyyk, 2006; Riffenburgh, 2007). The largest Antarctic glacier is Lambert Glacier in the Prince Charles Mountains of East Antarctica, which is ~400 km long and ~40 km wide; it moves at ~230 m/h near its entry to the mountains (Riffenburgh, 2007) (Figure 4).

The fastest moving Antarctic glacier is Shirase Glacier in eastern Dronning Maud Land, which moves ~2.3 km/year at the grounding line, while accelerating to ~3.11–3.5 km/year at the terminus of the floating ice tongue (Nakamura et al., 2007).

Two distinct types of glacier ice are distinguished in Antarctica: the first is "temperate ice" which is at a pressure melting point at the bottom of the ice sheet and the second is "cold ice" in the layers above it. During movement, the inland ice sheet moves basically by stratified flow of its internal layers, in which the upper layers move faster. In the mountain glaciers, in addition to this stratified flow, another possibility is of moving by glacier sliding over the rocky bedrock.

An "ice stream" is part of an inland ice sheet in which the ice moves much more rapidly than the surrounding ice. Most ice streams drain rapidly into the Antarctic Ocean. The terminal part of an ice stream becomes afloat into the ocean and forms a floating tongue or ice shelf. The largest ice stream–ice shelf system is the Lambert Glacier/Amery Ice Shelf system, located in East Antarctica.

Glaciers and ice streams carry rock debris and deposit the debris either along the way or at the terminus; these deposits are called "moraines." The debris formed below the glacier are termed "ground moraine," debris along the sides of the glacier are called "lateral moraines," debris moving along the central line of the glacier at the surface are "medial moraines," and debris deposited at the end of the glacier are named "terminal moraines" (Clifford and King, 1975). When a glacier recedes, it leaves imprints behind in the form of debris, which can provide evidence of the extent of past glaciation. These moraines can also be dated by Thermoluminscence Dating (TL) method, which provides quantified data about the glacial history of that area (Philip and Leonard, 2004).

Antarctic ice shelf

An "ice shelf" or a "glacier tongue" is glacier ice, which while moving seaward floats on seawater but still remains connected to the mainland (Figure 2). An ice shelf becomes progressively thinner toward the sea. Ultimately, it breaks under the effects of tidal swells and glacial push to give rise to icebergs.

While floating, ice shelves keep growing in thickness both from snow deposition on the surface, as well as from bottom freezing of seawater. During the polar summer, the ice shelves waste mostly by calving into icebergs. A smaller amount is also lost by surface melting, streaming, evaporation, and ablation (William and Christiansen, 2004).

The grounding line of a glacier is defined as the line of transition of grounded ice (ice moving over rocks) to floating ice (ice over sea waters) of a glacier that extends from land to ocean. Often the glaciers have a "grounding zone," rather than a clear-cut grounding line. The ice shelves are very thick at the grounding line, at times exceeding 1,000 m, but when they reach the seacoast, the thickness is reduced to ~100–150 m. Depending on the original thickness and the local conditions, the thickness of the ice shelf projecting above the sea level ranges between ~2 and 50 m (Herzfeld, 2004).

There are two huge ice shelves in Antarctica, namely the Ross Ice Shelf and Filchner Ice Shelf. The Ross Ice Shelf in the Ross Sea exceeds ~550,000 km^2 in area, while the Filchner Ice Shelf in Weddell Sea is ~420,000 km^2.

An "ice rise" is an ice-covered island. It is dome shaped but the bedrock may or may not rise above the sea level. It represents a localized grounding of the ice shelf.

An "ice-doline" or "ice-crater" is a large oval-shaped depression in an ice shelf, where ice has caved in. Depressions or undulations on the surface of normally flat ice shelves are due to uneven flow of ice. These depressions are more common within the last 30–50 km from the coast and their amplitude ranges from 5 to 10 m in height and 1–5 km in length. Near the grounding of ice shelves over the seabed or over submerged islands, the grounded ice generates a damming resistance, resulting in pressure waves within the spreading ice. The result is the formation of depressions on the landward side of the grounded area. When the surface ice melts during the polar summer, some of the near-coast depressions become filled with freshwater that is potable (Herzfeld, 2004).

Any differential movement of outlet glaciers or ice streams over the glacier bed, for example, where the bed topography is uneven, generates cracks within the ice. These cracks are termed "crevasses." Some of the deep crevasses can extend right down to the basement, that is, to a depth of ~2,000 m or more in the Antarctic ice. Also, when the ice shelves rise and fall under the effects of swells and tides, crevasses are generated. Crevasses on the ice shelf can also form near ice rises or obstructions. Most of the Antarctic crevasses get camouflaged by snowfall and snowdrift and can be detected only by aerial reconnaissance of the glacier area.

Ice shelves continually break into the sea, so forming icebergs. The ice shelf may act as a barrier to glacier flow, and ice shelf disintegration may result in glacier surging, which in turn may lead to elevated discharge of land-based

ice into the sea. Discharge of land-based ice above MSL is a net contribution to rising sea levels (Riffenburgh, 2007).

Antarctic icebergs

An iceberg is a large floating piece of ice that has broken off from the ice shelf (Figure 9). The breaking process generating an iceberg from the ice shelf is termed "calving." Freshly calved icebergs are often tabular and flat. Some of the larger iceberg such as the one calved out from Filchner Ice Shelf in 1986 had an area of about 210×92 km.

Basal melting and selective side erosion by sea wave action makes an iceberg unstable, causing it to tilt or even rotate in the water. This gives birth to oddly shaped icebergs, which can be domal, pinnacled, pyramidal or blocky, etc. Sometimes tunnel through icebergs is also observed.

The floating upper side of the ice, projecting over the waters, is termed the "hummock"; while the downward projection of the ice, which is hidden below the seawater, is termed the "bummock." These bummocks are dangerous for ships navigating in Antarctic waters.

Icebergs may disintegrate into smaller pieces, around the size of small houses, called "bergy bits," which typically have a height of less than 5 m and an area of about 300 m^2.

Further breaking up leads to the formation of "growlers." Growlers typically have a height of less than 1 m above the water and an area of $\sim$20 m^2. Being so small, the growlers are difficult to detect on the radars; yet these can still have a mass of more than 100 tons. Growlers pose the gravest risks for ships navigating in Antarctic Ocean, even for the modern well-equipped ships (Riffenburgh, 2007).

Lastly, the growlers may disintegrate into "brash ice," which is made up of wrecked fragments of other ice, with each fragment less than 2 m in size.

Sometimes, the broken fragments of ice get frozen together again due to a sudden drop in air temperature, giving the appearance of small rafts which are welded together; this is termed "ice breccia."

Icebergs are used as proxies for global warming. With increasing temperatures, more ice shelves are likely to disintegrate, leading to birth of a larger number of icebergs (Walton and Doake, 1987).

Antarctic sea ice

Seawater, being highly saline, does not freeze at 0°C, but at a temperature of $\sim$1.9°C. The first freezing of seawater produces tiny crystals of ice in suspension, termed "frazil ice" (Figure 1).

Later, these tiny ice crystals coagulate to form an oily or soupy surface on the seawater, which is called "grease ice."

With further freezing, small spongy white lumps of ice are formed, which are a few centimeter across; these aggregations of ice crystals are termed "shuga."

Antarctica, Figure 1 Frazil ice.

Antarctica, Figure 2 Ice shelf in Central Dronning Maud Land.

These floating fragments of ice coalesce together to form bigger pieces of "pancake ice" or "ice cakes" (Figure 7). Pancakes generally range from 30 cm to 3 m in size. The rims of the pancakes are raised by the constant collisions with one another.

With further freezing, the pancakes join together to form "floes." These may become interlocked by thrust-fingers alternately over and under each other, and are then termed "finger rafted ice."

When the thickness of finger rafted ice is less than 10 cm, it acquires a thin elastic crust of ice, which bends easily with waves and swells; this is termed "nilas."

Nilas, which are less than 5 cm thick, are usually rather dark in color and are thus called "dark nilas"; while those that are more than 5 cm thick, gradually acquire a lighter color and are termed "light nilas."

Nilas form only in saline waters, as the salt content gives it the typical elasticity. When freshwater or water of low salinity freezes, the growing ice crystals exclude solute and are almost free of salt; the result is a similar feature but lacking in elasticity, these rigid ice forms are termed "ice rinds."

With further freezing, the nilas become thicker and lose their elasticity; the resultant sea ice is thicker than 10–15 cm and it is termed "gray ice." Under the effect of waves and swells, it rafts and breaks. Further cooling increases the thickness of gray ice and when it goes up to ~70 cm, it is called "white ice."

"Ice cakes" are an intermediate stage in the freezing of pancake ice into floes, where the size of each cake is typically less than 20 m. By contrast, small floes are 20–100 m in size and big floes may range from 500 to 2,000 m.

A collection of floes constitutes a "pack." When the floes are not in contact with each other or are loosely lumped together with many leads and polynyas, the concentration of ice on the surface of the sea is generally less than 60%. This type of sea ice is termed "open pack ice." When the floes are very densely packed, with a concentration of 70–80%, it is termed "close pack ice." When no water is visible between the floes, then the pack ice has a concentration of 100% and is termed "compact pack ice" (Riffenburgh, 2007).

An area of pack ice less than 10 km across is called an "ice patch," while if it is more than 10 km in extent it is termed an "ice field."

When two different types of pack ice are seen together, the line of transition between the two pack areas is termed a "concentration boundary."

When individual floes of pack ice are pushed by winds or currents and ride over each other, these are termed "pressure ridges" or "ridged ice" (Figure 6).

If hummocks of ridged ice coalesce together and project to a height of more than 5 m above the water, and if these are floating separately from any other sea ice, then it is termed a "floeberg." This is fundamentally different from a typical iceberg because it is composed of saline ice, whereas an iceberg is made up of freshwater ice.

Coelescence of floes results in the formation of large "pack sheets." These float freely in Antarctic waters for tens of kilometers. Ultimately, they may bond together to form an unbroken continuity, termed "fast ice." The term originated because the fast ice is a sea ice which is "still holding fast to the coast," remaining attached to a rocky coast, an ice wall, an ice shelf, or even to a grounded iceberg. Fast ice typically extends for hundreds of kilometers from the coast.

Fast ice reaches its maximum extent in September and October every year. The average extent of fast ice is generally about 600 km from the coast. The greatest expanse of fast ice is seen in the Weddell Sea, where in peak winters it extends to ~2,500 km from the coast of Antarctica. The maximum total area of sea ice has been observed around Antarctica is ~20 million km^2, greater than the area of the continent itself is ~14 million km^2 (Gordon et al., 2000).

Open ocean water reflects about 5% of the solar radiation back into the atmosphere, while pack ice has a much higher albedo and reflects back about 85% of the incoming solar radiation. Thus, pack ice has a major impact on the energy balance of the Antarctic region.

The thickness of fast ice is generally 1–2 m. Fast ice of only one winter's growth is termed "young ice" and its thickness is typically 30 cm to 2 m. When the sea ice survives for at least two seasons, it becomes thicker, usually up to ~3 m, and is termed "multiyear ice."

Overall, wherever pack ice is present in a reasonable quantity, it hampers swell thus calms the sea surface. Static water freezes more readily compared to moving water, and therefore this surface calming promotes more rapid freezing. Thus, the very presence of pack ice acts like a nucleus around which more sea ice grows.

The boundary separating fast ice from pack ice or open water is termed the "fast ice edge." If the fast ice edge is full of chaotic pieces, it is termed a "flaw." If the flaw becomes wide and can be navigated by ship, it is termed a "flaw-lead" or simply a "lead."

An open water anomaly within the sea ice is termed a "Polynya" (Figure 10). Depending on its location, it is termed "shore polynya," "flaw polynya" or "recurring polynya," etc.

When the fast ice disintegrates and moves away from the coast, sometimes a narrow fringe of ice remains as a stable leftover on the coast, unmoved by the waves and tides; this is called the "ice foot." If this ice strip covering a coastal strip of low-lying area is backed by mountains, then the ice foot is termed "ice piedmont." These ice piedmonts rise gradually from the sea side and merge into ice walls or ice shelves. A very narrow ice piedmont, which is less than 1 km wide, is called an "ice fringe."

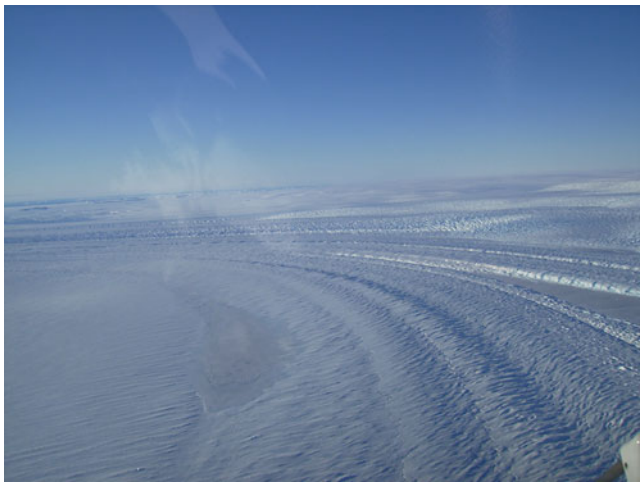
The contact of fast ice and the ice shelf is usually marked by a long coastal crack because of the cyclic action of the tides; this is termed a "tidal crack."

In the final stages of decomposition, all sea ice becomes honeycombed, marked with many holes. It is then termed "rotten ice."

Antarctic ice cores and climate change

In the interior of Antarctica, snowfall occurs every year and accumulates, due to the intense cold that precludes melting. This process has been going on for the past few million years. The pointers or proxies to the past climate, which are trapped within the ice, are atmospheric gases, traces of volcanic eruptions, particles of dust, pollen, and cosmic dust. In addition to these, the ratio of the oxygen isotopes within the ice gives information about the prevailing temperatures. Thus, ice cores can provide the atmospheric composition of that particular period, along with the air temperature at the time of snowfall, the season of the snowfall (summer or winter), and the amount of

Antarctica, Figure 3 Ice core retrieved in Antarctica.



Antarctica, Figure 4 Lambert glacier Amery coast.

Antarctica, Figure 5 Nunatak in Schirmacher area of East Antarctica.

precipitation (Cuff and Goudie, 2008; Petit et al., 1999) (Figure 3).

The Antarctic ice sheet on an average is ~2,000 m thick. In the basins of Wilkes Land, an ice thickness can be greater than 4 km, with a maximum of almost 4,700 m. The Antarctic ice sheet is an unparalleled repository climatic information of the past ~0.8 million years, which is the oldest age obtained from deep ice cores to

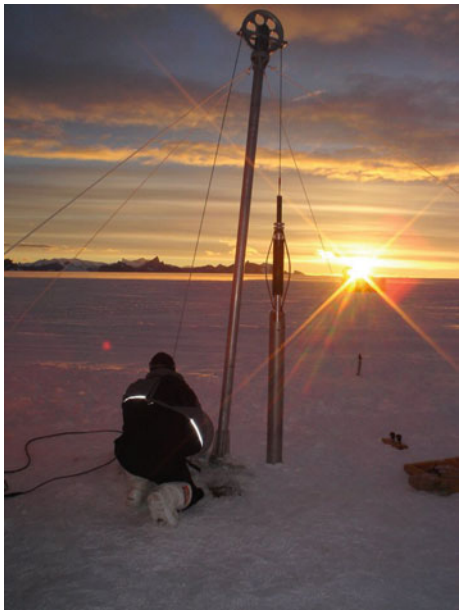
Antarctica, Figure 6 Hummocky ice.

Antarctica, Figure 7 Pancake ice.

date (Figure 8). The ice has preserved records for studying global climatic change, environmental pollution levels, mega volcanic eruptions, paleo-temperatures, and the composition of atmospheric gases through ages past (Cuff and Goudie, 2008; Petit et al., 1999).

At a burial depth of about 300 m, the specific gravity of ice touches 0.82 and then the interconnecting air passages within the ice are broken into individual confines, so creating individual air bubbles. When the snow is buried to a depth of more than a kilometer, the pressure of burial is so great that these air bubbles are squeezed into waxy gas clathrates that convert back into air bubbles when the pressure on the ice is released, for example, during the retrieval of ice cores from depth. These air bubbles provide very rare and unique samples of the past atmosphere (Hitoshi and Langway, 1982; Petit et al., 1999).

Oxygen has three stable isotopes – ^{16}O, ^{17}O, and ^{18}O; where the number of neutrons in the atomic nucleus varies from 8 to 10, respectively. The first isotope, ^{16}O,



Antarctica, Figure 8 Ice core drilled in Antarctica.

Antarctica, Figure 9 Tabular iceberg.

is the dominant one, accounting for less than 99% of the oxygen in natural waters. The heaviest isotope, ^{18}O, is quite rare, accounting for less than 0.2% of the oxygen in natural waters. At the time of snowfall, lower temperatures increase the proportion of ^{18}O in the snow. The ratio of $^{18}O/^{16}O$ obtained from the ice, when compared to that of the oceanic water (called Standard Mean Ocean water or SMOW), can be used to estimate the temperature at the time of snowfall. This ratio, termed $\delta^{18}O$, has become a standard tool in paleoclimatic studies of ice cores. By finding the temperature at the time of snowfall, individual snow layers can be labeled for summer and winter seasons and thus yearly cycles can be counted. Annual layers within the ice core samples can be counted back and dated just like annual tree rings (Petit et al., 1999).

The amount of carbon dioxide gas (CO_2) in the atmosphere is a crucial component that affects the climate. Ice cores from Antarctica are the only available direct source of information about the exact content of CO_2 in different periods during the past hundreds of thousands of years (Cuff and Goudie, 2008; Petit et al., 1999).

Attempts have been made to date the CO_2 gas present within the air bubbles by means of AMS ^{14}C dating methods. As far as precision is concerned, the results have been encouraging. The date of actual formation of the ice differs from the CO_2 gas age inside the bubbles by a few hundred years, due to the time lag that always occurs before air bubbles are sealed and cut off completely from the outside gases during burial. Thus, radiocarbon dating methods are not much used for ice core dating and isotopic analysis is mainly limited to oxygen and hydrogen isotopes (Petit et al., 1999; Morgan and van Ommen, 1997).

The individual seasonal layers within the Antarctic ice cores can occasionally be detected by visually observing the internal stratification. In places, the annual summer layers are slightly highlighted by the presence of dust particles. However, with greater depth of burial, the visual record becomes almost indistinguishable. Then the best tool for detection of seasonal layers is to analyze the cores at very short regular intervals for $\delta^{18}O$ values (Grootes et al., 2002). When the accumulation rates are high and when there is no melting and refreezing of layers, this method is very successful. But with increasing depths, the seasonal layers become more and more compact and it becomes difficult to use even this tool. At very great depths, especially near the bedrock, ice gets deformed by plastic flow, which almost eliminates seasonal snow layering (Petit et al., 1999; Budd and Radok, 1971).

Sometimes marker horizons can be detected within ice cores, which are recorded at many other places for comparisons. Major volcanic eruptions in the history of the earth, which affected global climate, have their signatures in Antarctic ice also. If these eruptions were of an explosive nature with a lot of ash content, the signatures are quite emphatic. In places, the ash particles are so characteristic of one particular eruption that these can be compared well with other global sites, leading to a very precise marker horizon (De Angelis et al., 1985; Laluraj et al., 2009).

Apart from ash and volcanic dust particles, volcanic gases also leave their imprints within the ice. Sulfur dioxide and hydrogen sulfide in particular are dissolved in cloud water and are scavenged from the atmosphere by snowfall dilute traces of sulfuric acid. This results in a more acidic snowfall, leading to acidity of glacier ice. After drilling, these acidic layers within the ice cores can be detected by abrupt changes in electrical conductivity of the cores and also by precise analyses of the chemical composition of snow and ice (De Angelis et al., 1985; Laluraj et al., 2009).

Antarctica, Figure 10 Ship birthed along ice shelf in a Polynya.

Recent nuclear explosions also leave global signatures and their fallouts can be detected in Antarctic ice cores, providing another type of recent markers (Wolff, 1990).

Climatic warming is amplified in the polar regions. The northern Antarctic Peninsula has warmed by ~2.5°C in the last 50 years, while the Southern Hemisphere appears to have warmed by ~1.5°C during the same period. As a consequence, many ice shelves in the peninsula, which were stable for the last 1,800 years, have suffered dramatic disintegration (British Antarctic Survey, 2001).

A few very deep ice cores has been extracted from the Antarctic ice sheet, including the Vostok, EPICA, Dome-C, and Byrd cores. These provide ice cores from depths of 3,000 m or more. The paleoclimatic record from these ice cores goes to a maximum of ~450,000 to ~800,000 years BP (Petit et al., 1999).

The analysis of air extracted from air bubbles in the EPICA-Dome C ice core shows that present-day levels of green house gases are higher than at any point during the past 650,000 years. The CO_2 is higher by 30%, while methane is higher by 170%. In the year 1780, the CO_2 levels were ~278 ppm, while now they are ~380 ppm, and still rising by $\sim 2 \times 10^{-6}$ atm every year. The methane content in ice cores is more variable but still correlates well with the advancing industrial age on earth. About 40% of CO_2 is absorbed by the oceans but 60% remains in the atmosphere. With the present trend, atmospheric CO_2 concentrations are likely to double by 2050. The CO_2 invasion may be leading to a transition in the oceanic carbon cycle, with unforeseen consequences (NPP, 2007).

The mass balance of the Antarctic ice sheet and glaciers should remain constant to avoid any rise in the sea levels. Surface warming and basal sliding may give rise to to a powerful feedback: more surface melting causes faster sliding and increased calving, which in turn leads to lowered surface, less resistance to sliding, and hence more melting (NPP, 2007).

A warmer atmosphere enhances snowfall in the interiors of large ice sheets, but increases ablation at the marginal zones. Satellite data have suggested that Greenland and Antarctic ice sheets are thickening in their interiors, while rapidly thinning at the peripheral areas (NPP, 2007).

Outlook

Antarctic ice is one of the most important climatic indicators today. Its icy layers have preserved an unbroken continuity of the climatic record for the past ~1 million years. Recent climate change (during the past ~200 years) is very distinctly observed in the ice. The air bubbles trapped within the ice also provide actual samples of the composition of the atmosphere, changing year by year. A clear and quantifiable relationship between the greenhouse gases (carbon dioxide, methane, and nitrous oxide) and the global temperature gradients is established by these annual records. This provides a unique opportunity to study the gradual changes taking place in our recent climate and thus helps in the design of models for forecasting the climate of the coming decades (Petit et al., 1999; Riffenburgh, 2007; Philippe, 1990).

Even the mass balance of the present ice sheet and sea ice is good indicators of the climatic changes that are taking place today. The scientific observations show that the peripheral parts of the Antarctic continental ice are shrinking very rapidly. The coastal ice edge of the glaciers is melting and retreating, the ice shelves are disintegrating

and floating away into the ocean, and the inland glaciers are surging and accelerating toward to the sea. All this suggests that the peripheral mass balance is negative and the ice sheet in the coastal areas is melting away (Riffenburgh, 2007).

However, in the interior of the continent, there are some scientific observations that show that the thickness of the ice sheet is increasing. Added to this is also the observation that the sea ice cover is also increasing. Satellite data has established that in 2007 the sea ice cover was the most extensive in the past 3 decades (Susan, 2007).

Even these two contradictory aspects fit well with current climatic models of global warming. The warming of the oceans provides more moisture to the huge circulatory systems around Antarctica, leading to more snowfall everywhere. While the higher snowfall in the coastal areas melts away due to rising temperatures, the interior of the continent never melts and preserves this extra precipitation.

The climatic models predict that with further rise in global temperatures, the sea ice in Antarctica would start "thinning" as is happening today in the Arctic. The coastal ice shelves would break away, leading to accelerated surge of the inland ice streams toward the sea. The slight rise in the thickness of the interior ice sheet would not be able to balance this huge mass-loss and Antarctic melting would substantially contribute to rising MSLs (Riffenburgh, 2007).

Since sea-level rise and changing climatic trends are crucial factors for the survival of human civilization, Antarctica remains a key scientific observatory for studying these changes. Observations on snow, ice, glaciers, ice shelves, and sea ice of Antarctica, coupled with analysis of shallow depth ice cores, are major tools for elucidation of contemporary climatic change. The scientific research stations spread around the Antarctic continent provide precious inputs for the prediction of climatic change on the planet and help to form part of an early warning system for rising global temperatures.

ANTI-ICING

Rijan B. Kayastha
Himalayan Cryosphere, Climate and Disaster Research Center (HiCCDRC), Kathmandu University, Dhulikhel, Kavre, Nepal

Definition

Anti-icing is the practice of applying chemicals to roadways to prevent forming of frost or ice from forming. It prevents bonding of frozen precipitation to road surface. Anti-icing chemicals are applied in liquid form (brine) to road surfaces. Liquid sodium chloride (NaCl) is the most effective choice for anti-icing above −10°C. The other anti-icing products are calcium chloride, magnesium chloride, potassium acetate, and calcium magnesium acetate. Each chemical has its own advantages and disadvantages. The major benefits of anti-icing are reduction in road accident, de-icing material, labor, and de-icer residue, winter cleanup work and costs, and accumulation of sand in drainage systems and beneath guardrails. Anti-icing practice is used mostly on roads to prevent forming of frost or ice. Initial applications can be made either as a pretreatment in advance of a storm event or as an early storm period treatment.

ANTI-SYNGENETIC ICE WEDGE

Pratima Pandey
Centre of Studies in Resources Engineering, Indian Institute of Technology, Bombay, Mumbai, Maharashtra, India

Definition

An ice wedge that grows progressively downward into a receding slope and in a direction perpendicular to the surface is called anti-syngenetic ice wedge.

Ice wedges or cracks in ground ice are generally classified into two main types: epigenetic and syngenetic. Epigenetic wedges grow wider rather than deeper whereas syngenetic wedges grow both wider and deeper more or less simultaneously. Field studies show that there is a third type, an anti-syngenetic wedge, which grows downward on receding slopes in a direction normal to the slope.

APPALACHIAN GLACIER COMPLEX IN MARITIME CANADA

Rudolph R. Stea
Stea Surficial Geology Services, Halifax, Nova Scotia, Canada

Definition

The Appalachian Glacier Complex is defined as a series of local ice centers and divides that developed in Maritime Canada during the Wisconsinan glaciation, effectively barring Laurentide ice from the region.

Introduction

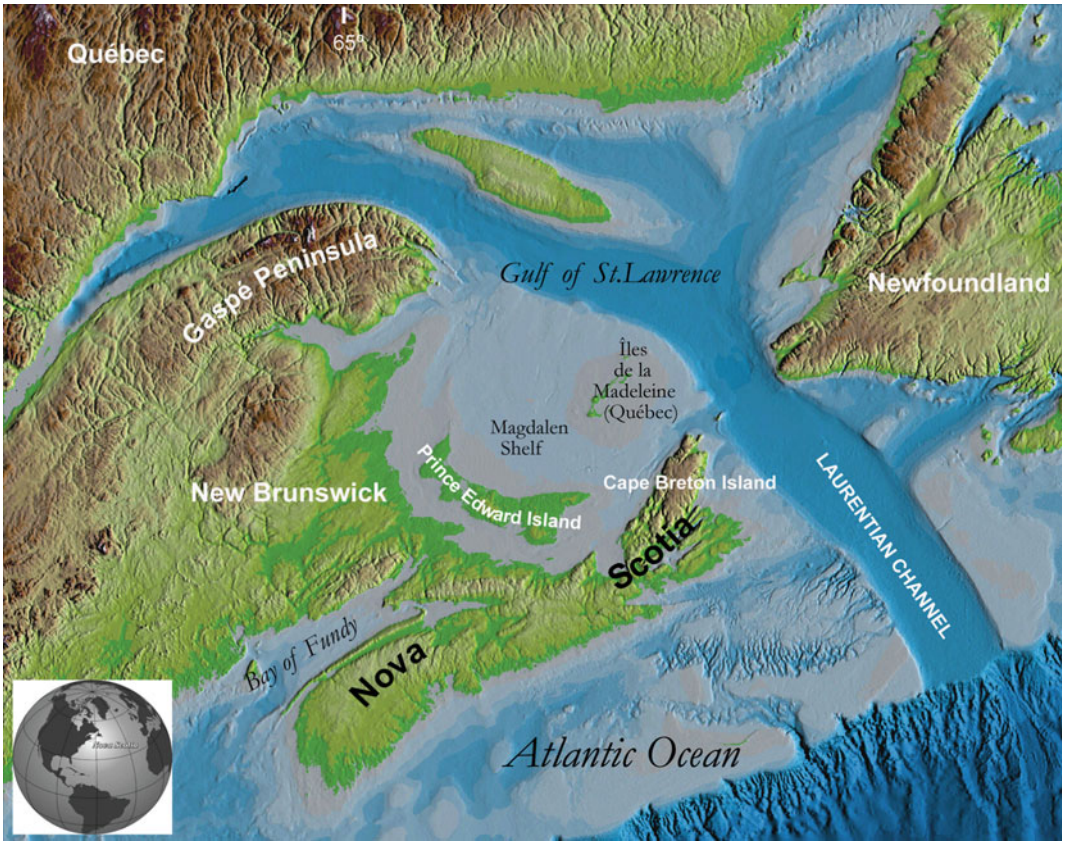
At the turn of the last century when the first geological maps were being completed in the Maritime Provinces of Canada (Figure 1), a controversy emerged about the nature of glaciation in the area that still resonates today. Was the ice local, originating in Appalachian upland areas or was it part of the Laurentide Ice Sheet (LIS) with its center in Québec.

These two opposing models of glaciation for the Maritime Provinces have come to be known as the "minimum" and "maximum" models. The maximum model invokes the LIS covering the entire region during the last glacial maximum (LGM) (~20 kyr BP) (Flint, 1971; Mayewski et al., 1981; Dyke et al., 2002). The minimum model evolved from the recognition of autonomous local glaciers in Maritime Canada (Chalmers, 1895), into a concept of small glaciers restricted to lowland terrestrial areas, and terminating just offshore of the land areas during the LGM (Grant, 1977; Dyke and Prest, 1987; Grant, 1989; 1994). The minimum model was found to be invalid when the land-locked ice margins defined in that model were radiocarbon dated at 13 ka ^{14}C years BP (Stea and Wightman, 1987), and the maximum extent of LGM glaciers was defined at the edge of the continental shelf (Mosher et al., 1989).

Recent studies have emphasized the role of ice streams in the Bay of Fundy and Laurentian Channel in the ablation of the LIS and in the formation of local ice divides (e.g., Mayewski et al., 1981; Belknap et al., 1989; Grant, 1989; Shaw, 2003). The model that eventually emerged to counter both extreme models is one of large, local ice divides situated over maritime Canada collectively termed the Appalachian Glacier Complex (AGC) that developed during the last glaciation (Wisconsinan), effectively barring the LIS from most of the region (Prest and Grant, 1969; Stea et al., 1998; Stea, 2004; Shaw et al., 2006).

Evidence that precludes the Laurentide Ice Sheet from the region

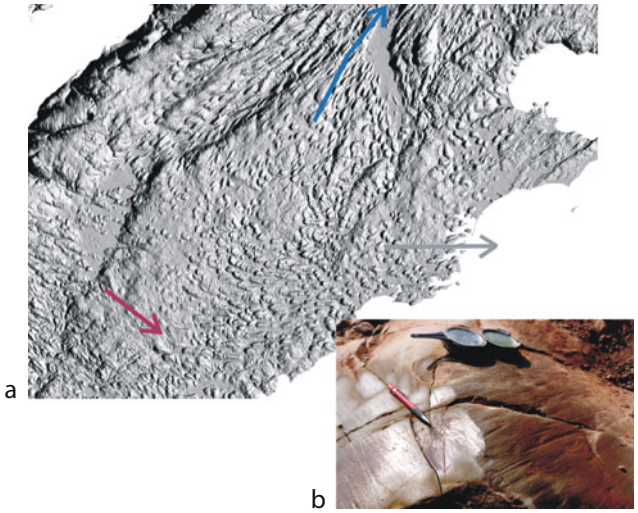
1. Ice flow patterns in Nova Scotia, Prince Edward Island, and eastern New Brunswick (NB) are dominated by a variety of local ice flow trends rather than



Appalachian Glacier Complex in Maritime Canada, Figure 1 Location map and topography of the study area.

a pervasive regional southward trend that would likely be the result of flow from the LIS centered in northern Quebec (Figures 1 and 2). A crucial area is northeastern NB and the Gaspé Peninsula where mapped flow patterns are dominated by Appalachian glaciers to the south rather than ice flow from the Laurentide in north (Pronk et al., 1989; Parkhill and Doiron, 2003) and erratics on the Chic-Choc range of the Gaspé Peninsula are exclusively Appalachian in origin (Olejczyk and Gray, 2007).

2. The coasts of eastern New Brunswick, northern Nova Scotia, and Cape Breton have been extensively surveyed by both bedrock and Quaternary geologists and Canadian Shield erratics have not been reported. Laurentide erratics from the Precambrian rocks of the Laurentian Highlands of Quebec, to the north of the St. Lawrence River, are known only from the area of the Saint John River valley in the northwestern part of New Brunswick (Figure 1; Rampton et al., 1984). If Laurentide ice centered in Quebec had crossed the region during the LGM abundant erratics would be expected as they are found in many areas of central Canada 300–500 km south of the shield margin (Prest et al., 2001). A petrologic and geochemical study of erratics from a type section along the Atlantic coast near Halifax, for example, confirmed the Appalachian origin of all crystalline erratics found there (Stea and Pe-Piper, 1999). Prest and Nielsen (1987) did report an anorthosite boulder in western PEI and suggested a Canadian Shield source, but the preponderance of Devonian-age Appalachian granite erratics associated with it and the known occurrences of anorthosite in the highlands of southern New Brunswick (Barr et al., 2001) suggest the possibility that the erratic assemblage is solely Appalachian in origin. More detailed petrologic or dating work needs to be done to define the sources of crystalline erratics in these regions.
3. One of the main lines of evidence supporting the minimum model and against the ingress of the LIS was the minimal loading of the lithosphere as defined by the degree of marine submergence (Grant, 1977). The 0 isobase (line of no submergence) occurs well within the Gulf of St. Lawrence and was taken as a proxy for the LGM ice margin. Stea et al. (2001), however, argued that the lack of submergence features was not a result of an ice margin but the delayed melting of local glaciers. Nonetheless, areas such as the head of the Bay of Fundy deglaciated at around the same time as regions covered by the LIS in the Gulf show considerably less submergence.



Appalachian Glacier Complex in Maritime Canada, Figure 2 (**a**) A drumlin field in southeast Cape Breton showing the juxtaposition of several temporally-separate ice flow phases as shown by varying orientations of drumlins, palimpsest drumlins and superimposed fluting on drumlins. Caledonia Phase eastward flow (grey) represented by eastward-trending drumlins in the southern part. Scotian Phase ice stream flow (blue) shown by converging, attenuated drumlins trending northeastward and late Chignecto Phase flow (purple) indicated by southeastward trending forms. The angular discordance and superposition of these drumlin trends within the same area precludes synchroneity of formation. (**b**) Crossing glacial striae, southeast Cape Breton Island. Early Caledonia Phase eastward striae (90°), preserved on the lee slope of an outcrop, with a younger southeastward ice flow imprinted on the top surface of the outcrop (Chignecto Phase-150°).

Similar lines of evidence were used to propose that Newfoundland was not covered by LIS during the LGM in spite of being much closer the to the Laurentide ice center (e.g., Grant, 1977). The Gaspé highlands (>1,000 m) formed a topographic barrier that probably blocked the LIS from the western part of the region and the 500 m deep Laurentian Channel funneled LIS ice streams away from the highland rimmed maritime provinces. These topographic entities defined the configuration of the LIS and AGC in Atlantic Canada.

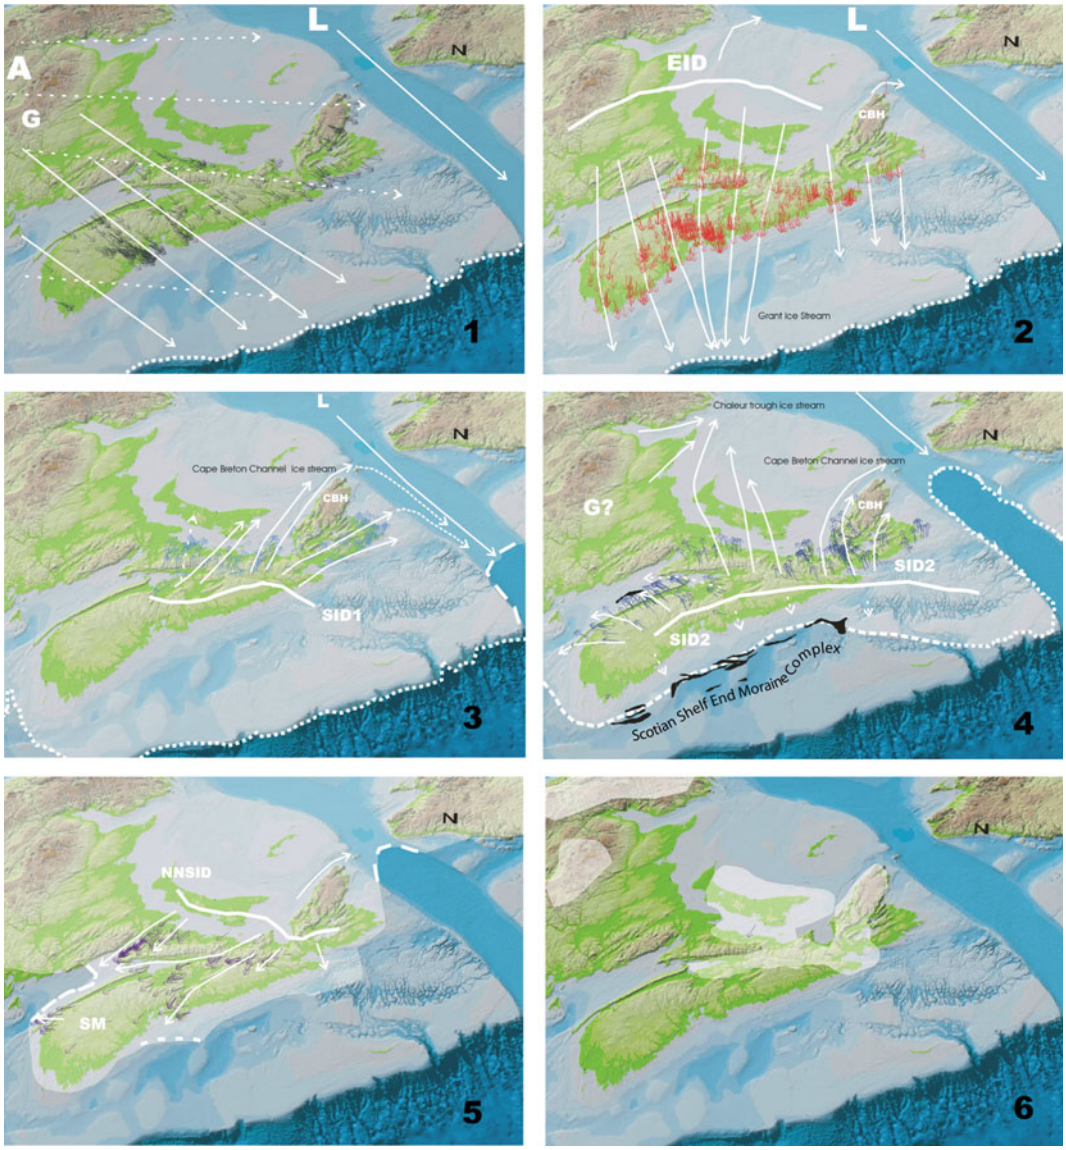
Summary: Evolution of the Appalachian Glacier Complex during the last glaciation (Marine Isotope Stages 4-2; 75-12 ka BP)

The ice centers and divides of the AGC shifted in time and place over the LGM producing a palimpsest of glacial landforms (Stea, 1994). These landforms include cross-striated bedrock outcrops and drumlin fields showing multiple long-axis trends, superimposed fluting, and lobate forms (Figure 2). Based on till provenance, offshore glacial sediments were correlated to their terrestrial counterparts, establishing crucial links between ice flow patterns on land and radiocarbon-dated ice margins offshore (King, 1996; Stea et al., 1998). From these empirical data five major flow phases were defined along with their offshore margins (Figure 3). During the Caledonia Phase in the early part of the last glaciation (Marine Isotope Stage MIS 4-75-60 ka BP), both eastward and southeastward-flows are recorded from glaciers in the Appalachian Highland of eastern Maine and central New Brunswick.The age and extent of the early eastward flow, stemming from Appalachian upland sources, is uncertain and may also represent a pre-Wisconsinan flow. These flows likely crossed Nova Scotia and extended to the continental shelf edge. The Caledonia Phase ended with a global period of ice retreat during MIS 3 (60-25 ka BP). During MIS 3 the Laurentian Channel cleared of ice but adjacent land areas remained covered by glaciers (Dredge and Thorleifson, 1987). During the subsequent cooling in the Late Wisconsinan (MIS 2-25-12 ka BP) remnant glacier ice on the Magdalen Shelf (Figure 1) re-formed into an ice divide (Escuminac Ice Divide-EID) and southward flow from this divide has been termed the Escuminac Phase (Figure 3). Ice flow from the EID was generally southward over the region and extended out to the edge of the continental shelf. In previous publications, the Escuminac Phase was attributed to multiple ice centres, one in central New Brunswick (Gaspereau Ice Center-Seaman, 2004) and one over the Magdalen Shelf (Escuminac Ice Center – Rampton et al., 1984; Stea et al., 1998).

Just after 20 ka BP, at the start of a period of global warming the EID was reorganized as ice streams developed in marine channels bordering the Magdalen Shelf and in the Bay of Fundy. The progressive thinning of ice in the Magdalen Shelf and in the Bay of Fundy produced an ice divide (Scotian Ice Divide-SID) over mainland Nova Scotia and a general reversal of ice flow termed the Scotian Phase. Ice flow in northern mainland Nova Scotia rotated from northeastward to north-northwestward as the calving margin in the Laurentian Channel migrated landward. The margin of SID is marked offshore by the Scotian Shelf End Moraine Complex dated between 20 and 16 ka BP (Figure 3; King, 1996).

Responding to rapid global warming after 16.0 ka BP the SID reorganized into an east-west trending feature as the Bay of Fundy ice stream picked up momentum. Ice flow rotated from northwestward during the Scotian Phase to westward to southwestward into the Bay of Fundy from an ice divide over Prince Edward Island and northern mainland Nova Scotia (Northern Nova Scotia Ice Divide). This westward and southwestward ice flow pattern was termed the Chignecto Phase (Rampton et al., 1984; Seaman, 2004; Stea, 2004).

Between 16 and 12 ka BP local centers advanced and retreated, responding to mass balance changes during a time of fluctuating northern hemisphere climate. Chignecto Phase glaciers eventually dissipated and their margins retreated landward. Isolated marine and terrestrial remnants of the Chignecto Phase glaciers re-advanced significantly during the Collins Pond Phase (Younger Dryas) just after 12.9 ka BP (Stea and Mott, 2005).



Appalachian Glacier Complex in Maritime Canada, Figure 3 Ice flow "phases", glacier flow lines and ice divides defined by landforms (drumlins, fluting, striae) indicative of glacier flow. Striation data plotted on the figures from Stea et al., (1992) and Grant (1994). An ice flow "phase" is defined as discrete, regionally mappable trends of striations and streamlined landforms of the same relative age (cf. Rampton et al., 1984). 1-Caledonia Phase (earlier eastward flow from Maine (A)) (Northumberland Glacier- Chalmers, 18). southeastward flow from the Gaspereau Ice Center (Rampton et al., 1984). 2. Escuminac Phase (dotted line) early eastward flow may represent pre-Wisconsinan flow phase southward flow from Escuminac Ice Divide (EID), Grant Ice Stream funneled into a marine channel offshore. 3. Scotian Phase ice flow initial NE flow phase and the development of the Scotian Ice Divide (SID 1), calving bay migration in the Laurentian Channel. 4. Main Scotian Phase with a linear ice divide straddling the peninsula of Nova Scotia and ice flow northwest and southeast from the divide (SID 2). Outlined in black offshore Nova Scotia is the Scotian End moraine Complex (King, 1996). 5. Chignecto Phase southwestward ice flow from an ice divide in northern mainland Nova Scotia (NNISD). 6. Collins Pond Phase ice flow from a local glacier advance during the Younger Dryas Chronozone.

ARCTIC HYDROCLIMATOLOGY

Jessica Ellen Cherry
International Arctic Research Center and Institute of Northern Engineering, University of Alaska Fairbanks, Fairbanks, AK, USA

Synonyms

Arctic hydrometeorology; Arctic water cycle; Cold region climatology; Northern hydrology

Definition

Arctic hydroclimatology is the study of water in the climate system of the far north. It can be differentiated from Arctic hydrometeorology in that it is generally concerned with longer than synoptic timescales. Physical climatologists typically focus on trying to quantify the fluxes and stocks of freshwater in the Arctic. The domain of

interest includes the Arctic hydrologic catchment, which extends as far south as 45°N, but also includes transport of freshwater in the ocean and atmosphere in and out of the Northern Regions.

Fluxes of liquid, vapor, and frozen water between the land and the atmosphere include precipitation, evapotranspiration, and sublimation. Water stored on land includes that in snow cover, glaciers, lakes, rivers, in vegetation, and in ice-rich permafrost. Fluxes of water in the coastal areas include river runoff, air–sea interactions, and atmospheric transport and may be strongly influenced by distributions of sea ice in the shoulder seasons. Freshwater in the ocean is mixed, evaporated, stored, and transported as liquid as well as sea ice. Clouds also play an important role in the climate of the Arctic, not only as a means for moisture transport, but also as a driver of both radiative warming and cooling, depending on the cloud type and location.

System components

The balance between precipitation and evapotranspiration is the fundamental driver of freshwater storage in the Arctic. Annual and seasonal patterns of precipitation vary widely from south to north and between coastal and continental climates. In general, there is more precipitation in the south than in the north, because relatively warm moist air is being transported to these regions from the midlatitudes. By the time these air masses reach the high Arctic, much of that heat and moisture has been lost *en route*. Coastal regions in the Arctic tend to get more precipitation than inland locations, whereas those in the midlatitudes tend to have more moderate seasonal differences in temperature and precipitation patterns. Values can range from 1,600 mm per year in coastal Norway to 150 mm per year in Northern Greenland (AARI, 1985). In most locations throughout the Arctic, more precipitation falls in the warm season than in the cold season, although the ground may be covered with snow for much of the year.

The precise amount and distribution of precipitation and evapotranspiration in the Arctic are both poorly known. Continuous, long-term observations (50 years or more) of precipitation exist at only a few locations. While hundreds of additional stations were added throughout the Arctic during the latter part of the twentieth century, many of these were closed or converted to automated observations toward the end of the century. Stations where enough measurements are made to credibly calculate evapotranspiration are limited to a handful across the whole Arctic. Precipitation, in addition to being sparsely observed in the Arctic, is extremely difficult to measure. Large biases occur in the measurement of solid precipitation, because precipitation gauges are subject to wind-induced undercatch. The gauge itself creates a disturbance in the flow of the atmosphere that causes particles, particularly snowflakes, to fall preferentially away from the gauge. Intercomparison studies of gauge performance (Yang et al., 2005) have estimated wind-induced undercatch to be up to 150% or more of recorded precipitation in Arctic conditions. Because solid precipitation can occur at any time of year in the Arctic, this measurement bias is particularly detrimental to accurate estimates of total precipitation. Other types of measurement biases include mechanical failures (especially problematic for automated gauges), evaporation and wetting losses (when liquid sticks to the inside of the gauge and is not measured). Gauges also fail to measure trace precipitation, which may account for a large portion of total precipitation in the Arctic (Yang et al., 1998).

River discharge, where it is measured, is considered to be one of the more robust hydroclimatological system observations. However, geophysical features such as permafrost cause considerable braiding of rivers in the far north, making discharge in all but the mouths of the larger rivers difficult to estimate. Ice flow during breakup can make it difficult to capture the peak discharge if sensors get damaged. Finally, large numbers of the Arctic rivers remain entirely ungauged. Remote sensing and other techniques are being explored to remedy this problem and the other challenges of hydrologic measurements, but have limitations for estimating historical fluxes. McClelland et al. (2006) report the average combined discharge of rivers into the Arctic Ocean as approximately 2,500 km^3/year over the period 1964–2000 and they also suggest that discharge has increased over 10% during this era. The cause of this increase is the source of considerable debate and may include increases in precipitation, thawing of ground ice, increased contributions from groundwater, and glacial melt.

Shallow lakes are a prominent feature of the Arctic, in part because continuous permafrost can act as an impermeable boundary for liquid water. For example, the Arctic Coastal Plain, which has a total area of 55,964 km^2, has 9,545 km^2 (~17%) of its surface covered by lakes (Arp and Jones, 2009). Bathymetry data and therefore direct estimates of volume have been measured in only a handful of these lakes, although Jefferies et al. (1996) and others have developed techniques to estimate volume from remote sensing. The balance of water in these lakes is generally driven by the difference between precipitation and evapotranspiration in the drainage, however, warming soil or other landscape disturbances may cause degradation of permafrost and lake drainage. The prominence of surface waters in the Arctic poses an interesting juxtaposition: as a measure of annual precipitation, the Arctic is very dry. However, long winters and impermeable permafrost causes what water there is to be mainly trapped at the surface. The result is a large amount of recycling of water between the land and atmosphere during the summer months.

A discussion of the role of glaciers in the Arctic hydroclimatology will be left for other entries in this encyclopedia. Suffice it to say that glacier mass balance is closely tied to precipitation and temperature trends and that glacial melt constitutes a significant portion (10% or

more) of river discharge in regions such as Southeast Alaska and Scandinavia.

Freshwater in the ocean, including sea ice, has important interactions with climate over longer timescales than it does on land or in the atmosphere. River discharge and maritime precipitation are both significant sources of freshwater in the ocean. Formation of sea ice rejects most of the brine back into the water, creating a layer of dense water. The balance of ice formation and freshwater inputs contribute, along with temperature differences, to buoyancy-driven circulation in the ocean. In turn, this influences the fluxes of heat and moisture between the atmosphere and ocean that modulate not only arctic climate, but also the whole Earth. Measurements of changes in ocean freshwater are also difficult to obtain. Remote sensing can be used to estimate precipitable water in the atmosphere, but is limited to the satellite era and the fluxes of water between the atmosphere and ocean are not directly measured. In the ocean, manual salinity measurements and automated sensors on moorings can be used to monitor freshwater content, but are very expensive to obtain and are limited to a single point (on a mooring) or a temporary transect in a research vessel, typically in late summer during the sea ice cover minimum.

Natural variability and anticipated hydroclimate changes in a warmer world

All components of the Arctic hydroclimate cycle have a strong component of interannual variability. Large-scale climate dynamics such as those associated with the El Niño-Southern Oscillation, the Pacific Decadal Oscillation, and the Arctic Oscillation also tend to drive variability in the arctic water cycle on the timescale of several years to decades. In addition to this, frequent variability is thought to be long-term variability associated with a large-scale planetary warming. However, the scale of natural variability in most components of the hydroclimate system is several orders of magnitude larger than the scale associated with climate change.

Although the change may be small and for the reasons discussed above difficult to measure, precipitation and evapotranspiration are both expected to increase in the warmer climate projected by the Intergovernmental Panel on Climate Change (IPCC, 2007). A warmer atmosphere will drive additional evaporation, which will lead to enhanced precipitation.

It is debatable whether this climate change signal is evident in historical precipitation, for example. However, there is relative consensus that the increase in Arctic river discharge over the twentieth century is associated with climate change and intensification of the hydroclimate cycle, as well as with natural variability (Déry et al., 2005; McClelland et al., 2006). Melting of ground ice is thought to be a much smaller component of this increase in discharge than is increased precipitation (McClelland et al., 2004).

Vegetation changes in the Arctic have also been observed, particularly an expansion of shrubs that utilize more water than existing biomes. The consequences of vegetation change for other climate feedbacks are considerable. A few examples include interception of snow by shrubs leading to changes in ground thermodynamics; they have a different color than existing vegetation that alters the energy absorption and spring snow melt, and they transpire at a different rate than other plants.

Warming and degradation of permafrost will alter the hydroclimate of the Arctic considerably. As the land surface warms, the seasonally thawed portion of the soil deepens, and the soil can store more water. This could lead to less surface water storage by draining lakes. There is already evidence of this in Siberia, in regions of discontinuous permafrost (Smith et al., 2005). If precipitation were to remain constant, this could lead to less recycling of moisture between the land and atmosphere. How an increase in precipitation would balance with an increase in the subsurface storage of water is unknown.

Summary

Arctic hydroclimatology includes many components of the physical climate system that interact regionally as well as feedback on the global climate system. The remoteness and harsh environment make quantification of the arctic hydroclimate system components difficult. Measurement biases and high natural variability make long-term change detection challenging, but experts anticipate this to become more evident with time and the development of better measurement techniques.

ARTIFICIAL GROUND FREEZING

Rijan B. Kayastha
Himalayan Cryosphere, Climate and Disaster Research Center (HiCCDRC), Kathmandu University, Dhulikhel, Kavre, Nepal

Definition

Artificial ground freezing (AGF) is a technique of freezing of pore water in saturated and partially-saturated soil which changes the thermal and mechanical properties such as stiffness, strength, and creep behavior of soil. This change in properties increases the load-carrying capacity of the frozen soil which is exploited in various construction works. Originally, the AGF was first developed by F.H. Poetsch in 1883. Poetsch's process involves the circulation of a refrigerated coolant through a series of subsurface pipes to extract heat, thus converting the soil water to ice, creating a strong, watertight material. Most ground freezing systems are quite similar in principle, with subtle differences in the engineering aspects of the individual sites. The single most important component of a ground freezing system is the subsurface refreezing system, consisting of a series of refrigeration pipes installed with various drilling techniques. The quantity, spacing, depth, and size of the refrigeration pipes are unique to each site, and determined on the basis of the thermal and hydraulic properties of soils, construction schedule, and cost effectiveness.

The cooling medium varies depending on the required application. Where very rapid freezing is required, liquid nitrogen is used with temperatures well below −150°C. For most applications however, a secondary coolant such as calcium chloride (brine) or ethylene glycol is used. This secondary coolant is chilled using large portable refrigeration plants which employ ammonia as a primary refrigerant. These refrigeration plants are typically mounted on conventional over-the-road trailers and are electrically powered using commercially available electricity.

Once the system has been drilled and installed, it operates continuously as a closed system requiring constant monitoring with occasional plant adjustment and coolant flow modifications. After the initial freezing has been completed and the frozen barrier is in place, the required refrigeration capacity is significantly reduced to maintain the frozen barrier.

Use: AGF is employed in tunneling, during open excavations, and for retaining structures.

ARTIFICIAL PRODUCTION OF SNOW

Carmen de Jong
The Mountain Institute, University of Savoy, Le Bourget-du-Lac, France

Synonyms

Artificial snow; Man-made snow; Programmed snow; Snow production; Technical snow

Definition

Artificial snow is produced by rapidly freezing water into ice crystals under high pressure.

Introduction

The artificial production of snow serves two objectives: on the one hand, artificial snow is necessary for laboratory experiments to simulate snow and avalanche processes, on the other hand, it is produced commercially as a surrogate for natural snow to cover ski runs where natural snowfall is missing or uncertain. It is also produced in indoor centers for skiing as well as outdoors in cities for events. It can be produced in virtually all climate zones, even in hot, arid countries like Israel. Dubai hosts the world's largest indoor ski center. Artificial snow is now produced on nearly all ski runs globally that are affected by large variations in snowfall, that have insufficient natural snowfall or that are effected by climate change. This includes the Alps, Pyrenees, Rockies, Andes, Carpathians, nearly all skiable Mediterranean mountains (e.g., Mount Hermon) and newer developments such as in the Yabuli mountains (China), etc. Some ski runs are covered by 100% artificial snow (layered with natural snow), in particular in the United States. However, many ski runs especially in the Alps and semiarid regions rely entirely on artificial snow for part of their season.

Short history of artificial snow

Artificial snow was first produced and patented from snow canons to cover ski runs by Art Hunt, Dave Richey, and Wayne Pierce in 1950 in the United States. In Europe,

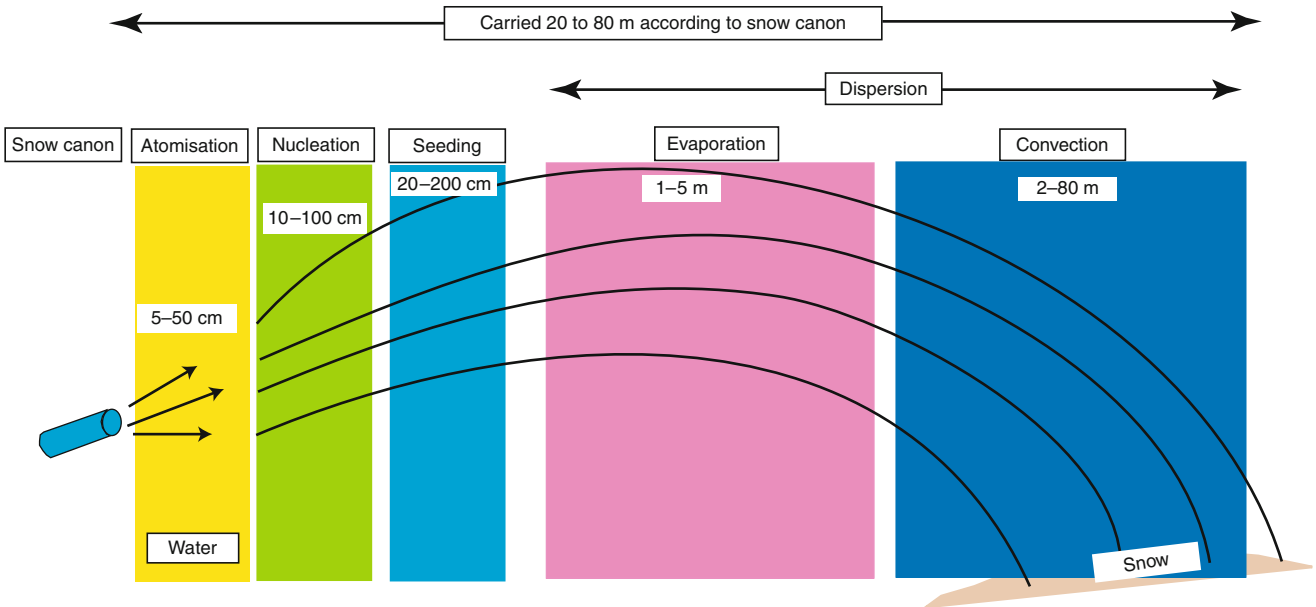
artificial snow production was introduced only in the 1970s. Since then, artificial snow has been used commercially. Artificial snow production has increased exponentially and is now produced at a large scale and altitudinal range worldwide. In the European Alps, it covers up to 70% of the ski runs (for example in Italy) up to an altitude of 3,200 m. The most dynamic increase in artificial snow infrastructure has occurred since the mid-1980s, parallel with strong climate change marked by more erratic snowfall events and the increase in global warming. Nowadays, artificial snow is produced for all world cup winter sport events to ensure homogenous ski runs.

In the Alps, nearly 250 km^2 of ski runs are prepared using artificial snow, costing nearly 3 billion Euros per year for construction and maintenance and consuming approximately 600 GWh per year. At present 1 m^3 of artificial snow costs between 2.50 and 5.00 Euros.

Production of artificial snow

There are two principal methods used for producing artificial snow, based on internal and external mixing of air and water. For the first method, water is cooled to just above the freezing point and then pumped under high pressure together with compressed air into a mixing chamber inside the snow gun or snow canon (Figure 1). It is then ejected through one principal nozzle as a mixture of air and water to the outside. For the second method, compressed air and compressed water are channelled separately inside the snow gun or snow cannon to the outside and mixed during the ejection. The compressed water exits several primary and secondary nozzles and is mixed outside with the compressed air that exits via two principal valves perpendicular to the water nozzles.

The most important processes occur within the first 50 cm outside the snow canon. As the water and air mixture exit the nozzle, it expands and cools off rapidly. This zone is dominated by atomization of water into fine droplets (on average between 200 and 300 µm in size), accompanied by the onset of nucleation and seeding. Nucleation is part of a first-order phase change, in this case it is the process by which the water droplets freeze into ice particles (on average 50 nm in size). Seeding is the process by which water vapor condenses around a seeding nucleus, in this case an ice crystal, causing ice crystal growth (on average between 5 and 100 µm in size). However, water vapor and the potential for seeding, is limited to °C temperatures. Within the range of 50–100 cm, nucleation dominates followed by seeding. In the zone between 100 and 200 cm, seeding dominates and evaporation begins. At 200–500 cm, evaporation of water attached to the ice crystals dominates, supporting further cooling of the ice-crystals, freezing the remainder, and causing the ice crystals to grow in size. Dispersal occurs across a range of 1–80 m and includes evaporation and convection. Depending on the type of snow canon/gun, snow can be distributed over 20–80 m. Snow canons are mobile and placed on the ground, so that artificial snow can be pumped from 1 to 2 m height at a distinct angle into the air. Snow guns are fixed installations, usually at 10 m height pumping artificial snow at an angle towards the ground. The third method, used mainly in indoor centers, is to freeze water by compressing air together with water and liquid nitrogen. Nowadays the production of artificial snow is computer controlled. Large purpose-built reservoirs supply water to a central "snow factory" which then pumps both water and air at high pressure through a network of underground



Artificial Production of Snow, Figure 1 Production of artificial snow.

pipes to a series of snow-guns/canons. The snow guns/canons automatically switch the snow-making process on and off according to the prevailing local meteorological conditions.

Optimal conditions for snow production include low relative humidity, low wind speeds, and temperatures below −3°C. At high wind speeds, artificial snow is dispersed into the atmosphere rather than deposited on the ground and can be carried away for long distances. Temperatures above −3°C are suboptimal for snow production since the water droplets do not freeze rapidly enough and will fall to the ground as cold rain (Figure 2). Another problem is that if the water droplets freeze but the ground is still too warm, the ice crystals melt when reaching it. Unless enough snow is produced to cool the ground to low temperatures to keep the snow, this technique is not very energy efficient. In Zermatt, Switzerland and Pitztal glacier, Austria however, a snow production machine has been installed that can produce artificial snow even at air temperatures of +20°C (IDE snowmakers). This technique could be used to upgrade downhill runs with sufficiently low surface temperature even under unfavorable warm weather conditions. In order to produce artificial snow at temperatures above −3°C, some countries authorize the addition of condensation nuclei, such as ash, silver iodide, kaolin, soaps and detergents, fungi, or lichens. The most widely-used additive is "Snomax," a freeze-dried protein powder derived from the Pseudomonas syringae bacterium that helps initialising ice crystallization. Snomax is authorized in Switzerland and the United States.

Modern snow guns can produce up to 96 m^3/h of snow transmitting a water flow rate of up to 638 L/min.

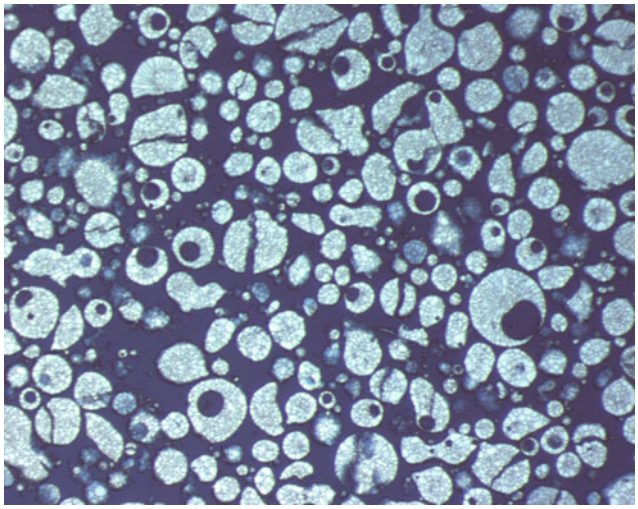
Characteristics of artificial snow

The grain size distribution of artificial snow lies between 0.05 and 2 mm. Compared to natural snow, with a grain size of 0.2 to several mm, artificial snow crystals are much smaller and also have a different grain size and shape. Whereas natural snow is dendritic in shape, artificial snow is spherical, consisting of small, rounded particles. Since artificial snow is produced very rapidly, the ice crystals may still contain a pocket of air, a bulge or may even be broken (Figure 3) (Fauve and Ryner, 2004). Artificial snow resembles the final stage of natural snow after several weeks of metamorphosis through sublimation and melting and refreezing.

Due to its small grain size and high degree of compaction, artificial snow has a much higher density (300–500 kg/m^3) than uncompacted, fresh natural snow, on the whole it is four times denser (Rixen et al., 2003; Jones and Devarennes, 1995). Its conductivity is more than ten times higher than natural snow, typically above 85 μS/cm. This is due to its high density and high ion concentration. Depending on the geology of the water source area, mineral concentration can be considerably higher, for example, magnesium and calcium can be 40 times and 10 times higher respectively. Due to its high density, artificial snow can be 60 times harder than natural snow. Snow hardness measurements of 36 N for artificial snow compared to 0.6 N for uncompacted natural snow (Keller et al., 2004).

The thermal properties of artificial snow also differ from natural snow. During the winter season (e.g., from December to April), measurements show that the temperatures remain homogenous, fluctuating around the 0°C

Artificial Production of Snow, Figure 2 Artificial snow production at temperatures above −3°C (Photo: Kees Woolthorn).



Artificial Production of Snow, Figure 3 Crystal shape of artificial snow, showing broken crystals (Photo: Mathieu Fauve).

(Rixen et al., 2003). In contrast, compacted natural snow stays well below 0°C at −3°C to −5°C under the same atmospheric conditions. The isothermal conditions render artificial snow more prone to melting and refreezing during the daytime.

Chemical/mineral properties

The salinity of meltwaters from artificial snow is extremely high compared to natural snow (Jones and Devarennes, 1995) (see above, conductivity). On average, the mineral and ion concentration in artificial snow meltwater is four times higher than in the surrounding streams causing a local input of ions (Rixen et al., 2003). This is because water used for snowmaking is abstracted from groundwater and river water that has a higher mineral concentration than precipitation. It is also possibly due to enrichment effects of stagnating snow as water vapor sublimates and evaporates into the atmosphere.

Climate change and artificial snow

Since the mid-1980s, climate change has clearly visible effects on the frequency of snowfall events, snowpack thickness, and snow duration. Most mountains, together with the whole northern hemisphere, show a clear decrease in total amount of snow and the length of the winter season. In the Col du Porte, (Massif Chartreuse, altitude 1,505 m) France, snow height has decreased by more than half a meter over the last 50 years and the snow season has decreased by several weeks (Meteo France). In other higher latitude sites there has been more than 4 m decrease in snow depth (Barth, 2007). Since skiing is based primarily on snow as a natural resource, the inconsistency of snowfall and snow duration associated with climate change has caused more and more ski resorts to resort to the artificial production of snow. As the regional snowline is climbing higher, the replacement of natural snow by artificial snow guarantees continuous skiing on the ski runs.

The exponential increase in snow production infrastructure goes parallel with the current trend of global warming temperatures. More and more ski resorts worldwide are being equipped with snow-making infrastructure to ensure snow during the whole season and over all runs.

However, global warming itself is limiting snow production, with some ski resorts already unable to produce snow at temperatures above the threshold during warm winters (Steiger and Mayer, 2008). Local conditions such as aspect (orientation) of ski slope, altitude, patterns of inversion, and exposure to foehn winds play a major role. With the expected increase in temperatures between 1.5°C and 6°C by the end of the century, the altitudinal limit of snow making could rise by between 250 and 1,000 m. As the periods with subzero temperatures will be shorter, the preseason preparation of artificial snow will also become more uncertain.

Another major limiting factor is the availability of water. Large quantities of water are necessary for snow production, approximately 3,300 m^3/year per hectare, (up to 0.2 m^3/s and snow cannon). Under the current trend of climate change, water is distributed more unequally over time and its availability at high altitudes is limited due to the limited catchment size and groundwater reservoirs.

Environmental effects of artificial snow

Meteorological

Artificial snow is commonly produced in large amounts during a whole week in the autumn, that is, October in preparation of the winter ski season. The amount of artificial snow produced is usually the equivalent of natural snowfall during the whole winter season. It is stored in large mounts for later redistribution over the ski runs shortly before the ski runs are opened. The snow is not produced during natural snowfall. During its production, tiny particles from evaporating snow crystals are emitted into the atmosphere. The local ultrafine particle concentration during artificial snow production can reach numbers comparable to polluted atmospheres ~20,000/cm^3 in contrast to approximately 5–800/cm^3 under normal clean conditions (Junkermann, personal communication). First results show that 90% of the artificial snow produced particles are smaller than 50 nm in size. These particles are too small to act as cloud nucleation nuclei (CCN), since cloud nucleation nuclei have to exceed 50 nm in size to allow condensation of water for the formation of rain or snow. On a regional scale, the remaining 10% still can double the number of climate relevant CCN.

Hydrological

Artificial snow perturbates the water cycle at two stages: firstly when water is abstracted from sources, streams, groundwater and interbasin transfer and stored in

preparation for snow production resulting in a local, temporary deficit in water. This deficit is caused not only by the direct abstraction of discharge from the streams and groundwater but also by a loss in evaporation at three stages: in the water storage reservoirs, during its production, and during its redistribution and storage over the ski runs. It is estimated that about 30% of water is lost by evaporation and is not re-issued into the basin (Wemplel et al., 2007). Since artificial snow requires large amounts of water, water has to be stored in appropriate reservoirs. These can reach volumes of up to 400,000 m^3 comparable to a medium-sized dam. As water availability is becoming more and more limited, the construction of artificial snow water reservoirs is becoming more and more widespread. Unfortunately, theses have major impacts on the landscape and hydrology (Figure 4). Often reservoirs are built in depressions that are either wet zones and therefore environmentally sensitive areas or even biodiversity hotspots.

Secondly, when water is re-issued into the environment through snowmelt from the local catchments or is imported from other catchments, a local surplus of water can result. A shift in the seasonality of discharge and an increase in flood discharge have been modelled (de Jong and Barth, 2007). Meltwater from artificial snow runs produces on average two times more runoff than natural snow because of the increased thickness of artificial snow on ski runs and its higher density (Rixen et al., 2004).

Water quality and health

Several studies have been carried out on the effects of the additive "Snomax," derived from the Pseudomonas syringae bacteriumn. Although the bacterium is sterilized before use and no traces of it are found after use, the mixture is favorable to the proliferation of other potentially pathogenic bacteria (Dinger, 2006). Poor water quality used for snow production, derived from reused water can also have effects on human health (AFSSET, 2008).

Ecological

Changes in snow density of artificial snow can cause significant changes in soil and vegetation processes (Rixen et al., 2008; Wipf et al., 2005). The dense, thin snow cover of artificial snow leads to changes in soil insulation and relatively higher soil temperatures, which consequently increases net N mineralization. A denser snow cover furthermore results in a delay in plant phenology of up to 5 weeks after melt-out.

Soil and ecology are affected by the nature and duration of artificial snow cover. Since it is highly compacted and further compressed by piste preparation and machine grading, artificial snow remains on the ski runs on average 3–4 weeks longer than natural snow (Keller et al., 2004; Teich et al., 2007). This delays vegetation development and reduces the length of vegetation period (Wipf et al., 2005). In addition, the compaction of snow and soil causes both to become impermeable, preventing water infiltration and causing increased surface runoff. This often triggers erosion. Local water logging and permanent change in plant community can occur where slope profiles are short (Pröbstl et al., 2006).

Noise pollution by snowmaking machines can perturbate wildlife. For example, lower bird species diversity was detected in the coniferous forests along ski runs

Artificial Production of Snow, Figure 4 Water storage reservoir being built for artificial snow production (Photo: Benjamin Damelet).

with artificial snow production in the western Italian Alps due to negative edge effects caused by noise (Laiolo and Rolando, 2005).

Summary

Although artificial snow is produced on skis runs for over 50 years, scientific literature on artificial snow still remains very limited. Technical details of snowmaking are available in detail, showing that conditions for snowmaking are limited to certain meteorological conditions, such as temperatures below –3°C. The scientific basis of an artificial snow climatology is in the process of development. It shows that snowmaking may be limited through climate change in the future. The environmental impacts of artificial snow are very diverse and require interdisciplinary analysis.

ATMOSPHERE-SNOW/ICE INTERACTIONS

Timo Vihma

Definition

Interactions between the atmosphere and snow/ice are due to exchange of heat, mass, and momentum at the air-snow/ice interface. Through the exchange, interactive dynamic and thermodynamic processes take place at a wide range of spatial and temporal scales in the atmosphere and snow/ice.

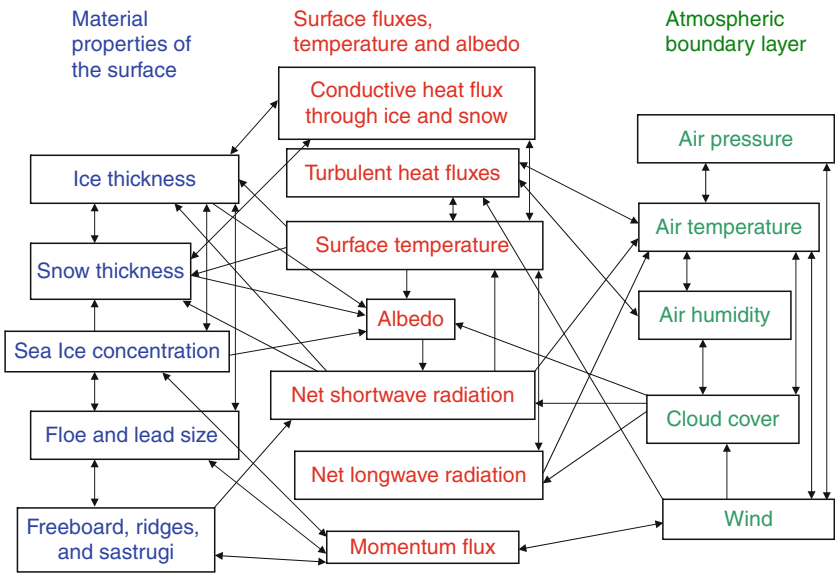
Introduction

The atmosphere-snow/ice heat exchange includes solar shortwave and thermal longwave radiation, as well as turbulent fluxes of sensible and latent heat, the latter related to sublimation/condensation. The heat exchange processes modify the heat content of snow/ice and the atmospheric boundary layer (ABL), defined as the air layer, typically 0.1–1 km high, where the direct effects of the earth surface are felt at time scales of hours. The changes in the heat content result in metamorphosis, melt, freeze, or transport of liquid water or water vapor in snow/ice and in buoyant or stabilizing dynamic forces in the ABL. Cooling of sloping snow/ice surfaces commonly results in generation of katabatic winds and sometimes katabatic jumps. Mass exchange includes precipitation, sublimation/condensation, surface erosion due to drifting or blowing snow, and deposition of aerosols. Mass exchange results in thickening or thinning of the snow cover, changes in the surface properties, and changes in the atmospheric water content. Changes in the snow/ice surface properties further affect the surface heat balance and exchange of momentum, while changes in the atmospheric water content affect the radiative transfer, convection, condensation, and precipitation. The exchange of momentum is due to wind stress over the snow/ice surfaces. The wind stress depends on the aerodynamic characteristics of the snow/ice surface and the thermal stratification. Depending on the resistance of surface particles (or larger bodies, such as sea ice floes) against motion, the wind stress may solely result in the dissipation of momentum or also in sea ice or snow drift.

A schematic presentation of the atmosphere–snow/ice interaction processes is shown in Figure 1. The surface fluxes of momentum, heat, and moisture, as well as the surface temperature and albedo (see *Albedo*) interact with both the material properties of the snow/ice surface and the structure of and processes in the ABL. Some of these interactions are discussed here in more detail. For deposition of atmospheric impurities, not addressed here, see *Chemical and Microbe Records in Snow and Ice*, and *Chemical Processes in Snow and Ice*.

Thermal interaction between the atmosphere and snow/ice

Snow and ice surfaces have properties that generate particular boundary conditions for the radiative and turbulent heat exchange. First of all, the surface conditions are affected by both thermodynamic and dynamic processes. The latter, including sea ice and snow drift, may generate rapid changes in the boundary conditions for radiative and turbulent fluxes. Second, snow has a low heat conductivity (see *Snow*). Hence, the snow surface temperature rapidly adapts to changes in the atmospheric forcing. While remaining low compared to other surface types in the earth, the snow heat conductivity may, however, rapidly vary due to the changes in snow wetness. Also, the snow thickness and density (see *Snow Density*) vary a lot in time and space. Hence, the conductive heat flux and the response of the surface temperature to atmospheric forcing changes in time and space. Further, while the turbulent fluxes of sensible and latent heat usually depend interactively on the surface-air differences in temperature and moisture, this is not the case over melting snow. The temperature of melting snow does not exceed 0°C, which eliminates the effect of the turbulent fluxes on the surface temperature.



Atmosphere-Snow/Ice Interactions, Figure 1 Schematic diagram of atmosphere–snow/ice interactions.

Surface energy balance

The surface energy balance over snow and ice can be presented as:

$$H + \mathrm{LE} + (1-\alpha_S)(1-\beta)\,\mathrm{SWR}\downarrow + (1-\alpha_L)\mathrm{LWR}\downarrow + \mathrm{LWR}\uparrow + C + P = 0 \quad (1)$$

where SWR↓ is the downward solar shortwave radiation, α is the surface albedo, β is the fraction of the shortwave radiation penetrating below the surface, LWR↓ is the downward longwave radiation, LWR↑ is the upward longwave radiation, C is the conductive heat flux from below the surface, and P is the heat flux due to precipitation. All fluxes are here defined positive to the snow/ice surface. Accordingly, $(1-\alpha_L)\,\mathrm{LWR}\downarrow$ is always positive, the net shortwave radiation $(1-\alpha_S)(1-\beta)\,\mathrm{SWR}\downarrow$ is always positive or zero, and LWR↑ is always negative, while the sign of H, LE, C, and P varies from case to case. Four terms in Equation 1 (H, LE, LWR↑, and C) directly depend on the surface temperature. Hence, Equation 1 provides an equation for surface temperature, assuming the snow/ice surface as an infinitely thin layer with no heat capacity.

In the absence of solar radiation in winter, the major terms in Equation 1 are usually the net longwave radiation, $(1-\alpha_L)\mathrm{LWR}\downarrow + \mathrm{LWR}\uparrow$, and H (Persson et al., 2002). The net longwave radiation is in winter usually negative, of the order of a few tens of W m^{-2}, and balanced by H and C. Due to the larger heat conductivity of ice than snow, C is larger for ice, in particular for thin sea ice (see *Heat and Mass Transfer in Sea Ice*). For a snow surface, C may be significant during conditions of rapid surface cooling: a large temperature gradient in the upper snow layers compensates for the low heat conductivity. The direct effect of precipitation is usually negligible in Equation 1, but precipitation affects the snow/ice mass balance and surface albedo (Pirazzini, 2004), and thus indirectly also the heat balance. In the case of sea ice, precipitation affects the mass balance via snow ice formation due to ocean flooding and superimposed ice formation due to refreezing of melt water.

In summer, the solar radiation usually dominates in Equation 1, in particular over ice surfaces with α_S lower than that for snow. Under a thick cloud cover, the net longwave radiation is close to zero or even positive. Compared to solar radiation, the turbulent fluxes are usually minor, in particular over sea ice, where thermal differences between the atmosphere, ocean, ice, and snow are minor in summer (Vihma et al., 2009). Under cloudy skies with a strong wind, the magnitudes of turbulent fluxes may, however, exceed the net shortwave and net longwave radiation.

Radiative fluxes

From the point of view of solar radiation, the particular properties of snow and ice are: (a) snow and ice crystals are subject to metamorphosis, (b) the surface albedo is high and highly variable (see *Albedo*), (c) solar radiation penetrates inside the snow and ice cover, and (d) the snow extinction coefficient is highly variable. All these properties interact mutually.

The instantaneous incoming flux of solar shortwave radiation over snow and ice is controlled by the solar zenith angle, cloud fraction, cloud properties (liquid water and ice content and droplet/crystal size distribution), air humidity, and amount of aerosols. The cumulative daily flux additionally depends on the length of the day, reaching its maximum in clear sky conditions during summer solstice in the South Pole and North Pole. In the latter, however, clear-sky conditions are rare in summer. Under cloudy skies, the transfer of solar radiation is a very complex process due to, among others, multiple reflections between the cloud base and snow/ice surface (Pirazzini and Räisänen, 2008). A recently discovered effect on the absorption of solar radiation in the Arctic is the soot concentration in snow.

The LWR↑ depends on the fourth power of the surface temperature (T_S) and on the surface emissivity (ε), which for snow and ice surfaces is typically 0.97–0.98:

$$\mathrm{LWR}\uparrow = \varepsilon\,\sigma\,T_S^4 \quad (2)$$

where σ is the Stefan–Boltzmann constant (5.67×10^{-8} W m^{-2} K^{-4}). The LWR↓ depends on the vertical profiles of the air temperature and emissivity, and is accordingly affected by the amount of water vapor, cloud fraction, and cloud properties. Under clear skies at an air temperature of 0°C, LWR↓ varies by 25 W m^{-2} depending on the amount of water vapor in the atmosphere (Prata, 1996). In the case of cloud formation, LWR↓ is even much more strongly affected (Curry et al., 1996). From the point of view of longwave radiation, snow is approximately a gray body, i.e., the emissivity is close to absorptivity. Hence, α_L is typically 0.02–0.03, but strongly increases for melting snow.

In polar regions, the cloud radiative forcing at the sea surface is positive for most of the year, i.e., clouds increase the downward longwave radiation more than they reduce the downward shortwave radiation. In the Arctic Ocean the period of negative cloud radiative forcing may be as short as 2 weeks in the melting season (Intrieri et al., 2002).

Turbulent surface fluxes

The turbulent air–snow/ice exchange of heat consists of the fluxes of sensible and latent heat. Within a few millimeters of the air–snow/ice interface the exchange is, in fact, due to molecular diffusion. The turbulent fluxes above this viscous sub-layer control, however, the efficiency of the air–snow/ice exchange. The direction and magnitude of the sensible heat flux is controlled by the potential temperature difference between snow/ice surface and air. The latent heat flux is related to sublimation: the flux of latent heat is the water vapor flux (in kg m^{-2} s^{-1}) multiplied by the sum of the latent heats of evaporation

and melting. The direction and magnitude of the latent heat flux is controlled by the air-surface difference in specific humidity. The specific humidity of snow/ice surface is the saturation specific humidity corresponding to the snow/ice surface temperature. Both in the case of sensible and latent heat, the magnitude of the flux is also affected by the wind speed, aerodynamic roughness of the surface, and the atmospheric stratification, which control the efficiency of turbulent mixing above the snow/ice surface.

Hence, in numerical models for snow thermodynamics, weather prediction, and climate simulations, the fluxes of sensible heat (H) and latent heat (LE) are parameterized using the so-called bulk-aerodynamic formulae:

$$H = \rho\, c_p C_{HEZ}(\theta_Z - \theta_S)V_Z \tag{3}$$

$$\mathrm{LE} = \rho\, \lambda\, C_{HEZ}(q_Z - q_S)V_Z \tag{4}$$

where θ is the potential temperature, q is the specific humidity, ρ is the air density, c_p is the specific heat of air, C_{HEZ} is the turbulent exchange coefficient for heat and moisture, and V is the wind speed. Subscript "s" refers to the surface and "z" to a height in the air. In addition to height z, the exchange coefficient C_{HEZ} depends on the roughness lengths for momentum (z_0) and heat/moisture (z_T), and on the thermal stratification usually expressed by the Monin–Obukhov theory (Monin and Obukhov, 1954). For a snow cover without vegetation penetrating through it, z_T depends on the roughness Reynolds number (Andreas, 1987), while for a snow-covered forest $z_T \approx 0.1 \times z_0$. The z_0 of snow and ice is discussed in the section on dynamic interactions.

In conditions of stable stratification, i.e., $\theta_Z > \theta_S$, H is directed from air to snow. With increasing stability under a constant wind speed (increasing $\theta_Z - \theta_S$), the downward H first increases. When the stratification becomes very stable, as often over snow and ice during calm, clear-sky nights, the reduced turbulent mixing starts to dominate over the effects of increasing $\theta_Z - \theta_S$, and H starts to decrease. This acts as a positive feedback mechanism for the increase of $\theta_Z - \theta_S$. Hence, the air and snow surface become thermally decoupled, and $\theta_{2m} - \theta_S$ may reach 10 K. The low heat conductivity of snow favors decoupling, as C does not contribute much to prevent θ_S from decreasing. In such conditions the parameterization of H and, hence, the modeling of the evolution of surface and air temperatures are sensitive to the exact presentation of the stability dependence of C_{HE}, which represents a major challenge for both numerical weather prediction and climate models.

The direction and magnitude of H and LE strongly depend on the air-mass origin. In cases of warm-air advection over snow/ice, H is downward (as sometimes also LE), and a shallow, stably stratified ABL develops (Tisler et al., 2008). The largest sensible heat fluxes are observed in such cases: the warm-air advection is often associated with moderate or strong winds, which prevents the decoupling. On the contrary, if the air mass originates from large ice sheets, it is usually close to thermal equilibrium with the underlying surface, and the turbulent fluxes are smaller.

In temperatures of $-10°C$ and lower, the latent heat flux is a minor component in Equation 1. The saturation specific humidity is so low that even with the air humidity approaching zero, the difference $q_z - q_s$ and thus also LE keep small in magnitude. In melting conditions under dry air, for example under Föhn winds, LE may become a large component in Equation 1 (Granskog et al., 2006).

The heat exchange processes are particularly complex over sea ice, which is typically broken by cracks, leads, and polynyas. In winter, these areas of open water release large amounts of heat to the atmosphere; the sum of H and LE may be several hundred W m^{-2} below zero, while over sea ice (usually covered by snow), H is typically positive and LE close to zero (Persson et al., 2002). Accordingly, extreme variations in the surface fluxes take place even at spatial scales of meters.

The turbulent surface fluxes can be measured by the so-called eddy-correlation technique, which is based on the measurement of high-frequency fluctuations in the vertical wind component, air temperature, and specific humidity. A sampling rate of approximately 20 Hz is needed to resolve the contribution of small turbulent eddies to the vertical transport of heat and moisture. In the case of sensible heat flux, the measurements are usually made by applying a sonic anemometer: the travel times of three orthogonal ultrasonic signals are measured, and the wind components and air temperature are solved from them. For latent heat flux, fast-response hygrometers are used.

Boreal forest

From the point of view of atmosphere-snow heat exchange, boreal forest represents a particular environment because (a) snow is present both on the ground and trees, (b) the aerodynamic roughness of forest is much higher than that of snow/ice surfaces without penetrating vegetation, and (c) radiative transfer through the forest is a complex process (see *Snow Cover and Snowmelt in Forest Regions*). The exchange of sensible and latent heat takes place both between the air and the snow on the ground and between the air and the trees, which may be partly snow-covered. The air within the forest canopy is sheltered: both wind speeds and the solar radiation flux are reduced from their values above the canopy. Hence, the canopy air acts as a buffer for heat exchange between snow and the atmosphere above the forest canopy.

The surface albedo (α_S) of bare ground and snow-free trees is much lower than that of the snow surface and snow-covered trees. In spring, trees become snow-free earlier than the forest ground. Hence, the amount of shortwave radiation reflected from the forest-snow-ground system strongly depends on the solar zenith angle and the forest density. During large zenith angles in dense forest, most of the solar radiation is absorbed in the snow-free trees, while for small zenith angles and sparse forest,

a larger part of the solar radiation reaches the snow-covered ground and is reflected back to the atmosphere. The energy balance of a boreal forest is a challenge for climate and numerical weather prediction models. See Bartlett et al. (2006) for recent model developments.

Effects of snow/ice surfaces on atmospheric thermodynamics

The basic mechanisms for snow/ice surfaces to affect atmospheric thermodynamics are related to the effective cooling of the surface and, in warming conditions, to the upper limit of 0° for the surface temperature. If we compare the state of the ABL over snow/ice surfaces and neighboring bare ground or open sea, we practically always observe lower surface temperatures over the snow/ice surface (sea ice in summer is an exception). Over continents, the colder surface is most commonly due to the high shortwave albedo and longwave emissivity, but the low heat conductivity of the snow pack may also play a role. Over sea ice, this insulating effect dominates in winter.

Due to the cold surface, H often becomes positive and the ABL becomes stably stratified. This reduces turbulent mixing, prevents convective circulations, and reduces near-surface wind speeds (Stull, 1988). Under very stable stratification, the air temperature increases upwards, i.e., there is a temperature inversion. The generation of a temperature inversion is not necessarily only via surface cooling; also the heat advection in or above the ABL and direct radiative cooling of the air are often important. The mechanisms may also involve positive feedbacks: surface cooling decreases convection and favors subsidence in the atmosphere, which reduce cloud formation. This further enhances longwave cooling of the surface and the air itself, yielding to stronger inversions.

Hence, it is not surprising that strong temperature inversions are common over snow/ice cover. King and Turner (1997) reported a case measured in the winter of 1967 at the Plateau Station, Antarctica (79.2°S, 40.5°E, 3,624 m above sea level) calling it "...probably the most strongly stably stratified boundary layer observed anywhere on Earth." The air temperature increased by 21 K from the snow surface to the height of 32 m in the air. Also, the mean temperature profiles in the Antarctic and Arctic include strong temperature inversions. Over the Arctic Ocean in winter, the inversion is usually surface-based, extending to the height of 1.2 km with a temperature increase of 10–12 K (Serreze et al., 1992). In summer the inversions are weaker, typically 5 K, and their base is elevated some 200–400 m from the surface. In the Antarctic sea ice zone, the sea ice is mostly seasonal and thinner (0.6–1 m) than in the Arctic. Further, the sea ice concentration is lower and sea ice is located in lower latitudes on average. Hence, the winter-time temperature inversions are assumed to be weaker than in the Arctic, but there are not much data to prove this. Temperature inversions also favor condensation of fog and low clouds, in particular in cases of warm-air advection over snow/ice surface.

In polar regions in summer, although the Sun does not set or only sets for a few hours, the variations in the solar zenith angle may generate diurnal cycles in the surface heat balance components over snow and ice, although strongly reduced from those over land surfaces. In the Antarctic sea ice zone, Vihma et al. (2009) observed diurnal cycles in 15 surface or near-surface variables. A simplified picture of the causal chain is that the driving force, the incoming shortwave radiation, most directly affects the diurnal cycles in the reflected solar radiation and snow surface temperature. These further affect the outgoing longwave radiation, surface albedo, and the turbulent fluxes of sensible and latent heat. The diurnal cycles in the air temperature as well as the specific and relative humidity follow in this causal chain, where the variables most indirectly affected are the incoming longwave radiation and wind speed. The base height of low clouds is affected by the air temperature and moisture, as well as the incoming and reflected shortwave radiation.

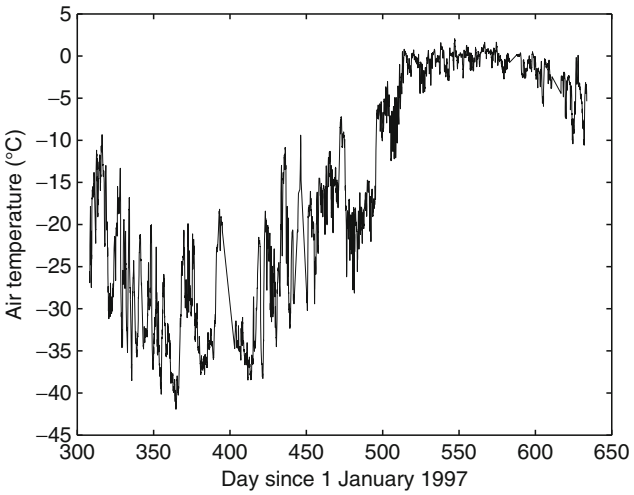
The snow and ice surface temperature cannot exceed 0°C. In the melting season, the snow/ice surface and the ABL are closely coupled via the sensible heat flux and longwave radiation. Hence, if the air temperature tends to rise significantly above zero, the heat is used to melt snow or ice. If the air temperature tends to drop much below zero, meltwater in the snow or, in the case of sea ice, leads to freezing, and the latent heat of freezing is released, preventing a significant decrease of the near-surface air temperature. The effectiveness of these processes is demonstrated in Figure 2, which shows the year-round time series of 2-m air temperature (T_{2m}) in the drifting ice station SHEBA (Persson et al., 2002). In the melting season (days 515–600 in Figure 2), the variability in T_{2m} is much smaller than in winter. The maximum T_{2m} in the melting season is 2.1°C and the minimum was −4.5°C, while in winter T_{2m} varies even by 20° at the time scale of days.

The latent heat of melting plays a role also in the climate change in the Arctic. Vihma et al. (2008) compared the air temperature observations at the drifting ice station Tara in the Arctic Ocean in spring-summer 2007 against Russian drifting station data in 1937–1938 and 1950–1991. Although the Tara data showed 7.0°C higher mean T_{2m} for April, the mean T_{2m} for July was the same as at the Russian station (−0.2°C).

Dynamic interaction between atmosphere and snow/ice

Orographic effects of ice/snow slopes on the atmospheric dynamics

In conditions of a temperature inversion, the densest air is located closest to the snow/ice surface. Hence, over a sloping surface, the gravity force generates a downward flow. Such flows are called katabatic winds, the name originating from the Greek word katabatikos – going



Atmosphere-Snow/Ice Interactions, Figure 2 Time series of 2-m air temperature at the drifting ice station SHEBA in the Beaufort Sea in 1997–1998.

downhill. According to a strict definition, only winds with gravity as the dominating force are katabatic. Due to the large scale of the sloping glaciers in the Antarctic and Greenland, Coriolis force becomes important, and therefore downslope flows are not pure katabatic winds, although usually called such.

Katabatic winds typically occur in the lowermost tens or a few hundreds of meters of the atmosphere, and the maximum speed often occurs a few meters or a few tens of meters above the surface. Katabatic winds may occur in a large range of spatial and temporal scales. Local katabatic winds are developed at night time on mountain slopes in mid and low latitudes. In the case of large mountain glaciers, katabatic winds may prevail through the day even in mid-latitudes. In the Antarctic and Greenland, katabatic winds are remarkably unidirectional, persistent, and strong (King and Turner, 1997). Due to their shallowness and sensitivity to small-scale variations in the topography, katabatic winds represent a challenge for numerical weather prediction and climate models.

Already Prandtl (1952) and Ball (1960) developed simple analytic models for katabatic winds, based on the equations for advection and turbulent diffusion of momentum and sensible heat in a gravity-driven flow. Despite the simplicity of these models, they performed well in reproducing the large-scale features of the wind field over Antarctica. In coastal regions with steeper and more complex topography, the analytic models are, however, not applicable, and high-resolution numerical models are needed. Experiments applying numerical models have also resulted in new points of view on the factors controlling the wind field over the Antarctic ice sheet. On the basis of model sensitivity tests excluding the radiative cooling of the snow surface, Parish and Cassano (2003) suggested that the role of katabatic winds in the Antarctic boundary layer may be overemphasized and that the adjustment process between the ambient pressure field and the orography of the continental ice surface may be the primary cause of the Antarctic wind field.

Katabatic winds may also be accompanied by a katabatic jump (King and Turner, 1997). In the upper parts of the slope the katabatic flow takes place in a shallow layer with blowing snow, and the Froude number (Fr) of the flow exceeds unity. The flow is affected by surface friction, leading to the convergence of momentum. In the narrow region of the katabatic jump, turbulence and vertical velocities are strong, lifting snow as a high wall. A lot of turbulent kinetic energy is dissipated, and downstream of the katabatic jump the downslope flow is much weaker ($Fr < 1$) but takes place in a thicker layer. The katabatic jump is basically similar to the common hydraulic jumps in rivers, but the physics is more complicated, as the flow includes both air and snow.

Frictional effects of snow/ice surfaces on the atmosphere

In the ABL, the momentum balance is achieved between the Coriolis force (term in the left side of Equations 5a and 5b), the pressure gradient force (first term in the right side), and the frictional force (second term in the right side):

$$-f\,v = -\frac{1}{\rho}\frac{\partial p}{\partial x} + \frac{\partial}{\partial z}\left(\frac{\tau_X}{\rho}\right) \tag{5a}$$

$$f\,u = -\frac{1}{\rho}\frac{\partial p}{\partial y} + \frac{\partial}{\partial z}\left(\frac{\tau_Y}{\rho}\right) \tag{5b}$$

where f is the Coriolis parameter, p is the atmospheric pressure, and τ is the momentum flux, with components in the orthogonal horizontal directions x and y. τ depends on the wind speed and the drag coefficient C_{DZ}, and can be parameterized at the atmosphere-snow/ice interface as

$$\tau = \rho\, C_{\mathrm{DZ}}\, V_{\mathrm{Z}}^2 \tag{6}$$

where subscript "z" indicates the reference height for C_{DZ} and V_{Z}. C_{DZ} further depends on the aerodynamic roughness length z_0 and the thermal stratification:

$$C_{\mathrm{DZ}} = \left(\frac{k}{\ln(z/z_0) - \psi_{\mathrm{M}}}\right)^2 \tag{7}$$

where k is the von Karman constant (0.4) and Ψ_{M} is an empirical function describing the effects of thermal stratification on the vertical mixing of momentum. Ψ_{M} depends on the stability parameter z/L, where L is the Obukhov length (Obukhov, 1971).

To quantify the frictional effects of snow and ice surfaces on atmospheric dynamics, we need information on z_0. Laboratory experiments can be made to develop relationships between z_0 and the geometric properties of the surface, but field measurements are usually needed to

reliably determine z_0 over snow and ice. The aerodynamic roughness of snow-covered surfaces typically ranges from 10^{-5} to 10^{-4} m (King et al., 2008), but during summer in glacier ablation zones z_0 may reach 0.1 m (Smeets et al., 1998). Over boreal forest, the presence of snow cover does not significantly change z_0, which is year-round about one tenth of the canopy height (Stull, 1988).

If generated, sastrugi may affect z_0 of snow-covered surfaces. As sastrugi are streamlined by the wind, z_0 does not necessarily increase with increasing geometric dimensions of sastrugi, analogously to ocean waves (large waves in balance with the actual wind have a very small z_0). More important is the alignment of wind with respect to the orientation of sastrugi. Lowest z_0s are observed when wind has blown long from a constant direction, while z_0 is largest after changes in the wind direction. On the basis of measurements over Antarctic sea ice, Andreas and Claffey (1995) found that when the wind continued from a constant direction and streamlined the surface, C_{DN10m} could decrease by as much as 30% in 12 h. If the wind direction then shifted by as little as 20°, C_{DN10m} immediately increased significantly.

The presence of drifting or blowing snow also affects the properties of turbulence in the ABL. This is partly due to the exchange of heat and moisture between the snow flakes and air and partly due to the exchange of momentum.

Effects of wind on snow

Sastrugi affect the wind field, while the formation of sastrugi depends on the capability of the wind to lift snow in the air. Drifting snow is defined as snow lifted by wind up to a height of 2 m. Drifting snow is rolling and bouncing turbulently above the surface. Blowing snow is defined as snow lifted to a height of 2 m or more above the surface, and existing in such quantities that horizontal visibility is reduced to less than 11 km. During blowing snow events, it is in practice usually not possible for a ground-based observer to distinguish between the snow lifted by the wind and eventual snow fall. The presence of blowing snow is one of the requirements for a storm to be called as a blizzard. The preconditions for drifting or blowing snow are that the wind speed is strong enough, typically at least 6–8 m s^{-1}, and the snow density is small. Wet snow will not be lifted even by a strong wind. Andreas and Claffey (1995) observed that when the wind speed exceeded 8 m s^{-1} the surface was continually changing due to drifting or blowing snow: sastrugi were building and eroding. Due to formation of sastrugi, snow-covered surfaces are not isotropic, but have a preferred direction dictated by the wind history.

An important problem related to the living conditions in harsh climates is the difficulty in keeping roads open during snow storms. Visibility reduced by blowing snow also poses problems for aviation. By depositing snow on roofs and around entrances, drifting/blowing snow also generates problems for buildings. Hence, operational forecasts of drifting and blowing snow are needed. Drifting or blowing snow is also important with respect to the release of avalanches. Deposits of snow drifts in the starting zones of snow avalanches contribute substantially to the release of avalanches as well as their sizes. Hence, sophisticated avalanche forecasting systems include components to estimate the amounts of drifting/blowing snow. Coupled with atmospheric models, dynamic snow models have been developed to simulate drifting and blowing snow. The most sophisticated ones include predictive equations for concentration, mass mixing ratio, shape parameter, fall velocities, and radar reflectivity for blowing snow, as well as visibility in blowing snow.

When snow particles are in the air, the exchange of heat and moisture is strongly enhanced as each particle is continuously ventilated on its entire surface. Hence, in addition to operational applications, information on the sublimation from drifting/blowing snow and the transport of snow by wind are needed in climatological studies. For example, Gordon et al. (2006) showed that the inclusion of blowing snow sublimation improves the results for snow depth predictions in Canada. Dery and Yau (2002) suggested that the combined processes of surface and blowing snow sublimation remove significant amounts of annual precipitation over Antarctica and the Arctic Ocean. Large amounts of snow may be transported by wind, but the effects of this transport on the snow mass balance are usually only locally important. Averaged over large areas, the divergence of mass transport through wind redistribution is generally two orders of magnitude less than surface and blowing snow sublimation (Dery and Yau, 2002). Coastal regions and sea ice margins make, however, an exception: snow transported to the open sea represents a sink for the snow mass balance.

Another effect of wind on the snow cover is wind packing, which results in an increase in snow density (see *Snow Density*).

Effects of wind on sea ice

Sea ice consists of undeformed ice cover as well as rafted and ridged ice flows of variable thickness, in places separated by cracks, leads, and polynyas. Compared to most snow-free continental surfaces, the surface of ice-covered seas is in any case relatively homogeneous with respect to roughness, but in winter very heterogeneous with respect to temperature (Vihma and Haapala, 2009). The surface type may change rapidly due to ice motion, and more slowly due to ice and snow thermodynamics. Over the marginal ice zone, the ABL is often under modification, adjusting to its changing boundary conditions. Hence, wind forcing on sea ice drift is an interactive process.

Already Nansen (1902) observed that in the Arctic Ocean the mean drift speed of ice is 2% of the wind speed and the drift direction deviates 30° to the right from the wind. Somewhat larger drift-to-wind speed ratios have been observed in the Antarctic sea ice zone, where the average ice concentration is smaller, which reduces the

internal ice resistance. Through its effects on the ice drift, the wind forcing also generates divergence, shear, and vorticity in the ice motion field.

As indicated in Equations 6 and 7, the air–ice momentum flux τ depends on the wind speed, surface roughness, and stratification. The large-scale roughness length z_0 of a broken sea ice cover depends on the skin friction of level ice and the form drag generated by pressure ridges, flow edges, and sastrugi. Hence, relevant parameters for z_0 of sea ice are the ice concentration (area fraction covered by ice flows), freeboard (depends on the ice and snow thickness according to the Archimedes law), flow size distribution, as well as ridge height and density (number of ridges per unit area). Taking into account the effect of sastrugi is more challenging because the effect depends on the history of wind direction with respect to the ice flow. Over sea ice, the stratification in the ABL is typically stable, which reduces τ. Localized convection may, however, occur over leads and polynyas, which enhance the turbulent mixing and τ. In winter, the effect of stratification may dominate the variability of C_{DZ} (Uotila (2001). Lüpkes and Birnbaum (2005) and Stössel et al. (2008) have improved parameterizations of z_0 and τ in the atmosphere, sea ice, and ocean models. In practice, problematic aspects in modeling the momentum flux over sea ice are that the sea ice conditions change rapidly, and we often lack accurate information on the essential parameters.

Atmospheric moisture transport and its effects on precipitation in the Arctic and Antarctic

The mass budgets of the Antarctic and Greenland ice sheets are controlled by precipitation, iceberg calving, melt water discharge, basal melt of underwater parts of the ice sheets, sublimation, evaporation, condensation, and net export of blowing snow. Precipitation is the only significant source term in the mass budget. As evaporation and sublimation are close to zero over most parts of the ice sheets, there are no significant sources of water vapor to the atmosphere. Hence, precipitation is dependent on the atmospheric moisture transport from the surrounding oceans. Further, via the cloud radiative forcing the moisture transport strongly affects the heat budget of ice sheets.

The atmospheric moisture transport to the Arctic and Antarctic has been studied on the basis of rawinsonde soundings, surface-based observations on precipitation and evaporation, and satellite data, and atmospheric reanalyses. Atmospheric model results have been applied to analyze the modeled precipitation minus evaporation and to calculate the meridional moisture flux and its convergence. The effects of cyclones on the moisture transport have been addressed and the origins of weather systems that have precipitated over the Antarctic have been identified by trajectory analyses.

The poleward moisture transport can be divided into the contributions of mean meridional circulation (MMC), stationary eddies (SE), and transient eddies (TE), i.e., moving cyclones. The total moisture transport is dominated by transient eddies both in the Arctic (Sorteberg and Walsh, 2008) and Antarctic (Tietäväinen and Vihma, 2008). In the Antarctic coastal areas, the mean meridional circulation contributes to the northward transport, but this effect is compensated for by the southward transport by stationary eddies. The convergence of the meridional water vapor transport, yielding precipitation, is at its largest at the Antarctic coastal and sea ice zones. Interannual variations in the water vapor transport are related to a large-scale circulation pattern called the Southern Annual Model.

In the Arctic, the largest northward moisture transport takes place in the Atlantic and North Pacific sectors, while weaker southward transport prevails over the Canadian archipelago. The meridional moisture transport and net precipitation are in winter and spring related to the Arctic Oscillation (AO) index. The interannual variability in moisture transport is mainly driven by the cyclone activity over the Greenland Sea and East Siberian Sea (Sorteberg and Walsh, 2008). In the polar regions, most of the moisture transport takes place in the lowermost 2 km of the atmosphere.

Conclusions

The interactions between the atmosphere and snow/ice take place at a wide range of spatial and temporal scales. Differences exist between sea ice, terrestrial snow, and glaciers in the way they interact with the atmosphere. These are related to the differences in the thickness and heat capacity, which affect the time scale of interactions, and the mobility of the surface, which affects the nature of interactions. The physics of direct interactions is, however, basically similar for sea ice, terrestrial snow, and glaciers. The direct interactions at the air-snow/ice interface are microscale processes: absorption, reflection, and emission of radiation, dissipation of momentum, and molecular diffusion of heat and moisture. The turbulent exchange of momentum, heat, and moisture is characterized by spatial scales from 10^{-2} to 10^{2} m, i.e., the processes take place in the ABL. The ABL wind, air temperature, air humidity, clouds, and fog are typically affected by the surface exchange processes at time scales of hours. The properties of the ABL affect the synoptic-scale weather and further the large-scale circulation and transport of heat and moisture.

In addition to their general effects on the evolution of weather, atmosphere–snow/ice interactions include particular processes that require attention in operational forecasting. These are avalanches, drifting snow, freezing of roads, snow storms with blowing snow, advection fog over snow and ice, strong katabatic winds, and sea ice growth, drift, and ridging. To improve operational services for the general public, navigation, aviation, road traffic, and skiers, research on atmosphere–snow/ice interactions has been carried out for decades. With the recent growing signals of climate change and its polar amplification, research on atmosphere–snow/ice interactions has

extended and oriented more towards climate-scale processes. Still, large uncertainties remain in the quantitative knowledge on several key climate processes, calling for more research efforts. These processes include (a) the natural and anthropogenic factors controlling the snow/ice surface albedo, (b) the interaction of albedo, radiative transfer, and cloud physics, (c) turbulence in the very stable ABL, (d) radiation-turbulence interactions, (e) interaction of katabatic and synoptic-scale winds, (f) factors controlling the meridional transport of heat and moisture to polar regions, and (g) the effects of the decadal-scale reduction of snow and ice cover on the atmospheric heat and moisture budget and circulation.

Definition

Atmospheric circulation. Patterns of horizontal and vertical air movements above earth surface, mainly including movement strength and direction.
Glaciochemical records. Chemical species data recorded in glacier snow/ice.

Since chemical species were analyzed from ice cores retrieved from glaciers or ice sheet and were used to investigate climate and environmental changes in 1960s, the environmental significances of glaciochemical records has been acknowledged by the researchers. Glaciochemistry is mainly influenced by atmospheric chemistry which has been stored in the glacier by dry and wet deposition. Atmospheric chemical species are affected by their sources and transport strength (namely atmospheric circulation change). Therefore, the glaciochemical records have been used not only in reconstructing the paleoenvironmental changes, but also for understanding the changes in atmospheric circulation.

In Arctic, glaciochemical records have been used to investigate changes in atmospheric circulation patterns over the Greenland Ice Sheet (Mayewski et al., 1994, 1997; Appenzeller et al., 1998) and Mt. Logan (Kang et al., 2005) since 1990s. For example, major ion series developed from a sub-annual scale sampling of the GISP2 ice core from central Greenland were calibrated with instrumental series of sea level pressure (SLP) to provide proxy records of major marine (Icelandic Low) and terrestrial (Siberian High) atmospheric circulation over the past 1,400 years (Meeker and Mayewski, 2002). Using sodium concentrations from a Mt. Logan ice core, a 292-year history of the Aleutian Low was constructed which revealed a dramatic intensification of atmospheric circulation over the North Pacific region since the twentieth century.

On a hemispheric scale, more detailed relationships between glaciochemical records and atmospheric circulation in spring were provided. For an instance, an enhanced spring Arctic High weakens dust aerosol transport from central Asia to subarctic regions (e.g., southern Greenland and Yukon Territory), but strengthens transport of dust to the Himalaya (e.g., Mt. Everest). An intensification of the Siberian High may strengthen transport of dust aerosols to Greenland, and an enhancement of the Tibetan High strengthens transport to Himalaya and Yukon regions in spring. A stronger spring Azores High favors dust transport to both the Himalayas and south Greenland. On a regional scale, a deepened spring Icelandic Low and Aleutian Low increases transport of dust aerosols to Greenland and the Yukon Territory, respectively (Kang et al., 2002, 2003).

In Antarctic, glaciochemical records from the western and eastern Antarctic Sheet are closely correlated with atmospheric circulations over the southern hemisphere which was used to reconstruct changes in SLP and wind strength (Reusch et al., 1999; Kreutz et al., 2000; Souney et al., 2002; Xiao et al., 2004; Yan et al., 2005). For example, crustal ion concentrations from three West Antarctica ice cores (Siple Dome, ITASE00-1, and ITASE01-5) are closely correlated with circumpolar zonal wind and westerly wind, as well as Antarctic Oscillation (Yan et al., 2005). A 250-year multivariate glaciochemical record from Princess Elizabeth Land was used to reconstruct SLP over the southern Indian Ocean, which has a strong coherency summer transpolar index, and its decadal-scale variability suggests shifting of the polar vortex (Xiao et al., 2004).

Summary

Relationships developed between glaciochemical records from bipolar and Asia and atmospheric circulation (such as SLP, wind strength) demonstrate that ice core records provide a proxy for the reconstruction of atmospheric circulation. Furthermore, understanding the changes in atmospheric circulation is one of great contributions for global change research.

AUTOMATED GLACIER MAPPING

Frank Paul
Department of Geography, University of Zurich, Zurich, Switzerland

Glacier mapping; Glacier outline digitizing; Multispectral classification

Definition

Automated glacier mapping generates digital glacier outlines in a vector format from automated classification of remote sensing data.

Historical background

Glaciers and icecaps were in the focus of satellite observations at the time when the first data from the Landsat mission (1972) became available. While the large regions covered by satellite data were always considered as a benefit for glacier related applications, mapping of glacier extent was introduced quite late. Early applications focused on discriminating snow from ice and mapping of snowlines (Østrem, 1975; Rott, 1976) or analysis of glacier movement and flow characteristics (Krimmel and Meier, 1975). It has to be noted that in the early days of data analysis (1970s), most work was performed on contrast enhanced photographic prints rather than with digital data (e.g., Dowdeswell and Cooper, 1986). The full potential of directly analyzing the digital data from computer compatible tapes (CCTs) was delayed until appropriate computers became available in the late 1980s. The use of Landsat digital data in the context of glacier mapping was forwarded by Rundquist et al. (1980). Howarth and Ommanney (1986) discussed the possibility to use Landsat data for creating glacier inventories, and Della Ventura et al. (1987) compared mapped glacier extents with inventory data. Compared to the 4-band MultiSpectral Scanner (MSS) sensor at about 80 m spatial resolution that was used for these early studies, an important step forward was achieved in 1984 with the availability of higher resolution (30 m) data in six spectral bands from the Thematic Mapper (TM) sensor. With its capability to discriminate snow from clouds and the increasing computer performance, largely automated glacier mapping at a global scale became feasible.

The first methods for automated snow cover mapping from TM were proposed (Dozier, 1984; Dozier and Marks, 1987) and a number of spectral investigations of glaciers with TM data were conducted (e.g., Hall et al., 1987, 1988, 1989, 1990; Orheim and Lucchitta, 1987; Rott and Markl, 1989; Williams et al., 1991). Techniques for the largely automated mapping of glacier extent was first presented in the 1990s (e.g., Bayr et al., 1994; Aniya et al., 1996; Binaghi et al., 1997; Jacobs et al., 1997) followed by a comparison of different glacier mapping techniques by Sidjak and Wheate (1999). In that year, the satellites Landsat 7 (sensor ETM+) and Terra (sensor ASTER) were launched and glaciers were one of the main targets from the beginning (Raup et al., 2000; Bindschadler et al., 2001). The related initiative Global Land Ice Measurements from Space (GLIMS) was started (Kieffer et al., 2000) and glacier mapping from simple and robust semi-automated techniques (Paul, 2002a) combined with GIS-based glacier data assessment were established (Paul et al., 2002).

In parallel to these applications, the global terrestrial network for glaciers (GTN-G) was established (Haeberli et al., 2000) within the framework of global climate related observing programs (GCOS/GTOS). Within GTN-G, repeated glacier inventories from satellite data were constituted at the Tier 5 level (e.g., Haeberli, 2006).

The sensitive reaction of glaciers to small climatic fluctuations designated them as key climatic indicators (IPCC, 2007) and it become clear that the point information as stored in the former world glacier inventory (WGI) from the 1970s (WGMS, 1989) is difficult to use for change assessment. To overcome this drawback, the GLIMS glacier database was designed to store glacier outlines in a digital vector format (Raup et al., 2007). Indeed, the most efficient way to fill this database is by applying largely automated glacier mapping techniques to large amounts of satellite scenes.

The recent opening of the entire USGS Landsat archive for the public (USGS, 2008) and the availability of accurate and robust mapping methods for clean to slightly dirty glacier ice (Albert, 2002; Paul and Kääb, 2005) will largely facilitate the generation of a more or less complete global digital baseline data set of glacier outlines. Apart from the global aspect of glacier mapping and inventory creation (e.g., for improved calculation of their contribution to sea-level rise), also regional (e.g., hydropower, discharge), and local aspects (tourism, natural hazards), have created much attention for the requirement of establishing a global baseline glacier inventory (GCOS, 2006; Raper and Braithwaite, 2006; Schiermeier, 2010). Only such a 2D vector dataset of glacier outlines will allow to perform the required change assessment for sufficiently large and representative samples.

Below, the applied semi-automated glacier mapping methods are described and challenges to be considered are discussed. The focus is on multispectral (optical) rather than microwave sensors and especially on Landsat TM/ETM + type sensors, which are most frequently used for glacier mapping. In principal, the methods work with all sensors that have similar spectral bands. A disadvantage of optical sensors is their dependence on cloud conditions, i.e., glaciers can only be mapped when they are not covered by (optically thick) clouds. Another important point to consider is snow conditions. Seasonal snow can mask the true glacier perimeter, which implies that glacier mapping becomes difficult or impossible. In order to reduce the workload for processing, the available satellite images should be carefully analyzed for cloud and snow conditions before they are processed.

Spectral properties and available sensors

The surface of a glacier is composed of snow, firn (i.e., 1 year old snow), ice, water, and debris (e.g., rock, pebbles, dust, soot) with a highly variable fraction of each component from glacier to glacier and in the case of ice, snow, and water also in the course of a year. With a focus on temperate glaciers as they appear at the end of the ablation season and neglecting debris cover and liquid water, the physical properties of the glacier surface are determined by snow with variable grain size (i.e., glacier ice can be seen as metamorphosed snow with large grain size). This implies that methods which automatically map snow cover (e.g., Dozier, 1989) do also work for glacier mapping. In the following, the focus is on the optical properties of snow; an overview for other parts of the electromagnetic spectrum (e.g., microwaves) is given by Rees (2005). The spectral characteristics of the debris cover on a glacier strongly depend on the lithology of the source material and vary from place to place. Debris on glaciers can in general not be automatically distinguished from other debris (e.g., in the glacier forefield) using spectral or other techniques (e.g., Bishop et al., 2001; Paul et al., 2004a) but should be included as a part of the glacier (Raup and Khalsa, 2007). Hence, glacier outlines have to be inspected and corrected manually during post-processing. This is in most cases accurately possible as human recognition is able to trace the glacier perimeter based on very subtle reflectance variations, but for such glaciers the extent mapping from spectral classification is better called semi-automated.

The spectral properties of snow have been investigated in the field (e.g., Grenfell et al., 1981; Qunzhu et al., 1985) and modeled numerically (e.g., Dozier, 1989; Warren, 1982). Both approaches reveal a high spectral reflectance of snow in the visible part of the spectrum (with a large dependence on contamination and a very small one on grain size), a decreasing reflectance in the near infrared (with decreasing dependence on contamination and an increasing one on grain size), and very low reflectance in the middle or shortwave infrared (with little dependence on contamination and a strong one on grain size). Spectral reflectance obtained from satellite data have frequently been used to distinguish between ice and snow zones (facies) that are partly different from those identified in the field (e.g., Bronge and Bronge, 1999; Hall et al., 1987; Williams et al., 1991; Williams and Hall, 1998; Winther, 1993). For example, a superimposed ice zone (belonging to the accumulation area) cannot be detected due to the spectral similarity with the ice in the ablation zone.

The distinct spectral reflectance characteristics of ice and snow with the low reflectance in the shortwave infrared (SWIR) could thus be used for a thematic classification. As the related spectral range is located in a region of high atmospheric transparency (see Figure 1), a sensor covering the SWIR is found on several satellites (e.g., Landsat TM/ETM+, Terra ASTER/MODIS, SPOT HRV, IRS 1 C/D LISS III). A brief overview of major sensor characteristics is compiled in Table 1. Automated classification of clean glacier ice is based on the reflectance differences of a SWIR sensor with a sensor in the visible to near infrared (VNIR). As spatial resolution is closely related to swath width (following the rule: the higher, the smaller), the optimum sensor for glacier mapping combines high spatial resolution with a large area covered. In this regard, the Landsat TM/ETM + sensors are close to an optimum as the smallest reasonable glacier size might be close to 0.01 km^2 which is about 11 TM pixels. Under optimum mapping conditions this number of glacier pixels is well recognizable with TM. For higher spatial resolution panchromatic sensors, it is an asset for glacier mapping when the spectral range of the sensor does not extend

[1]Summary of five individual bands

too much in the near infrared, as this strongly degrades the contrast between bare glacier ice and surrounding rock.

Applied methods for glacier mapping

In general, the processing of satellite images can be divided into three phases: pre-, main, and post-processing. Some of the required steps for pre-processing have been discussed above (scene selection based on quicklooks). Additional steps include data download and format conversion, preparation of RGB composites for later editing and maybe orthorectification. The latter corrects the elevation dependent location shifts of each pixel and requires a digital elevation model (DEM) and a set of ground control points. The main processing is then the application of the selected mapping method and creation of glacier outlines using raster to vector conversion. In the post-processing phase, glacier outlines are visually controlled using the contrast enhanced RGB composites and corrected where required. These corrections include in general wrongly mapped water surfaces (with or without ice on it), debris-covered glacier tongues, attached seasonal snowfields, and sometimes regions in cast shadow. For multitemporal applications it is recommended to digitize a separate glacier basin layer that also separates possible seasonal snowfields from the main glacier and provides ice-ice divides in the accumulation area (Paul, 2002b; Paul et al., 2002; Paul and Kääb, 2005). This will guarantee that change assessment always refers to the same entities. A set of rules that should be considered when contiguous ice masses are separated into individual entities is given by Raup and Khalsa (2007).

Automated methods that have been used for mapping of clean glacier ice include maximum likelihood classification (mlc), ISODATA clustering (iso), principal component analysis (pca), normalized difference snow index (NDSI), and band ratios (Paul, 2001). In principal, all these methods work on raw digital numbers (DN), which implies that atmospheric or terrain correction is not required. Empirical tests have shown that results are even worse after such corrections, because the required DEM introduces noise and blurs the spectral signal as a result of coregistration errors (Paul et al., 2002). The result of the mlc, iso, and pca methods (along with some others) does depend on the scene content and requires a considerable pre-processing workload for each image. Moreover, the obtained results are less accurate than from the other two methods (e.g., Albert, 2002), which implies that they are used only seldom. From the point of frequent monitoring or application to hundreds of scenes, more simple methods are preferable. Also for this reason the

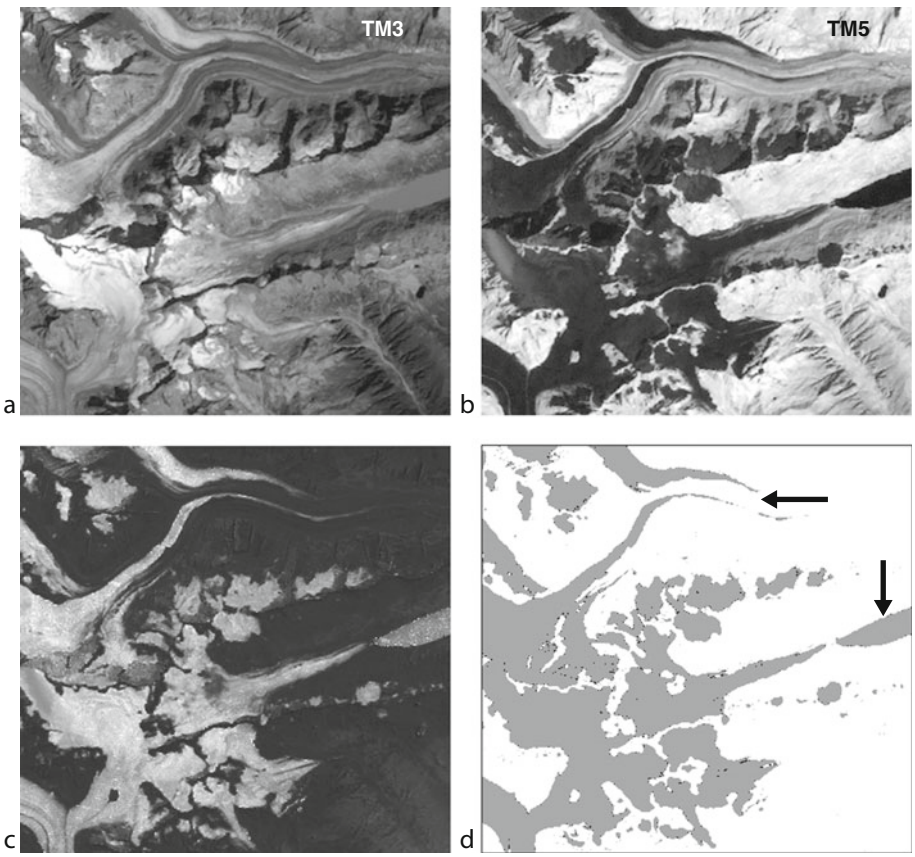
NDSI [(TM2 − TM5)/(TM2 + TM5)] and simple band ratios (TM3 or 4/TM5) are more popular (cf. Racoviteanu et al., 2008). A direct comparison of both methods has shown that they are of a similar accuracy but the NDSI has a somewhat higher pre-processing workload (Paul and Kääb, 2005). The following discussion is thus restricted to the ratio method.

The most flexible and accurate version of the ratio method is based on TM/ETM + bands 1, 3 and 5 (ASTER 1, 2 and 4) and uses two thresholds (t_1, t_2) that have to be interactively selected by on-screen comparison. In pseudo-code the algorithm for each pixel of the scene is (Figure 2):

IF (TM3/TM5 > t_1) and (TM1 > t_2) then
pixel = glacier else pixel = other

While the first threshold (t_1) separates glaciers from other terrain, t_2 allows to correct misclassification in regions of cast shadow without glaciers. The general rule is to select the correct thresholds in shadow regions with the aim of minimizing the workload for post-processing. This decision is scene dependent as it depends on the distribution of (small) glaciers in steep alpine terrain versus large glaciers or ice fields. When ice in deep shadows is correctly mapped, often rock in shadow (without ice) that is lit by bright snow surfaces through scattering is also mapped. When this misclassification can be corrected faster than for the glaciers in deep shadow, the t_2 threshold should be selected to map the (small) glaciers correctly. A threshold value of 2.0 (+/−0.5) for t_1 and 50 (+/−20) for t_2 provide in most cases a good glacier map as a starting point. The pixel value for "glacier" should be set to zero (black) and for "other" to 255 (white) in order to facilitate visual comparison.

Depending on the scene conditions (seasonal snow patches, noise in shadow regions), the application of a 3 by 3 median filter to the black and white glacier map can improve the classification further by removing isolated (snow) pixels and closing gaps due to a medial moraine (e.g., Svoboda and Paul, 2009). However, the filter also closes gaps at mountain ridges and reduces the size of small glaciers to a certain extent (the smaller the glacier the stronger the reduction in relative terms). A careful test and analysis of its influence is thus recommended.



Automated Glacier Mapping, Figure 2 Automated glacier mapping for a test site in the Swiss Alps. (**a**) Landsat TM band 3, (**b**) Landsat TM band 5, (**c**) TM3/TM5 ratio image, and (**d**) resulting glacier map (*dark grey*) after thresholding. Black pixels are added by the median filter, and light grey pixels are deleted. The *arrows* denote: missing debris cover (*top*) and a wrongly classified turbid lake (*middle*).

The ratio method does correctly map glaciers under optically thin clouds (Paul and Andreassen, 2009), scattered debris or a polluted surface (dust, soot), and deep shadows where it sometimes even surpasses human recognition. Compared to other methods the simple band ratio provides most accurate results and is very fast to apply (Albert, 2002). It is also quite robust as a change of the threshold value by 0.1 has little influence on the mapped glacier extent (Paul and Hendriks, 2010). In absolute terms the accuracy of the glacier mapping is difficult to determine as a comparable ground truth (e.g., same date, same spectral bands and higher resolution) is often not available (cf. Paul and Andreassen, 2009). Comparisons with manually delineated glacier outlines from higher resolution data sets indicate that the error is in general smaller than 3% of the total area but increases toward smaller glaciers (Paul and Kääb, 2005; Paul et al., 2003). Compared to the manual digitization of outlines for clean glaciers, the automated method is more consistent and not generalized, which is a great advantage for creating reproducible results. Though manual delineation must be applied for editing of classification errors during post-processing, also here large errors can occur in particular for debris-covered glaciers (Hall et al., 2003).

Post-processing

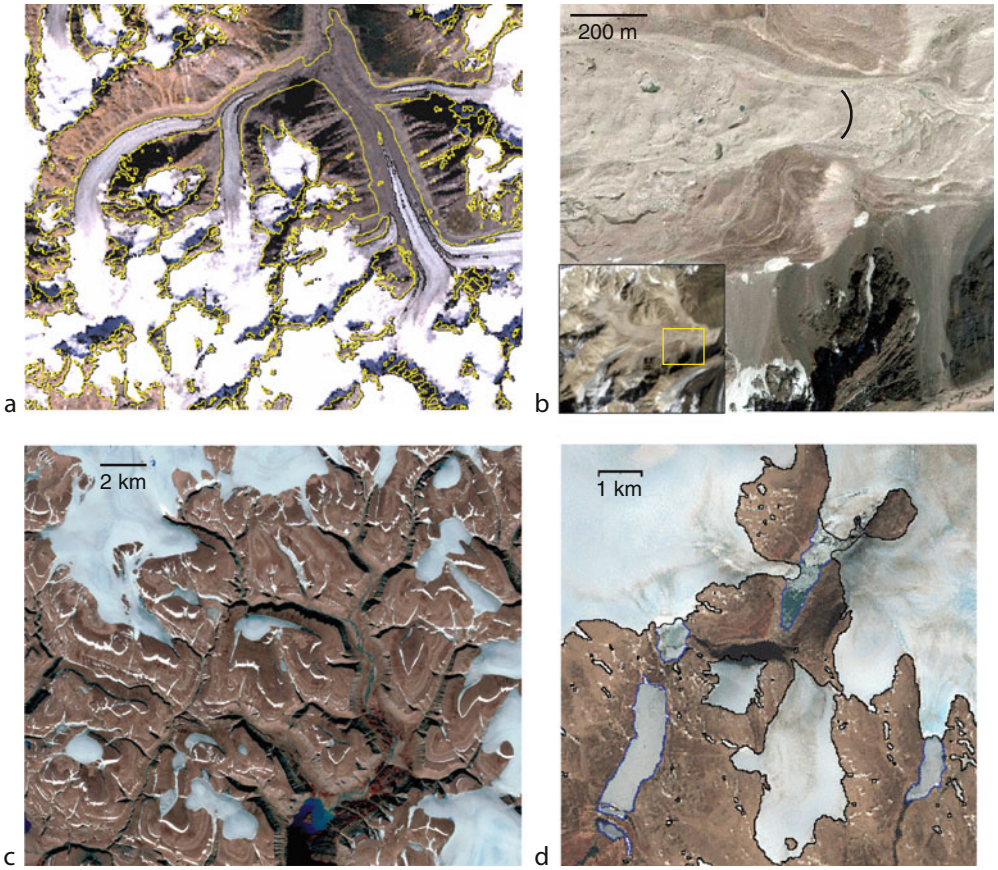
As mentioned above, there are some cases that require manual editing during post-processing. An overview on some frequent issues (e.g., debris cover, ice divides, snow conditions) is given in Racoviteanu et al. (2009). The maybe still largest bottleneck for generating accurate glacier outlines is debris-covered glacier ice. While it is in autumn images (end of the ablation season) in mid-latitudes still possible to identify debris-covered glacier ice from subtle illumination differences, this can be impossible toward lower latitudes with high solar elevations (e.g., western Himalaya). In part, additional data like slope information derived from a DEM (Paul et al., 2004a) or more sophisticated classification algorithms based on geomorphometric analysis (Bishop et al., 2001) and/or decision-tree classifiers (Bolch et al., 2007; Shukla et al., 2010) do provide very suitable first estimates of potentially debris-covered glacier regions. However, manual corrections and editing by a specialized analyst remains to be done to obtain the required accuracy. The problem of properly identifying debris cover on glaciers is also illustrated in Figure 3 a and b for a region in Alaska and Pakistan, respectively. In the latter case with high solar elevation, it is nearly impossible to recognize the glacier at all. Even at a much higher spatial resolution (1 m) it is very difficult to determine the outline and terminus of the glacier. So this issue is still an open area for scientific advancement.

Assuming that cloud-free images are available, another challenge for accurate glacier mapping is related to seasonal snow. At a first place, the number of suitable images are greatly reduced when only scenes are considered that have (nearly) no snow outside of glaciers. Once a scene with good mapping conditions is identified, regional characteristics of the topography can result in persistent seasonal snowfields that might partly hide glaciers in the accumulation region and lead to the related uncertainties of the true glacier extent. In other regions such snowfields might be perennial (i.e., exist more than a year) and do not change their extent for decades. Often it is not possible to decide whether ice is underneath such perennial snow fields or not (Paul and Andreassen, 2009) and it has been recommended to either exclude or mark them for an inventory (Paul et al., 2009c). The problem of identifying debris cover on glaciers is also illustrated in Figure 3a and b for a region in Alaska and Pakistan, respectively. In the latter case it is nearly impossible to recognize the glacier at all. The problem of distinguishing seasonal from perennial snow or ice is illustrated in Figure 3c. Many of the elongated snow ridges have probably ice underneath but this could not be decided based on this image alone.

In Arctic regions, lakes could still be covered by ice at the end of the ablation period or sea ice is found on ocean water. Both features will be classified as glaciers with any method and manual correction is required. While sea ice or ice bergs can be easily identified and removed from the classification, a TM band 4, 3, 2 composite supports the identification of ice covered lakes (it is also helpful for editing lakes that are not covered by ice). However, when frozen lakes look very similar to flat ice caps, even human recognition might fail to distinguish them (Figure 3d).

A special case is related to optically thick clouds (e.g., cumulus), which might cover a glacier partly or completely and lead to errors in the derived surface area. At first, all clouds have to be identified. This could be done on a band 5, 4, 3 false color composite (FCC) where only clouds are white (exceptions exist for low and thin clouds). In the case of a small cloud that is completely surrounded by glacier ice it can be assumed that ice is also underneath and the cloud outline can be deleted. A cloud that partly hides the glacier perimeter in the ablation area could be corrected for short sections by considering glacier flow and surrounding rock walls. When both options do not apply, multitemporal analysis and image mosaicing can be considered to correct the outline, or the glacier has, finally, to be excluded from the analysis.

A further special case is volcanic ash on the glacier surface. It could be found on several ice caps in Iceland (e.g., Vatnajøkul) and other glaciers close to volcanoes in Alaska or South America. While optically thick, the ash layers could be very thin in reality and might have the same surface temperature than the underlying ice. In this case, the thermal band (TM6) can be used instead of TM5 for the ratio method. The lower spatial resolution of the sensor is in general not a problem on large ice caps, but the DNs of TM6 should be resampled bilinearly to the resolution of the other sensors before.



Automated Glacier Mapping, Figure 3 Examples of four challenging regions that require careful manual editing. (**a**) Debris-covered glaciers (Alaska Range, USA). The *black lines* indicate the extent from the automated mapping, the *yellow lines* show the extent after manual correction. (**b**) A small and highly debris-covered glacier in Pakistan as seen with Landsat TM (inset). The *yellow square* denotes the region of the large image that is taken from Google maps. Even at this high resolution (about 1 m) it is nearly impossible to determine the glacier terminus (probably located at the *black line*). (**c**) Seasonal or perennial snow fields (*white*) with probable ice (*grey*) underneath (Devon Icecap, Canada). (**d**) Frozen lakes (*blue outlines*) that are hardly distinguishable from flat icecaps (Baffin Island, Canada).

Applications

Once glacier outlines have been determined, a large number of further applications are possible. Combined with a DTM, the creation of glacier inventory data (e.g., Paul et al., 2002; Paul and Kääb, 2005; Paul and Andreassen, 2009) is likely a next step. Change detection using mutlitemporal analysis will also be in the focus of applications in the coming years (e.g., Paul et al., 2004b). Combined with other satellite based products, a larger number of additional glaciological investigations can be performed (cf. Bamber, 2006; Racoviteanu et al., 2008; Paul et al., 2009b). This includes mapping of snow extent and subsequent determination of mass balance terms (e.g., Rabatel et al., 2005), determination of flow velocities from multitemporal analysis (e.g., Kääb, 2005; Berthier et al., 2004), calculation of glacier specific thickness change from DEM comparison (e.g., Paul and Haeberli, 2008), or distributed mass balance modelling over larger regions (Paul et al., 2009a).

Conclusions

Overall, the largely automated glacier mapping from thresholded ratio images is simple, fast, and accurate. It is not fully automatic as pre-, main and post-processing requires human intervention and expertise (e.g., threshold selection and final editing). However, it allows to map all areas covered by ice and snow independent of their size and is reproducible. Debris cover on glaciers and some special cases (clouds, frozen lakes, volcanic ash) require particular attention during post-processing but can be handled in most cases by an experienced analyst. The opening of the USGS Landsat archive and the free availability of the SRTM DEM and ASTER GDEM have set the stage

for a completely new dimension of glacier inventory creation (outlines and topographic parameters) from satellite data at a global scale.

BASAL SEDIMENT EVACUATION BY SUBGLACIAL DRAINAGE SYSTEMS

Darrel A. Swift
Department of Geography, University of Sheffield, Sheffield, UK

Definition

Basal sediment: The debris layer that exists at the ice–bedrock interface of a glacier or ice sheet and that is produced by glacial erosion of the underlying bedrock.
Basal sediment evacuation: The removal of basal sediment from the ice–bed interface by glacial and/or glaciofluvial sediment transport; most frequently used to describe the flushing of basal sediment from the ice–bedrock interface by subglacial water.
Subglacial drainage system: The network of drainage pathways at the ice–bed interface that convey water to the glacier margin or terminus.

Introduction

Contemporary observations and theoretical analyses demonstrate that, for *Temperate Glaciers* (qv), the entrainment and transport of basal sediment by fluvial processes dominates all other glacial sediment transport (*Sediment Entrainment, Transport, and Deposition*, qv) processes (see Hallet et al., 1996; Alley et al., 1997). Basal sediment evacuation by the *Subglacial Drainage System* (qv) therefore dominates in glacial *Sediment Budgets* (qv) (Alley et al., 1997), and the high *Suspended Sediment Load* (qv) of most glacier-fed rivers presents a major difficulty for the management and use of meltwater (Østrem, 1975; Bezinge et al., 1989; Bogen, 1989).

Sediment entrainment by subglacial water is difficult to observe directly. However, the relatively rapid transit of water through the subglacial drainage system means that the suspended load of glacier-fed streams should reflect closely the processes of sediment entrainment at the glacier bed. Analysis of the sediment load of glacier-fed streams has therefore been applied widely as a means of elucidating the processes of basal sediment evacuation (e.g., Gurnell et al., 1992; Clifford et al., 1995; Hodgkins, 1996; Willis et al., 1996; Hodson and Ferguson, 1999; Swift et al., 2005a).

Controls on basal sediment entrainment and evacuation

Investigation of basal sediment evacuation has been confined largely to the analysis of suspended sediment time series from glacier-fed rivers in temperate alpine environments (see, e.g., reviews by Gurnell [1987a, 1995] and Gomez [1987]). These studies have highlighted considerable temporal variation in basal sediment evacuation at a wide range of scales (e.g., Bogen, 1988, 1996; Collins, 1990; Clifford et al., 1995) (*Suspended Sediment Dynamics*, qv) that has been linked to a complex array of subglacial processes. Nevertheless, hydrologically-driven seasonal evolution of the subglacial drainage system (*Glacier Hydrology*, qv) has been shown to exert a key control on rates and patterns of basal sediment evacuation because it greatly influences how and where subglacial water accesses, entrains, and transports basal sediment (e.g., Gurnell et al., 1992; Swift et al., 2005a).

Essential concepts

The processes of subglacial erosion and subsequent comminution of erosion products at the ice–bedrock interface (*Glacial Erosion*, qv) generate significant quantities of debris characterized by an extremely wide size distribution. The extent to which such debris accumulates at the ice–bedrock interface in the form of a basal sediment layer (*Till*, qv) will depend largely on the efficacy of sediment evacuation by glacial and fluvial processes. Fluvial

Vijay P. Singh, Pratap Singh & Umesh K. Haritashya (eds.), *Encyclopedia of Snow, Ice and Glaciers*, DOI 10.1007/978-90-481-2642-2,

sediment transport is widely appreciated to dominate basal sediment evacuation (e.g., Alley et al., 1997), but the efficiency of basal sediment evacuation by fluvial processes is dependent on subglacial water having sufficient competence and capacity to entrain and transport available sediment, as well as being able to access basal sediment sources and/or stores.

Fluvial sediment entrainment and transport processes in the subglacial environment are largely similar to those that operate in subaerial streams (e.g., Alley et al., 1997). Notably, the efficiency of sediment transport or evacuation reflects, on the one hand, the competence and capacity of flow, and on the other, the size and accessibility/availability of sediment. Flow strength is therefore critical because it determines both flow competence (the largest particle a given flow is able to carry) and flow capacity (the total quantity of sediment of a given size that the flow can carry). Although flow strength is best defined in terms of flow energy or boundary shear stress, many sediment transport studies use flow velocity or discharge (*Discharge/Streamflow*, qv), which in general provide convenient and acceptable approximations.

Both discharge and suspended sediment transport can easily be measured in glacier-fed streams (*Suspended Sediment Concentration*, qv). As a result, the predictably strong relationship between these two factors has been demonstrated by a very large number of studies. However, many such studies have also reported changes in basal sediment transport that have occurred irrespective of discharge, and these range from short-term flushes of sediment lasting minutes or hours, to longer-term changes over a single melt season or a series of melt seasons. Such changes have been attributed to both the subglacial processes that determine basal sediment availability and the ease with which available sediment sources and/or stores can be accessed by elements of the subglacial drainage system.

Importance of subglacial drainage system morphology

Two morphologically distinct types of subglacial drainage exist beneath most temperate glaciers and, in the case of polythermal glaciers, beneath warm-based ice. The most widespread system, both spatially and temporally, will be some form of *distributed system*. Such systems convey small volumes of water derived largely from *basal melting* via a physically tortuous flowpath that may include flow within linked cavities, thin water films, and/or porous sediments. Changes in discharge within this system are accommodated largely by changes in the number or size of individual flowpaths and not by changes in flow velocity. Hence, despite being spatially extensive, such systems entrain and transport only the very finest fractions of available sediment (e.g., Humphrey and Raymond, 1994; Willis et al., 1996; Alley et al., 1997).

The efficiency of basal sediment evacuation increases significantly if a *channelized drainage system* is present. Channel systems typically form in summer in response to the very large quantities of surface melt that are conveyed to the glacier bed via *Moulins* (qv) and *Crevasses* (qv). Although physically and temporally discrete, channels convey large discharges at very high velocities, and are also sufficiently large to transport all but the very largest fractions of basal sediment. The resulting competence and capacity of the channel system is such that the annual glacial sediment budget may be dictated almost entirely by the annual spatial and temporal extent of channelized drainage (e.g., Alley et al., 1997; Swift et al., 2005a). Furthermore, a number of mechanisms related to the inception and growth of the channel network are considered to influence temporal patterns of basal sediment evacuation.

One important reason why the channelized system is so efficient at transporting sediment is because the increase in flow velocity that occurs as a function of discharge is extremely nonlinear when flow is confined within a subglacial channel. Alley et al. (1997) demonstrated theoretically that the transport capacity of unconfined channels typically varies as Q^2 because changes in discharge can be accommodated equally by changes in flow depth, width, and velocity. However, for subglacial channels, which can only be enlarged by melting of the channel walls, rapid changes in discharge will be accommodated almost exclusively by changes in flow velocity, such that transport capacity will vary up to $Q^{4.5}$. Swift et al. (2005a) demonstrated that such relationships were a major factor behind seasonal changes in the efficiency of basal sediment evacuation at Haut Glacier d'Arolla, Switzerland, where sediment transport during periods of distributed drainage was shown to vary as $Q^{\sim 2.3}$, and during periods of channelized drainage was shown to vary as $Q^{\sim 3.2}$.

Observations at surging glaciers (*Glacier Surging*, qv), such as Variegated Glacier, Alaska, also demonstrate the importance of drainage system morphology for basal sediment evacuation (e.g., Humphrey et al., 1986; Kamb and Engelhardt, 1987; Humphrey and Raymond, 1994). Surging occurs when the channelized drainage system fails to develop as expected, promoting high basal water pressures and hence rapid basal sliding that further discourages channel formation. These studies show that basal sediment evacuation remains low during each surge, despite distributed drainage having wide access to the glacier bed, and despite high rates of basal sliding that should enhance rates of both basal sediment disturbance and subglacial erosion. In contrast, flushing of basal sediment occurs as the surge ceases and channelized drainage is reestablished.

Importance of basal sediment availability

Changes in sediment availability (and also accessibility) are believed to be significant because the sediment loads of glacier-fed streams are often only weakly correlated with discharge at annual scales. For example, Bogen (1989, 1996) linked poor correlation between annual sediment load and discharge from various Norwegian glaciers to changes in subglacial erosion rate, but also changes in the

location of arterial subglacial channels across successive melt seasons. Similarly, Gurnell (1995) linked annual sediment load from Tsidjiore Nouve, Switzerland to the rate of glacier advance, citing changes in sediment availability as a result of the rate of disturbance of subglacial drainage.

Studies of sediment transport in glacier-fed streams at shorter timescales have identified changes in sediment availability during specific periods of the melt season. For example, enhanced availability of basal sediment has commonly been observed in spring and has been explained in terms of: (1) a build-up of basal sediment over winter as a result of the absence of surface melt reaching the glacier bed (e.g., Liestøl, 1967; Hooke et al., 1985; Collins, 1989, 1990); (2) unprecedented access of water to the glacier bed as surface melt swells the distributed system (see previous references); (3) enhanced disturbance of existing subglacial drainage pathways and/or sediments as a result of enhanced rates of *Glacier Sliding* (qv) (e.g., Collins, 1989; Hooke et al., 1985); and (4) drainage system reorganization associated with the rapid incision and growth of a channelized drainage network (e.g., Collins, 1989, 1990; Anderson et al., 1999).

Another common observation is an overall decline in sediment availability during the melt season. This has been attributed both to the reduced ability of water to access basal sediment as flow becomes increasingly confined to discrete channels (e.g., Collins, 1989, 1990; Gurnell, 1987b; Gurnell et al., 1992) and to the exhaustion of sediments that are accessible to such channels (e.g., Østrem, 1975; Hooke et al., 1985). Nevertheless, a number of studies have demonstrated increasingly efficient evacuation of basal sediment during the melt season (e.g., Clifford et al., 1995; Vatne et al., 1995). Swift et al. (2005a) demonstrated that this may be a result of the increasing peakedness of surface melt production during the melt season, as this should promote: (1) an associated increase in the sediment transport capacity of subglacial channel flow (Clifford et al., 1995; Swift et al., 2005b); and (2) an increasingly strong diurnally reversing subglacial hydraulic gradient that should encourage basal sediment to flow or deform toward channels (Vatne et al., 1995; Swift et al., 2005b).

Short-term controls on basal sediment evacuation

On hourly to weekly timescales, temporal patterns of sediment transport are controlled largely by discharge, particularly the diurnal changes in discharge that reflect the temporal pattern of surface melt production (e.g., Gurnell, 1987b; Clifford et al., 1995; Willis et al., 1996). However, diurnal patterns of sediment transport are complicated both by *Hysteresis* (qv), where sediment concentrations at equivalent discharges on the discharge hydrograph are observed to be higher on the rising limb than on the falling limb, and by flushes of sediment on a variety of temporal scales that may or may not be related to changes in discharge.

Hysteresis is commonly evident both during individual diurnal discharge cycles (e.g., Leistøl, 1967; Østrem, 1975; Collins, 1979; Bogen, 1980; Hammer and Smith, 1983; Gurnell, 1982, 1987b; Willis et al., 1996) and over multiple discharge cycles or events, notably where the magnitude of a discharge peak fails to equal or exceed that of a previous peak (e.g., Leistøl, 1967; Østrem et al., 1967; Church, 1972; Collins, 1979; Gurnell, 1982, 1987b; Richards, 1984; Schneider and Bronge, 1996). Leistøl (1967) suggested that such hysteresis occurred because changes in discharge in a subglacial channel are accommodated at least partly by changes in flow width, such that flow on the rising limb accesses successively larger areas of the glacier bed, whereas flow on the falling limb is confined to areas that have been stripped of basal sediment. Transport hysteresis might also reflect velocity hysteresis, which describes the characteristically higher flow velocities that occur on the rising limb (e.g., Richards, 1984).

Flushes of sediment lasting hours or days have been linked to rapid changes in flow routing. For example, flushes commonly occur during spring as surface melt promotes the reorganization of distributed drainage pathways into discrete channels (Collins, 1989, 1990) and as incipient channels release stored water and sediment from within a swollen distributed system (Warburton and Fenn, 1994; Anderson et al., 1999). Flushes have also been linked to short-term injections of water into the distributed system resulting from intense rainfall (e.g., Raymond et al., 1995; Denner et al., 1999), the drainage of ice-marginal or intra-glacial water stores (e.g., Collins, 1979; Beecroft, 1983), or temporary blockages in subglacial channels (e.g., Collins, 1990). The injection of water into the distributed system may further facilitate flushing by enhancing ice-bed separation and basal sliding (e.g., Anderson et al., 1999; Hooke et al., 1985; Raymond et al., 1995; Swift et al., 2005a).

Shorter pulses of sediment, often lasting only seconds or minutes, can also contribute significantly to the total annual sediment load (Gurnell and Warburton, 1990). These have been linked largely to instabilities in elements of the subglacial drainage system, including: (1) the establishment of new drainage pathways or the migration of existing ones (e.g., Collins, 1979, 1989, 1990; Gurnell, 1982, 1995; Gurnell and Warburton, 1990; Gurnell et al., 1992; Willis et al., 1996; Hodson et al., 1997; Vatne et al., 1995; Hodson and Ferguson, 1999); (2) disturbance of basal sediment or subglacial flowpaths by sudden changes in the rate of basal sliding (e.g., Willis et al., 1996; Swift et al., 2005a); (3) blockage of channels by channel-roof failure (e.g., Lawler et al., 1992); and (4) the deformation and/or collapse of basal sediment toward or into adjacent channels (Collins, 1979; Vatne et al., 1995; Clifford et al., 1995; Bogen, 1996).

Feedbacks and significance for glacial erosion rates and sediment yields

Efficient evacuation of basal sediment is likely to be very important in glacial systems (*Glacial Ecosystems*, qv) because erosion of subglacial bedrock will be limited

where debris at the ice–bedrock interface accumulates to form a basal sediment layer (Alley et al., 1997). Efficient flushing of debris is likely to maintain glacial erosion by enhancing ice–bedrock interaction that is also likely to enhance the comminution of larger debris (*Crush*, qv) that is produced at the ice–bedrock interface by subglacial quarrying (Swift et al., 2002). The efficiency of basal sediment evacuation by subglacial drainage is therefore likely to be a dominant control on glacial *Erosion Rate* (qv) and *Sediment Yield* (qv).

The high sediment competence and transport capacity of subglacial channels indicates that the extent to which a spatially extensive channelized drainage network evolves during the melt season is also likely to be extremely important in dictating erosion rates and annual sediment yields (Swift et al., 2002; Swift et al., 2005b). Glaciers that evolve limited channelized systems and have predominantly distributed drainage are likely to have thicker and more extensive basal sediment layers that discourage ice–bedrock interaction and promote the entrainment and transport of sediment by glacial processes. The efficiency of basal sediment evacuation by subglacial drainage is therefore likely also to influence rates and styles of proglacial sediment deposition (Swift et al., 2002).

Areas of controversy and future research potential

Present understanding of basal sediment evacuation by subglacial drainage is limited largely to temperate ice masses. Few studies have been conducted at *polar* or *polythermal glaciers* (e.g., Hodgkins, 1996; Hodson and Ferguson, 1999), especially those glaciers that emanate from larger ice masses such as the Greenland ice sheet, even though the potential for surface melt to reach the ice–bed interface of such glaciers has now been demonstrated widely. As a result, the processes of basal sediment evacuation in such environments, including those that are associated with the seasonal evolution of subglacial drainage system morphology, may play an important but as yet poorly understood role in a wide array of subglacial processes at ice sheet scales.

The significance of fluvial sediment evacuation in glacial geomorphic systems is also poorly understood, most notably in terms of the importance of basal sediment evacuation in controlling rates of glacial erosion and resulting patterns of landscape evolution (*Glacial Geomorphology and Landforms Evolution*, qv) . Widely variable sediment yields (e.g., Hallet et al., 1996) indicate that glacier-to-glacier variation in the efficiency of basal sediment evacuation may be a critical control on rates of glacial erosion. Sediment transport by subglacial drainage may also play a critical role in the evolution of glacier-bed overdeepenings (*Glacial Overdeepening*, qv) (Alley et al., 2003) and their geomorphic impacts (*Glaciohydraulic Supercooling*, qv) (e.g., Swift et al., 2002; Cook et al., 2006). However, understanding is limited by an absence of sufficiently long-term records of sediment transport in glacier-fed streams, particularly with respect to bed-load (e.g., Alley et al., 2003).

Summary

Basal sediment evacuation by subglacial meltwater plays a key role in glacial systems. Notably, the efficiency of basal sediment evacuation is likely to determine the extent to which the products of glacial erosion are retained at the ice–bed interface (Alley et al., 1997), which is likely to dictate not only rates and patterns of subglacial erosion and glacial sediment yield, but also the proportion of debris in glacial versus fluvial sediment transport pathways, and as a result will greatly influence rates and styles of sediment deposition in ice-marginal environments (*Moraine*, qv) (see Swift et al., 2002). Nevertheless, the importance of basal sediment evacuation by subglacial water for glacial geomorphic processes has largely until recently been neglected by the glaciohydrological and glaciogeomorphological literature.

Definition

Base Flow: Between storms and runoff events, stream flow is maintained by groundwater discharge known as base flow, as long as the water table remains above the stream bottom (Delleur, 1999).
Groundwater: Groundwater is the liquid water flowing through aquifers. However, technically it includes soil moisture, permafrost, immobile water in very low permeability bedrock, and deep geothermal and oil formation water. It is the water (or ice) that resides beneath the ground surface in soil pore spaces and in the fractures of lithologic formations.
Aquifer: Aquifers are units of rock or an unconsolidated soil formation that can store and transmit a usable quantity of water.
Groundwater Flow: Groundwater flow occurs in soil and rock formations due to difference in hydraulic head or hydraulic potential within the unit or aquifer. The flow or discharge of groundwater is governed by Darcy's law, which is the product of the hydraulic conductivity or permeability of the rock or soil, the hydraulic gradient of the fluid, and the cross-sectional area of the aquifer.

Introduction

Groundwater is a component of the hydrologic cycle. Precipitation that falls on the land surface infiltrates into the ground until the rate of infiltration becomes less than the rate at which precipitation occurs. The excess precipitation at that point runs off the land surface into ditches, lakes, or streams and is called overland runoff. The amount of precipitation that infiltrates into the ground forms the groundwater. After entering the ground, the groundwater flows as lateral seepage due to capillary action of the soil pore spaces or percolates deeper into the subsurface to reach the groundwater table (top of groundwater saturation) and thus recharging the aquifer. Aquifers are bounded by streams. Groundwater discharges into streams when the water table rises above the streambed. This process is often referred to as the base flow. The amount of base flow a stream receives is closely linked to the permeability of rock or soil in the watershed. Readers are referred to Fitts (2002), Fetter (2001), Freeze and Cherry (1979), or McWhorter and Sunada (1977) for detailed description and hydraulics of groundwater flow and base flow.

Precipitation can occur in form of rain or snow. While the infiltration of rainfall has been studied extensively, the study of infiltration due to snowmelt and its impact on groundwater flow has been limited so far. Similarly, the study of base flow in seasonally freezing streams has also been limited. In northern latitudes, the dynamics of active layer (seasonally freezing soil) that stores significant quantity of infiltrated water as ice in winter or releases those as liquid water in spring has also been hardly studied. Williams (1970) studied groundwater flow in permafrost underlain lands in Alaska. He reports,

> Although groundwater in permafrost regions in Alaska occurs according to the same geologic and hydrologic principles prevailing in temperate regions, subfreezing temperatures result in profound modification of groundwater flow systems. Frozen ground is an impermeable layer, which restricts recharge, discharge, and movement of groundwater; acts as a confining layer; and limits the volume of consolidated deposits and bedrock in which liquid water may be stored.

Boulton et al. (1995) report,

> Ice sheets melting basally inject water into subglacial permeable beds under a maximum head equivalent to the total ice pressure." They conclude from their study on large aquifers in Sweden, the Netherlands, and Germany "that these large aquifers had a sufficient transmissivity to drain all subglacial meltwater; that groundwater heads, potential gradients and fluxes during glacial periods were very much larger than during interglacials; that proglacial permafrost played an important role in sustaining fluid overpressures in the ice sheet terminal zone; that during glacial periods major pressure pulses were driven through aquifer systems; and that groundwater systems were completely reorganized." Singh and Singh (2001) report, "The base flow (in glacial fed basins) is controlled by storage characteristics of the glacier and is determined by the delayed response of the basin.

Groundwater flow and base flow in permafrost regions

The study of groundwater flow and base flow systems in environments that are dominated by permafrost is quite sparse. Kane and Slaughter (1973) state that the understanding of groundwater flow in permafrost environments

have been grossly hindered due to the lack of subsurface data on permafrost. Kane and Slaughter state,

> Groundwater flow systems may be simply considered as comprising three components: recharge area, transmission zone, and discharge area... In permafrost settings, all three components (recharge, transmission, and discharge zones) can be affected by presence of local or regional areas of frozen ground. Permafrost in the recharge area can act as a barrier to downward water movement, thus restricting aquifer recharge. The presence of permafrost can affect groundwater movement in the transmission zone. For *suprapermafrost* groundwater, the permafrost forms an impermeable base; for *subpermafrost* groundwater, the permafrost acts as an overlying confining bed and thus creates a confined aquifer. Wells that penetrate permafrost to the subpermafrost groundwater are commonly artesian. The presence of permafrost in discharge zones can similarly influence the groundwater movement and yield.

Delleur (1999) states,

> ... permafrost under the right temperature may contain a mixture of unfrozen water and ice, or it may contain only ice. The unfrozen water exists as thin films adsorbed on surfaces of mineral particles and the thicknesses of the films are functions of temperature... Hydraulic conductivity in permafrost layers is a function of the temperature of the permafrost system, the thermal gradient and the available cross-sectional area of interconnected films of unfrozen water. Movement of groundwater is retarded in movement through permafrost, but permafrost acts more like a semi-confining bed of very low hydraulic conductivity and not like a completely confining bed of zero hydraulic conductivity. If the permafrost layers are fractured significantly, the higher overall hydraulic conductivity can be expected to be much higher than in unfractured permafrost.

An effect of base flow in the permafrost regions results in the formation of wetlands. Ford and Bedford (1987) provide a thorough review of the hydrology of Alaskan wetlands. They state,

> Little is known about the hydrologic behavior of arctic and subarctic wetlands (Roulet and Woo, 1986), including those that occur in Alaska... In the arctic and subarctic climates found in Alaska, water is present in solid phase for much of the year, and the influence of such typical high-latitude phenomena as glaciers, permafrost, and naleds (massive winter icings that occur in river valleys) on the volume, areal distribution, rate, and timing of water release become critical in understanding the hydrology of these high-latitude wetlands... Wetlands in continuous permafrost regions often have a perched water table in the active layer. The active layer is confined at the bottom by solid ice rich permafrost. The active layer thaws every year giving it a moving bottom boundary. This results in base flow change over the season and the runoff responds of a watershed on rain events therefore changes as the thaw season progresses. Climate change may affect the annual active layer development and change the rain fall responds and base flow of arctic streams (Reinhart and Jones, pers. com.). Ford and Bedford (1987) also state, "In discontinues permafrost zones little is known about how Alaskan wetlands affect groundwater recharge or about the areal extent and geographic distribution of wetlands maintained by groundwater discharge. However, some inferences can be drawn from the literature on individual arctic and sub-arctic drainage basins that are known to contain wetlands... Information on groundwater-flow systems in permafrost regions is sparse, although the pace of investigation is accelerating as development pressures encroach on high-latitude systems (e.g., Tolstikhin, 1978). Several characteristics distinguish groundwater hydrology in permafrost regions from that in other areas. First, rates of groundwater movement are generally lower than in equivalent temperate regions because of the increased viscosity of water at low temperatures (1.2–1.8 times higher) (Brandon, 1966; Church, 1974). Second, "ground-water" in these regions includes subpermafrost, intra-permafrost, and suprapermafrost (active layer) groundwater. In regions of deep, continuous permafrost, little or no hydraulic connection exists between the subpermafrost and suprapermafrost zones. Permafrost can act as an upper confining bed on the subpermafrost aquifer, which is typically artesian (Williams and Waller, 1966; Cederstrom, 1963; Kane and Slaughter, 1973; Linell, 1973)... In regions of discontinuous permafrost, there may be hydraulic connections between supra- and subpermafrost groundwater through unfrozen zones (taliks) that occur under lakes, rivers, and valley bottoms, and on south-facing slopes. Some taliks that are saline are also known as cryopegs (e.g., Cederstrom, 1961), and talik temperatures are therefore often below 0°C. If a thawed zone links the shallow and deep aquifers, artesian pressure can result in discharge to both wetlands and ponds (as base flow). In the larger northern river systems, groundwater discharge can be an important source of winter flow (Church, 1974). In many areas, however, seasonal frost can reach the permafrost table, restricting groundwater flow, increasing the hydrostatic pressure, and forcing water through cracks in the ice cover. As the continuous winter base flow rises to the surface and freezes in the frigid winter air, thick stream and river icings are created that can range in size from a few square yards to thousands of hectares (Dean, 1984)... these icings (also referred to as aufeis, or naleds) serve to redistribute total water discharge from small, continuous outputs during the cold season to a single, short-duration, catastrophic output at the beginning of the warm season (Sokolov, 1978). In spring, aufeis melt can comprise a significant portion of the total annual water volume of a river (Sokolov, 1978).

Snowmelt and groundwater flow or base flow

Bengtsson (1982) reports,

> There are often discussions about whether the snowmelt runoff takes place as overland flow at the base of the snowpack on the frozen ground, or whether the meltwater first infiltrates the frozen soil and thereafter contributes to an increase of the groundwater discharge. The problem has recently been discussed by Rodhe (1981), who from isotope studies found that most of the streamflow from a forested area in mid Sweden originated from groundwater. Similar studies have been made by Dincer et al. (1970) and Martinec (1975). Also in these investigations it was found that the main contribution to the peak streamflow was from groundwater (as base flow). Many hydrologists support the view that since the melt rate is rather low most of the melted snow infiltrates; others claim that since the ground below a snowpack is frozen, most of the meltwater flows along the ground. Of course, depending on the conditions both theories may be correct. The characteristics of overland flow and groundwater flow are, however, quite different... During a long cold winter runoff also takes place from a large groundwater basin. The

response of such basins to infiltrating meltwater is slow. The runoff from small groundwater basins ceases almost completely during a long winter. The interaction between infiltrating meltwater and streamflow depends on the characteristics of the groundwater basin and also on the conditions in the soil moisture zone (as the ground freezes). . . Observations over 6 years in the Luleâ region, cf. Bengtsson (1981), have shown that all the first meltwater infiltrates, and that the infiltration capacity of the frozen soil is very limited in the final phase of a long melt period. If it is assumed that the relatively large infiltration at the beginning of a melt period corresponds to a high recharge to the groundwater, and that the recharge is reduced in the later phase of the snowmelt, a steady state groundwater discharge is obtained also for aquifers of moderate hydraulic conductivity. . . From field measurements, Stephenson and Freeze (1974) found in their study that the mechanism of streamflow generation was subsurface delivery of meltwater over limited distances through shallow, highly permeable, low-porosity formations. From interpretation of the measurements by a mathematical model of transient saturated-unsaturated subsurface flow they also concluded that the peak streamflow came from early snowmelt near the stream. In their final discussion they showed that for soil conditions of very high and very low hydraulic conductivities, snowmelt is delivered promptly to stream channels as subsurface and overland flow respectively. The minimum response will occur in basins just permeable enough to sustain subsurface throughflow.

Glacial melt and groundwater flow or base flow

Most of the studies on interaction of glacial melt with groundwater systems has been based on reconstruction of geologic events from the past (e.g., Boulton et al., 1993 and references therein). Singh and Singh (2001) note that,

> An examination of streamflow from glacierized basin illustrates a considerable flow in the form of base flow during summer period. This base flow is controlled by storage characteristics of the glacier and is determined by the delayed response of the basin. Continuous drainage of water from various parts/locations governs the volume of base flow. It indicates that only a portion of the melt water produced each day reaches the snout on the same day. The remaining melt water is stored within the glacier, which gets delayed and adds to later day melt contribution (Martinec, 1970). In fact, the diurnal cycle of runoff also consists of a part of this continuing base flow. Investigations based on the tracer experiments, isotope studies and analysis of the runoff distribution suggest that the major contribution to base flow results from continuous runoff from the accumulation area (firn area), continuous drainage from the glacier lakes, water filled cavities and groundwater flow (Lang et al., 1979; Elliston, 1973; Collins, 1982; Stenborg, 1970; Tangborn et al., 1975). The base flow dominated with melt water from the accumulated area has higher time of concentration as compared with melt water generated in the ablation area.

Summary

Groundwater flow and base flow are impacted by snow, ice, permafrost, and glacial melt. Groundwater in permafrost regions occurs according to the same geologic and hydrologic principles prevailing in temperate regions; however, subfreezing temperatures result in profound modification of groundwater flow systems. Isotope studies have revealed that most of the streamflow from snowmelt runoff and main contribution to the peak streamflow originated from groundwater. An examination of streamflow from glacierized basin illustrates a considerable flow in the form of base flow during summer period. This base flow is controlled by storage characteristics of the glacier and is determined by the delayed response of the basin.

BED (BOTTOM) TOPOGRAPHY

Vijay Kumar
National Institute of Hydrology, Roorkee, India

Bed topography represents the shape and features of the riverbed. The shape of a riverbed is largely determined by the relief of the terrain through which river crosses. Riverbed topography varies due to local controls imposed by boulder, log, and gravel bar obstructions. Increased flow, as during a flood or high rainfall season, can make permanent changes to the riverbed by displacing rocks and boulders or by deposition of alluvium. In a meandering river, the riverbed topography is modified by the development of point bars at the inner side of each bend because of the localized deposition and erosion processes.

The riverbed topography affects the flow characteristics of a river. The frictional effects related to the riverbed topography make the flow of water in a river cross-section nonuniform. The river water may exhibit strong turbulence caused in part by certain features of the river topography. Riverbed topography is considered as a primary factor in creating rapids. Variation in riverbed topography influences the potential energy distribution at the boundary between the river and subsurface and could be a significant control on surface–subsurface interactions in the mountain rivers. Streambed topography influences groundwater–surface water interactions at a scale as small as channel bed slope units by creating localized pathways for stream flow in the subsurface that return to the surface a short distance downstream (Harvey and Bencala, 1993).

Measurement of riverbed topography plays a key role in validating sedimentary processes in experimental hydraulics. The repetitive measurement of riverbed topography is one of the common approaches used to estimate gravel load in rivers. The riverbed topography can be obtained by the measurement of set range lines by conventional land surveying equipment and techniques. New techniques of digital photogrammetry and image analysis (Westaway et al., 2003) and airborne LIDAR (Hilldale and Raff, 2008) can be used to generate riverbed topography.

BED FORMS (FLUVIAL)

Vijay Kumar
National Institute of Hydrology, Roorkee, India

Bed form can be defined as the feature developed on the bed of an alluvial channel due to the flow of water.

Bed forms are structures that are molded on beds where deposition takes place due to flowing water. Natural channels rarely have flat beds. When water carries loose grains across a horizontal bed of unconsolidated sediment, regular geometric patterns develop on the surface of the bed. Any particle that is larger than approximately 0.7-mm diameter will form visible topographic features on the riverbed or streambed. Shear stresses above the critical for transport will mold cohesion-less beds into discernible forms whose geometry depends on flow characteristics which in turn are influenced by those forms, resulting in complex feedback relationship (Knighton, 1998). Various concealed bed forms most commonly associated with sand bed are ripples, dunes, plane bed, and antidunes. Pebble clusters, transverse ribs, riffle-pool sequence, and step-pool systems are some of the bed forms developed in gravel bed streams. Sequences of steps and pools are generally formed in steep rocky channels.

The size and shape of bed forms depend on the flow strength and grain size. Very fine sand and silt are very easy to transport and erode. They form nice ripples, but do not form dunes when transported by water. Coarse sand and larger sediment are too hard to transport and erode to get ripples. For a given bed material size in the sand range, the sequence of ripples, dunes, plane beds, and antidunes is correlated with increasing flow intensity. At very low discharges, the bed of a sand stream may be dominated by ripples. As flow increases, sand dunes begin to appear on the bed. If discharge continues to increase, a point is reached when the flow velocity mobilizes the sand on the streambed and the entire bed converts again to a planar form. If discharge increases further still, antidunes may form.

BED ROUGHNESS

Vijay Kumar
National Institute of Hydrology, Roorkee, India

Bed roughness develops due to stream surface relief at the base of a flowing fluid and it exerts frictional effect on the flow in the stream. Bed roughness is considered to be smooth or rough depending on whether sediment particles project through the viscous sublayer at the base of the flow. Roughness generally increases with increasing particle size.

There are two components of bed roughness: (a) grain roughness which relates to the effects of the individual grains making up the channel bed and (b) form roughness which refers to features of bed forms such as ripples and dunes, created when certain alluvial substrates are moulded by the flow. Grain roughness refers to the shear forces created by sediment particles at the flow boundary. Grain roughness is mainly a function of relative roughness which is defined as the ratio of depth of flow and bed material size. Grain roughness can be the dominant component of the bed roughness where stream beds consist of gravel or cobbles.

The shape and size of in-stream sediment deposits, or bed forms contribute to the bed roughness. In sand-bed streams, form roughness is often considered more important than grain roughness (Knighton, 1998). Bed forms like ripples and dunes increase the roughness of the stream bottom, which tends to slow velocity and increase the depth of flow. Sediment cover of different sizes increases bed roughness.

Bed roughness plays an important role in streams. It helps to determine the depth or stage of flow in a stream reach. As flow velocity slows in a stream reach due to roughness, the depth of flow has to increase to maintain the volume of flow that enters the upstream end of the reach (a concept known as flow continuity).

BED STRENGTH

Vijay Kumar
National Institute of Hydrology, Roorkee, India

Bed strength (shear) represents the internal strength of the bed. It is determined by the amount of internal frictional resistance within the bed material. Bed strength depends on the sediment composition and the state of consolidation of bed. Shear strength increases when sediment grains are tightly packed together. Silt and clay particles, if present in a bed material, tend to stick together as a result of cohesive (attractive) electrochemical forces between the particles and so help in erosion resistance. Under normal flow conditions, there is a balance between the erosive power of the flow and the strength of the bed material. The changes in the channel form during major flood events, when the erosive power of the flow is greatly increased, depend on how much resistance is provided by the bed and banks. Bed erosion takes place when the bottom shear stress exceeds the strength, i.e., resistance forces, of the bed. The shear strength of the cohesive sediment bed is generally a linear function of the bed bulk density. Flowing water exerts shear stress on the bed material in the direction of flow. Shear stress is the frictional force per unit of bed area exerted on the bed by the flowing water. The faster the water velocity, the greater is the shear stress.

BENCHMARK GLACIER

Tobias Bolch
Department of Geography, University of Zürich-Irchel, Zürich, Switzerland

Synonyms

Reference glacier

Definition

A benchmark glacier is a glacier on which detailed direct measurements of seasonal glacier mass changes, meteorological environment, and streamflow variations are collected for an indefinite period, and which should be representative for a particular region.

Benchmark glacier, reference glacier and glacier monitoring

The term "benchmark glacier" was established as part of the monitoring strategy of the United States Geological Survey (USGS) (Fountain et al., 1997). The similar term "reference glacier" is in the monitoring strategy of the Global Terrestrial Network for Glaciers (GTN-G, http://www.fao.org/gtos/gt-netGLA.html) a glacier with a long-term, continuous, and continuing programme of mass balance observations. The benchmark and reference glacier concepts are similar; however, the reference glacier does not claim to be representative for other glaciers in a mountain range. The majority of benchmark glaciers were established during the 1960s as part of the International Hydrological Decade. The main objective here was to measure "typical" mass and energy processes on glaciers and to provide data on the resulting effect on streamflow in each mountain range in different climatic regions around the world (Fountain et al., 1997; UNESCO/IAHS, 1970). Hence, the selected benchmark glaciers are intended to be representative for a selected region or mountain range. Detailed direct measurements of seasonal glacier mass changes, glacier geometry, meteorological environment, and streamflow variations are to be collected at each benchmark glacier. Glacier mass balance shows a direct response to the climate variables and is hence a valuable component of climate monitoring. Front variation measurements are important complements to the mass balance measurements as they are less laborious, have a better global coverage (data available for about 1,700 glaciers worldwide, WGMS, 2008) and they extend much further back in time. The main drawback is that the length variations show an indirect climate signal, only.

Earliest glacier monitoring was initiated in 1894 for about 50 glaciers in the European Alps with the establishment of the International Glacier Commission (Haeberli, 1998). The longest record of continuous long-term measurements of glacier mass balance with ablation stakes on the glacier started at Storglaciären, Sweden in 1945. The benchmark glaciers have attracted new interest in the past decade because they are used to further understanding of the contribution of alpine glaciers to river run-off and global sea-level rise. The majority of the monitored glaciers have strong negative mass balances series. The global average shows moderate ice loss since the 1960s followed by accelerating mass loss since the middle or end of the 1980s up to recent years (WGMS, 2008).

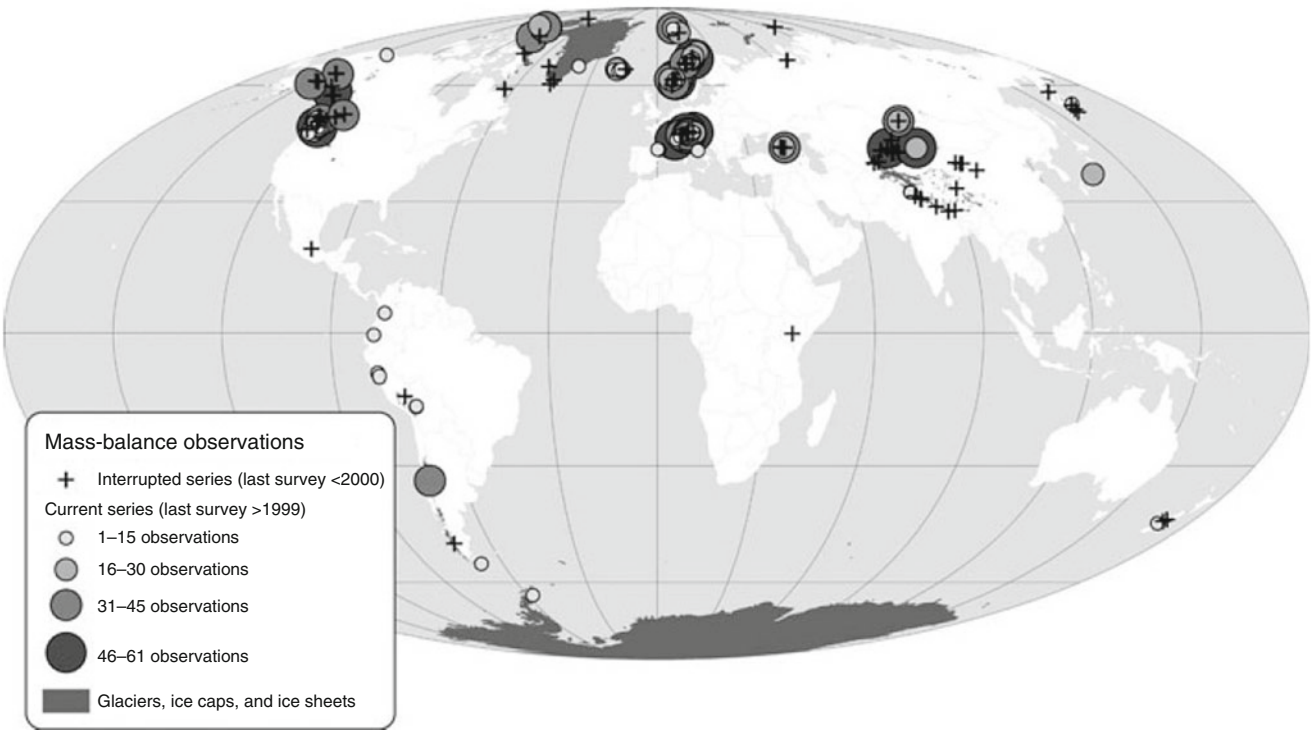
Distribution of benchmark glaciers and their representativeness for major mountain ranges

The distribution of benchmark glaciers with mass balance measurements are biased towards the northern hemisphere and Europe (Figure 1). Only about 10% are situated in the southern hemisphere. The longest mass balance series are found in the European Alps and Scandinavia. Other long-term measurements are located in North America and the high mountains of Asia. There is only one long-term measurement in the tropics (1979–1996, Lewis Glacier, Mt. Kenya). The large ice masses situated around the two ice sheets in Greenland and Antarctica, South America, and Northern Eurasia with few and short-term measurements are strongly underrepresented (Zemp et al., 2009). Altogether, there are mass balance measurements available from 228 glaciers, but only about 30 glaciers have continuous measurements since 1976 (Table 1). Mass balance measurements for 97 glaciers on the globe exist for the hydrological year 2006 (Zemp et al., 2009). Some measurements were begun in recent years in previously underrepresented regions such as the Andes, the Southern Alps in New Zealand, the Indian Himalaya, on the Tibetan Plateau, and the Antarctica in order to expand the worldwide coverage. However, other measurements were discontinued in the 1990s, especially in the high mountains of Asia (Caucasus, Tien Shan, Altay) (WGMS, 2008).

The intention in this chosen distribution of benchmark glaciers was to obtain representative data for mountain ranges in different climatic regimes. However, the choice of glaciers was often motivated by logistic considerations (e.g., accessibility). Hence, even when mass balance measurements do exist, their representativeness is often unclear. Fountain et al. (2009) found in a study on northwest USA that its benchmark glacier (South Cascade Glacier) is much larger, has a lower slope and its mass loss is greater than most other glaciers in the region. The glacier AX010 in the Nepal Himalayas with little longer term mass balance measurements (Fujita et al., 2001) is comparatively small (0.42 km² in 1999), low in altitude, and has no debris cover. Hence, it cannot be seen as representative for the Himalaya, as larger debris-covered glaciers are common in these mountains. In addition, its elevation is relatively low.

Discussion

The existing data from the benchmark glaciers are an important source of information on glacier changes over



Benchmark Glacier, Figure 1 Distribution of glaciers with mass balance observations (Source: Zemp et al., 2009, reprinted from the Annals of Glaciology with permission of the International Glaciological Society).

the corresponding period. However, further analysis is recommended in order to assess the representativeness of these glaciers for the corresponding mountain ranges and climatic zones (Fountain et al., 2009; Haeberli et al., 2007). Less intensive field studies on the mass balance of glaciers in the surrounding region ("Secondary Glacier Network," Fountain et al., 1997), front variation measurements, analysis of the Little Ice Age moraines, and remote-sensing-based analysis provide important supplemental data in order to assess the complexity for each glacierized region. A suitable method for assessing the representativeness of benchmark glaciers, besides measuring of length changes of surrounding glaciers, is the differencing of digital elevation models (DEM) (Paul and Haeberli, 2008). The glacier mass change is derived from a change in elevation over time (dh/dt). This so-called geodetic method requires exact elevation information for at least two periods in time (Bhamber and Rivera, 2007). Elevation data can be obtained by different methods such as altimetry (e.g., airborne LiDAR, ICESat GLAS); photogrammetry (stereo airborne or spaceborne imagery, such as from ASTER, SPOT); and interferometric synthetic aperture radar (InSAR, from repeat pass or single pass observations such as from ERS, Terra-SAR-X or the SRTM-Mission). Aerial imagery and data from reconnaissance satellite imagery such as Corona are suitable sources for extending the data back in time (Bolch et al., 2008). Topographic maps should be used with caution due to variing accuracy of the glacier outlines (Bhambri and Bolch, 2009). High accuracy can be obtained by airborne laser scanning (LiDAR). Geodetic derived mass balances and especially the latter method is an important source for calibrating the field measurements on mass balance as it can cover the entire glacier. The main advantage of remote sensing is that data can be obtained from glaciers or glacier sections which are difficult or not possible to access. Hence, new benchmark glaciers for remote-sensing-based monitoring could be selected. Remote sensing methods offer great opportunities for the future but cannot substitute for detailed field measurements on benchmark glaciers, as not all relevant data such as runoff can be obtained. In addition, all remote sensing methods need ground truth for verification and calibration.

Most of the relevant glacier data are collected by individual researchers and institutions with little funding, and compiled for public availability through WGMS. Not all data, however, is available through WGMS or other generally accessible databases such as the National Snow and Ice Data Center in Boulder/Colorado (www.nsicd.org). In order to improve the knowledge about the worldwide glacier changes and their consequences (e.g., sea-level rise), an approach combining detailed field investigations on benchmark glaciers with remote sensing

analysis and distributed mass balance modelling is recommended (Haeberli et al., 2007). New benchmark glaciers with intensive field studies in so far underrepresented regions should be established. These glaciers should be carefully selected based on statistical considerations concerning climate and glacier characteristics (size, dynamics, debris cover, accumulation area ratio, etc.) in order to match the goal to be representative. However, they need to be also accessible in order to be able to perform continuous measurements.

Conclusions

Benchmark glaciers have long-term continuous measurements and should be representative for a certain region. The existing detailed measurements on the selected glaciers are of high importance but they have to be checked for their representativeness. If required, the data has to be adjusted so as to be seen as representative. It is recommended to publish all available records, to extend the monitoring network to previously underrepresented regions with no or few measurements, and to monitor glaciers based on remote sensing in order to reach the major objectives of the benchmark glacier concept: to obtain a worldwide overview of glacier variability based on detailed measurements on selected representative glaciers.

Glacier Mass Balance

BIOGEOCHEMISTRY OF SEA ICE

David N. Thomas
School of Ocean Sciences, College of Natural Sciences, Bangor University, Menai Bridge, Anglesey, UK

Synonyms

Land-fast ice; Pack ice

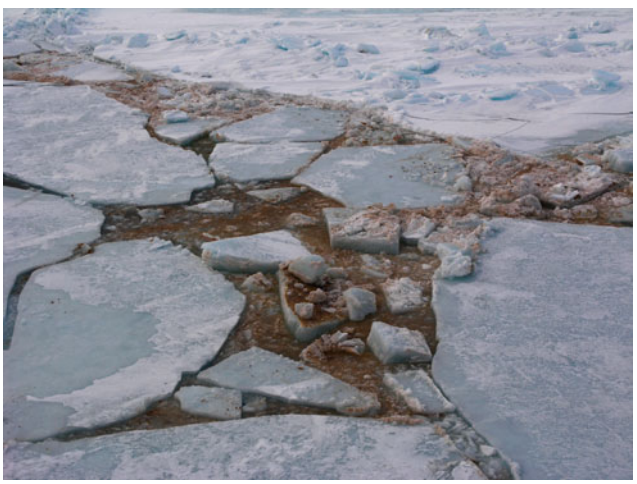
Definition

Salinity: The sum of all dissolved salts in grams per kilogram of seawater
Primary production: Photosynthetic carbon fixation per unit area, per unit of time.
Autotrophy: The ability to utilize inorganic carbon (usually CO_2) as the sole source of carbon for organic synthesis, based on energy from light (photoautotrophic) or from oxidation of inorganic compounds (chemoautotrophic).
Heterotrophy: The ability of an organism to obtain carbon for organic synthesis by metabolizing organic materials.
Psychrophilic: Describing an organism that lives and grows optimally at relatively low temperatures, usually below 15°C, and cannot grow above 20°C. Psychrophiles consist mainly of bacteria, algae, fungi, and protozoans; extreme psychrophiles can grow at subzero temperatures.

Introduction

Every autumn and winter, a fundamental transition occurs in the surface waters of the Arctic and Southern Oceans, and nonpolar seas such as the Baltic, Caspian, and Okhotsk. The surface waters of millions of square kilometers freeze to form an ice layer that varies from a few centimeters through to several meters thick, and which effectively separates the ocean from the atmosphere above. Ice made from seawater is a porous, semisolid matrix permeated by a labyrinth of brine channels and pores, and within these a diverse microbial assemblage, including viruses, archaea, bacteria, flagellates, and unicellular algae can thrive (Figure 1). The microbial assemblages are in turn a rich food source for grazing proto- and zooplankton, especially in winter when food in the water column is scarce (Brierley and Thomas, 2002).

The study of biogeochemical processes in sea ice originated from the long-established ecological studies of organisms living in or at the peripheries of ice floes in the Southern and Arctic Oceans. In the past 30 years, our knowledge of the diversity of organisms associated with the oceanic cryosphere and the ecological interactions of sea ice assemblages has received considerable research effort and these works are extensively reviewed (contributions in Thomas and Dieckmann, 2010). In an effort to more clearly emphasize the biological drivers for current sea ice research, Arrigo and Thomas (2004) concluded that the term ecobiogeochemistry would be a better reflection of current of the way must sea ice research is conducted. It will become clear during this short review that there is a case for describing the current multidisciplinary study of sea ice under the rather impractical term



Biogeochemistry of Sea Ice, Figure 1 Antarctic ice floes demolished by an ice-breaking research ship. Within the debris, the dark brown color of extensive sea ice assemblages is revealed.

of physico-ecobiogeochemistry: The unique temperature and salinity and space limitations within the frozen sea ice matrix mean that any study of biology, chemistry, or geochemistry that does not consider the pertinent abiotic drivers is considerably compromised.

Freezing of seawater

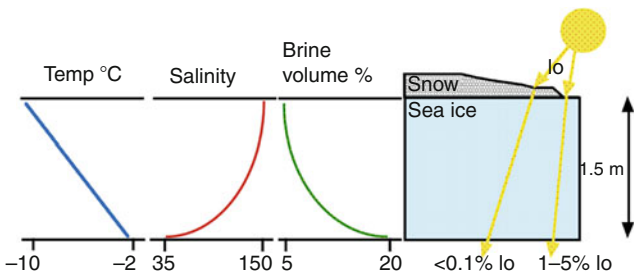
It is important to keep in mind that sea ice is ephemeral, and for most systems on Earth the life span of most ice formed in autumn or winter is less than 6 months. There are regions where multiyear sea ice is well documented, and in the past thick multiyear ice floes (over 5 years old) where a characteristic of the Arctic system that was often cited as one of the main characteristics that differentiated Arctic and Southern Ocean systems. However, with the recent well-recorded changes in Arctic sea ice extent and thickness (Serreze et al., 2007), it is predicted that within the next 2 decades, 90% of the sea ice on Earth will not be older than 1 year, and the majority of this will be probably only last less than 6 months.

When seawater freezes (at −1.86°C) ice crystals form and float to the surface of the water column where they collect. On further freezing, the crystals coalesce to form a rigid structure of ice, the form of which is greatly influenced by the nature of the turbulence of the waters in which the crystals are formed. As ice crystals grow, the dissolved constituents of the water are expelled, and this results in the formation of a system of channels and pores permeating the ice matrix. These are filled with concentrated brines derived from the ice crystal mass. Since temperature determines the mass of ice, therefore it also determines the volume of brine and the concentration of dissolved constituents, or salinity of that brine (Figure 2). At −6°C, the brine salinity is 100, at −10°C it is 145, and at −21°C it is 216. The brines are not static and gravity results in a high proportion of the brine draining out of thickening ice sheets and in time the ice becomes desalted. The bulk properties of ice integrate the ice mass and brine, so that although a piece of ice at −10°C may contain brines with a salinity of 145, the bulk salinity of ice when melted is less than 10. In the absence of any other processes (i.e., biological), the relationship between dissolved constituents (gases and ions) should lie on a conservative dilution line, and it is the correlation of measurements made on bulk ice samples with calculated dilution lines that are the fundamental of sea ice biogeochemical studies: Below the dilution line implies the biology has consumed the constituent, above that the biological activity has produced the constituent.

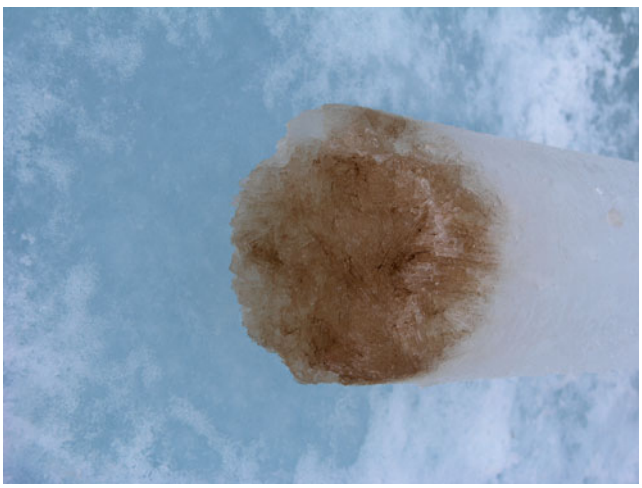
Ultimately, the distribution of biology in sea ice is limited by the space available, for example, a millimeter sizes crustacean cannot live in a micrometer-sized pore or channel. For this reason, the most concentrated biological accumulations in sea ice are found at the peripheries of ice floes (Figure 3), because they are in contact with the surrounding water or close to the freezing point of seawater. This means that the pore/channel space is large and the exchange of seawater means that replenishment or exchange of gases and nutrients is possible. However, typically just 5–10 cm into the ice away from the peripheral edges temperatures are of such that brine volumes are low and exchange processes are severely restricted (Figure 4).

Sea ice biological and chemical interactions

The biology that lives within the sea ice matrix exhibits a wide range of metabolic, physiological, and, in some cases, life-history strategies that enable them to withstand the temperature, salinity, and light gradients that exist across any ice floe (Thomas and Dieckmann, 2002). However, it should not be forgotten that any organism that is found in the ice is recruited from the open water plankton. It is true that many of the protists are psychrophilic and some have only been described in ice and so must



Biogeochemistry of Sea Ice, Figure 2 The physical nature of an ice floe is dominated by gradients in temperature, which in turn determine the salinity of brines and brine volume (porosity) of the ice. Likewise, the ice determines the light availability for photosynthesis. The incident irradiation (I_o) is very much reduced by the bottom of an ice floe where much of the biology is. This is significantly more reduced if snow covers the ice floe.



Biogeochemistry of Sea Ice, Figure 3 This tilted ice floe illustrates that the peripheries of the ice floe are where the biology concentrates.

Biogeochemistry of Sea Ice, Figure 4 The bottom of an ice core (9 cm in diameter) illustrating that most of the biology is restricted to the bottom 10 cm in the ice floe from which this core was taken.

be present in the plankton as dormant stages or cysts (e.g., ciliates and bacteria); however, there are many examples of organisms that are equally flourished in the plankton and ice.

When thinking about biogeochemical processes in aquatic systems, the balance between autotrophic and heterotrophic production and organic matter cycling and inorganic nutrient regeneration is mainly mediated through a complex microbial network. In the open ocean, the efficiency and impact of this network is strongly influenced by the distribution: for example, in reality there can be relatively large distances between microalgal autotrophs releasing organic matter into the water column and the bacteria that use such matter for growth. Resupply of nutrients or removal of gases are diffusion-driven, and as such are strongly influenced by turbulence on various scales from the micro through to the overturning of water masses. Organisms living within sea ice are of course very much more concentrated than in the water column, and therefore there is the potential that the biogeochemical processes are considerably more efficient, quicker, and enhanced. In contrast to this concept, naturally the light, salinity and temperature constraints in sea ice greatly influence the metabolism/physiologies of organisms, and the kinetics of biogeochemical processes, and in many cases these are slower than would be measured in open-water conditions. Therefore, in overall biogeochemical processes terms the consequences of dense accumulations of enhanced biological interactions may be a compensation for the suboptimal biochemical reaction rates.

It seems prudent to consider sea ice accumulations of biology and the biogeochemical characteristics that they have as being more akin to marine surface sediments in shallow waters and/or biofilms, rather than simply being a concentrated open-water network (Krembs and Deming, 2008). A consequence of life in the ice is that some metabolic processes cause significant biochemical changes in organisms that can markedly alter the geochemical "signatures" of the organisms when they sink to the ocean floor and are incorporated into marine sediments. An obvious result of this is that biochemical markers of previous sea ice extent over geological time are available to researchers (e.g., Belt et al., 2008).

Sea ice bacteria from Arctic ice have been shown to be active at temperatures down to −20°C, and motile down to −10°C (Deming, 2002; Deming and Eicken, 2007). It is thought that cryoprotectants such as antifreeze may be produced to inhibit ice crystal formation. The antifreeze proteins produced by bacteria are possibly part of the large pool of extracellular polymeric substances (EPS) located on the cell surface. In particular, the CFB group of bacteria is known for its abundant slime EPS production under decreasing temperatures. Such EPS have been found in other cold adapted bacteria and by unicellular algae isolated from sea ice. As a consequence, EPS concentrations in sea ice can be very high (Krembs and Deming, 2008).

There are ice-active substances (IASs) or ice-binding proteins (IBPs) produced by sea ice diatoms and bacteria. These (mainly glycoprotein's) have been shown to bind preferentially to ice crystals, causing pitting in the ice crystal surfaces. This pitting may in turn alter the optical properties of sea ice and may also help to maintain fine pore space structure. However, it might be that some interaction of the IASs/IBPs on the surface of cells increases the ability of cells to stick to ice surfaces, or is involved

in protecting cells from freeze-thaw damage (reviewed by Mock and Thomas, 2005, 2008).

Besides avoiding freezing, the transport of essential nutrients and gases through the cell membranes has to be guarantied under low temperatures and high salt concentrations. Hence, change increase in membrane fluidity is one of the most important acclimations during temperature reduction and is therefore well-documented particularly for bacteria. It is clear that a decrease in temperature leads to one or some combinations of the following changes: An increase in fatty acid unsaturation, a decrease in average chain length, an increase in methyl branching, and an increase in the ratio of anteiso-branching relative to iso-branching. Furthermore, polyunsaturated fatty acids (PUFA) are not normally detected in temperate bacteria but ω3 and ω6 fatty acids such as 20:5($n-3$) are often found in significant amounts in lipids of sea ice bacteria (reviewed by Mock and Thomas, 2005, 2008).

Besides temperature, salinity is probably the factor that has the greatest influence on the organisms living within the brine channel system, especially in cold ice where the brine salinities are typically three or four times seawater concentrations. The ability for diatoms to acclimate to hyperosmotic brine solutions is based on their ability to synthesize intracellular compatible solutes including amino acids such as proline and other cryoprotectants such as dimethylsulfoniopropionate (DMSP). Antarctic researchers have shown that very high concentrations of DMSP can be produced by ice algae assemblages reaching concentrations of over 1,500 nM, considerably more than seawater values that are typically below 50 nM (Trevena and Jones, 2006). DMSP is broken down to dimethylsulphide (DMS) and in remote ocean regions, DMS accounts for most of the non-sea salt sulfate in the atmosphere, and the oxidation of DMS in the atmosphere to aerosol particles and cloud condensation nuclei is part of a complex system of localized and global climate control. The greatest release of DMS from sea ice regions is associated with melting ice and the corresponding reduction in ambient salinity, when cells containing hypersaline-induced high concentrations of DMSP are released into the seawater. Periods of ice melt are also times when elevated grazing activity in ice edge waters will increase the release of DMS into surface waters and therefore into the atmosphere (Stefels et al., 2007). Of particular interest is the breakdown of DMSP to DMS and subsequently into methanesulphonic acid (MSA) which can be used as a proxy in glacial ice cores for past sea ice extent estimations (Curran et al., 2003; Dixon et al., 2005).

The still limited data on dissolved gases in sea ice brines indicate that when there is high primary production, and accumulation of large algal standing stocks in sea ice, the brines are characterized by substantial reductions in total inorganic carbon, pH values up to 11, and O_2 supersaturation (Papadimitriou et al. 2007). As stated previously, at high diatom standing stocks in the ice in general species diversity decreases. Gleitz and Thomas (1993) showed that as first-year sea ice grew and high algal standing stocks established the assemblages were dominated by only a very few small diatom species, and they suggested that pore and channel size was the major determining factor. However, Gleitz et al. (1998) subsequently concluded that it was the physiological capacity of these species to maintain high growth rates in the spring and summer, in connection with their life-history cycles, that may be the key to the prominence of so few diatom species in the ice for example. The ability to sustain photosynthesis at high O_2 and low CO_2 in a strongly alkaline environment will be a critical prerequisite for survival of algae within the ice. For example, the ability of algae actively to assimilate HCO_3^- at very low CO_2 (aq) concentrations is considered to be a decisive factor for the success of small diatom species common in sea ice algal assemblages (Gleitz et al., 1998).

Not all biogeochemical processes in sea ice are mediated by biology, and at low temperatures and high salinities, physicochemical processes are known to occur: Mineral precipitation from sea ice brine has been well characterized and the most thermodynamically consistent sequence of minerals precipitating from seawater derived brines during freezing is known as the Gitterman pathway and consists of calcite ($CaCO_3$) at −2.2°C, mirabilite ($Na_2SO_4.10H_2O$) at −6.3°C, gypsum ($CaSO_4.2H_2O$) at −22.9°C, hydrohalite ($NaCl.2H_2O$) at −22.9°C, sylvite (KCl) at −33.0°C, and $MgCl_2.12H_2O$ at −36.2°C. Documented observations of mineral precipitation in sea ice are still scarce in natural settings, but there is recent field evidence for ikaite formation in Antarctic late-winter sea ice (Dieckmann et al., 2008).

Summary

The frozen oceans and seas have held a wide-reaching fascination ever since the first explorers ventured into these realms. In the last 30 years or so, researchers have discovered that the ice is far from being a barren wasteland devoid of life. In contrast, sea ice supports a rich diversity and prolific life that is a vital part of the ecosystems over which the ice covers. The biogeochemical processes within sea ice have profound implications for the biogeochemistry of underlying waters and the ocean–atmosphere interactions. Our understanding of these processes is still hampered by the logistical difficulties in operating in such environments although this is being addressed in recent years as technology is developed that permits long-term programs of research to be established (see contributions in Thomas and Dieckmann, 2010).

BLUE ICE

Richard Bintanja
Royal Netherlands Meteorological Institute (KNMI),
De Bilt, The Netherlands

Definition

Localized bare-ice regions on the Antarctic polar plateau.

Blue ice areas, which until now have only been found on the Antarctic ice sheet, are formed when wind conditions can erode the snow. These are often more localized regions, usually only a few square kilometers in area, where the topography has induced a surface wind field that favors continuous erosion of snow, leaving bare (blue) ice. Usually, but not exclusively, these blue ice areas are found in the wake of mountains protruding through the ice surface. Over the course of time, strong, turbulent surface winds erode the entire snow deck. Once the ice layers are surfaced, snow is unable to stick to the smooth ice, preventing the blue ice area from being covered by snow again. Blue ice areas are characterized by subzero temperatures, so that melting is insignificant, which differentiates them from regular glacial ablations zones.

The persistence of blue ice areas is reinforced by strong sublimation rates. Since blue ice is darker than the adjacent snow fields, and hence the surface albedo lower, heating through solar radiation is more vigorous, creating a relatively mild local climate in which the ice surface loses mass through sublimation. While only a tiny fraction of Antarctica is covered by blue ice, their bluish appearance makes them fairly easily recognizable from space. If climate-induced changes in local temperature and wind somehow affect the spatial extent of blue ice areas, these regions may be used as an indicator of climate variations taking place over the southern continent.

Blue ice areas feature a number of scientific and practical applications. First, since the ice originates from compacted snow accumulated long ago in adjacent snow regions, it may be very old with the potential of yielding paleoclimatic information from the air bubbles inside the ice. Second, blue ice areas are essentially the ablation zone of a much wider catchment area, where under favorable conditions meteorites that fall into this catchment area can accumulate by converging ice flows. The vast majority of meteorite specimens found on Earth were collected on Antarctic blue ice areas on the polar plateau. Finally, because of their smoothness, blue ice areas are commonly used as landing strips for aviation; the regular occurrence of wind-induced surface ripples provides the grip required.

BOTTOM MELTING OR UNDERMELT (ICE SHELF)

Ashok Kumar Verma
Cold Regions Research Center, Department of Geography & Environmental Studies,
Wilfrid Laurier University, Waterloo, ON, Canada

The basal melting of a snowpack or a glacier is termed as bottom melting. This term often related with glacier ablation, or under-melt for sea ice (Menzies, 1995). Various convective phenomena are responsible for the bottom melting which mainly depends upon the bulk temperature and velocity of the water and for the sea ice, would be salinity. The addition of sensible heat can cause the internal melting of the ice cover which could be added to the ice through conduction or radiative process. The overall effect of heat flux is to raise the bulk temperature of the ice to the point where preferential melting begins. The presence of snow at the upper surface may affect the process and magnitude of the bottom melting as it diverges the heat transfer to the underlying ice layers (Lock, 1990).

The process of melting initiates at the vicinity of impurities and the grain boundaries. The effect of impurities following the melting can be seen as rotten ice which is a reflection of granular structure of the ice. These effects can be seen in the sea ice with the formation of different colors and forms of sea ice (Weeks and Ackley, 1986) (Armstrong et al., 1973). Intergranular melting weakens the ice cover in combination of several other mechanical actions arising due to the wind and water behavior. The combined effect of the thermal expansion and undercurrents are capable of opening fissures in the cover. Wind magnifies the effects of opening fissures to the fragmentation of the ice covers. Warming of surface layer of water induce the convective instabilities which accelerate the bottom melting processes.

BRASH ICE

Chelamallu Hariprasad
Centre for Studies in Resource Engineering,
Indian Institute of Technology, Bombay, Powai,
Mumbai, Maharashtra, India

Accumulation of floating ice made up of fragments less than about 2 m across is called brash ice. Brash ice often forms between the ice floes. Brash ice consists of frazil

Brash Ice, Figure 1 Description: Brash ice forming at sundown in calm glacier bay, Patagonia, Chile (http://www.dreamstime.com/abstract-brash-ice-image1851031, Dated on April 27, 2009).

Brash Ice, Figure 2 Description: Brash ice, icebergs on an ocean as smooth and shiny as a mirror, Neko Harbor, Andvord Bay, Antarctica (http://www.dreamstime.com/brash-ice-icebergs-on-an-ocea-image2131394, Dated April 27, 2009).

ice that grows during freeze-up as well as rudiments of fracturing and colliding floes. Brash ice also originates from sea ice that is breaking up or commonly as debris from calving ice bergs or ice bergs that break up as part of their ongoing erosion. Whenever one large piece of ice falls off another, brash is generated and can cover quite large amounts of sea. Brash ice is considered ideal for studies of the properties of completely fresh sea ice, particularly because brash ice is a slushy mixture of ice and water that characterizes the first phase of ice formation in turbulent water, forms more rapidly than ice that freezes solid (Figures 1 and 2).

CALVING GLACIERS

Charles R. Warren
School of Geography and Geosciences, University of St. Andrews, St. Andrews, Scotland, UK

Calving glaciers terminate in water and lose mass by calving, the process whereby masses of ice break off to form icebergs. Since they may consist of temperate or polar ice, may be grounded or floating, and may flow into the sea or into lakes, many types exist. They are widely distributed, but while lake-calving glaciers may exist in any glacierized mountain range, tidewater glaciers (Tidewater Glaciers) are currently confined to latitudes higher than 45°. Typically, calving glaciers are fast flowing and characterized by extensional (stretching) flow near their termini, resulting in profuse crevassing (Crevasses). They usually terminate at near-vertical ice cliffs, which are typically a few tens of meters in height but are sometimes as much as 80 m high. Calving activity above the waterline comprises a continuum from small fragments of ice to pillars the full height of the cliff. Below the waterline much ice may be lost through melting, but, in deep water, buoyancy causes infrequent but high magnitude calving events. In some settings, thermal erosion (melting) at the waterline can cause calving by undercutting the cliff. The calving process permits much larger volumes of ice to be lost over a given time than melting; this is seen spectacularly at the margins of ice shelves (Ice Shelf) from which tabular icebergs (Iceberg) with surface areas of many tens of square kilometers can be released. For example, over 35 days in 2002, an area of 3,250 km^2 of the Larsen Ice Shelf in Antarctica calved catastrophically, releasing 720 km^3 of ice into the ocean.

Glaciers calve faster in deeper water. This correlation between calving rate ($\underline{u}_c$ in meters per annum) and water depth (h_w) is linear, and can be simply expressed as $\underline{u}_c = c\underline{h}_w$. The value of the coefficient c varies greatly in different settings, being highest for temperate glaciers and lowest for polar glaciers. Also, for any given water depth, calving is an order of magnitude faster in fjords (Fjords) than in lakes, largely as a result of the effect of the different water densities on the buoyancy forces acting on the ice. Much of our understanding of the dynamics of calving glaciers stems from intensive studies of a small number of Alaskan glaciers (Alaskan Glaciers), particularly Columbia Glacier and LeConte Glacier (Meier, 1997; O'Neel et al., 2001). This work established the empirical u_c/h_w relationship, but left the physical processes behind it unclear. Modeling has subsequently shown that this relationship, and the contrasting calving rates in tidewater and freshwater, can be understood with reference to intricate feedbacks between calving and glacier dynamics (Dynamics of Glaciers) (Van der Veen, 2002; Benn et al., 2007). In essence, calving rates are controlled primarily by variations in longitudinal strain rates and ice velocities (especially sliding speeds), which determine the density and depth of crevassing.

Calving glaciers are significant for three main reasons:

1. *Glacier dynamics.* Calving glaciers comprise the most dynamic elements of many of the world's ice masses, and calving is the major means of ice loss from the two continental ice sheets of Antarctica and Greenland (Antarctica and Greenland Ice Sheet) (Rignot and Kanagaratnam, 2006). An understanding of calving processes is therefore critical for predicting cryospheric response to future climate change and consequent sea-level rise; our present limited understanding of the links between climate and ice dynamics hinders such predictions (Nick et al., 2009). During the waning stages of Quaternary glacial periods

Vijay P. Singh, Pratap Singh & Umesh K. Haritashya (eds.), *Encyclopedia of Snow, Ice and Glaciers*, DOI 10.1007/978-90-481-2642-2,

(Quaternary Glaciation), calving was the dominant process of mass loss around the midlatitude ice sheets, and calving processes strongly affected their patterns of growth and decay. Armadas of icebergs discharged during ice sheet collapses are believed to have caused global climate change by altering oceanic circulation. Calving has also accounted for the rapid collapse of ice shelves around the Antarctic Peninsula in recent decades, most notably the Larsen ice shelves.

2. *Non-climatic behavior*. Calving glacier fluctuations are highly sensitive to topographic controls, with advances and retreats often being punctuated by stillstands at topographic pinning points – locations of relative narrowing and shallowing. Some tidewater glaciers fluctuate cyclically, in ways unrelated to climate, over distances of tens of kilometers and over timescales of centuries to millennia. Therefore, neither the contemporary behavior of calving glaciers nor the geomorphological records from past fluctuations can be interpreted straightforwardly as indicators of climatic change (Warren, 1992; Vieli et al., 2001).
3. *Socioeconomic impacts*. Calving glaciers can provide resources for society, but they also represent significant hazards. Resources include tourism and the medium-term possibility of harnessing Antarctic tabular icebergs as a source of freshwater, while hazards include icebergs and glacier lake outburst floods (Glacier Lake Outburst Floods). With continued global warming (Global Warming and Its Effect on Snow/Ice/Glaciers), calving may lead to rapid and sustained loss of ice from the marine ice sheet (Marine Ice Sheet) of West Antarctica, in turn causing global sea-level rise of 3–4 m (Sea-Level).

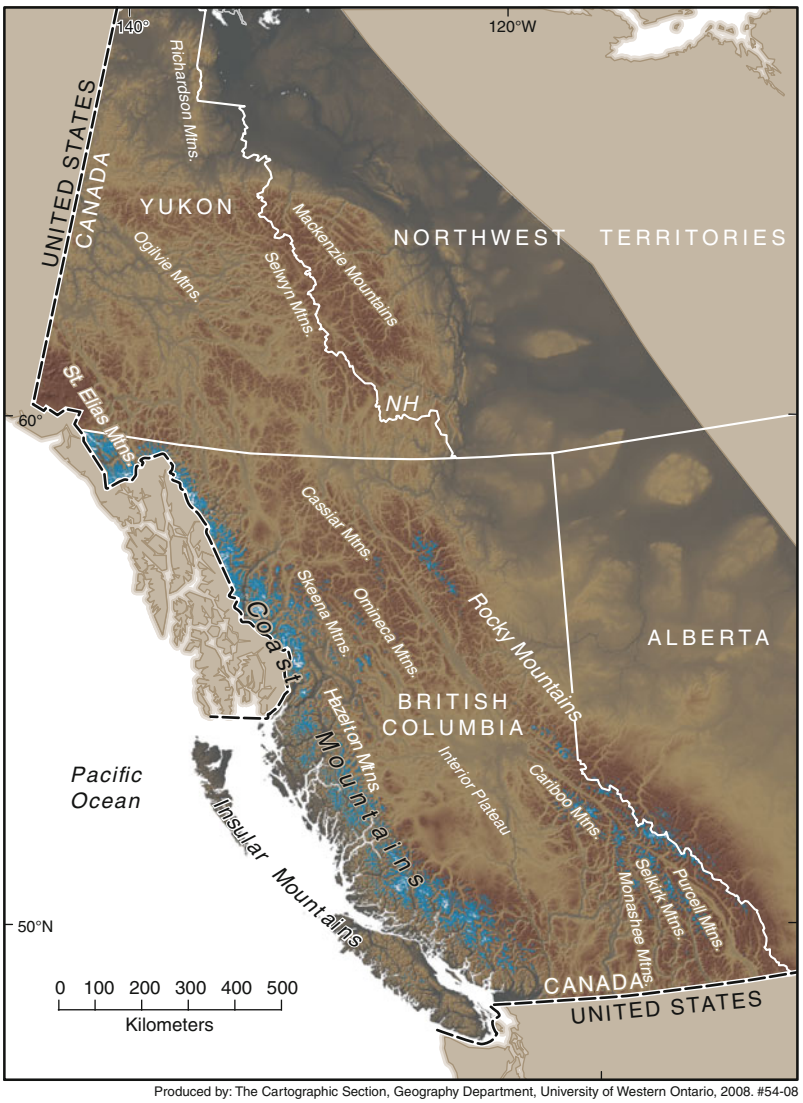
Definition

Alpine glaciers cover about 26,000 km^2 of British Columbia and westernmost Alberta. The glacier source areas are cirques and plateaus above about 1,500-m elevation in several mountain ranges that trend northwest through the two provinces. Some glaciers in the Coast and St. Elias Mountains extend down to elevations below 500 m asl and one (Grand Pacific Glacier) calves into the sea. This article summarizes the distribution of glaciers in British Columbia (B.C.) and Alberta, discusses the mass balance and climatology of the glaciers, and describes historical changes in ice cover.

Introduction

The total area of glaciers in British Columbia (B.C.) and Alberta is about 26,000 km^2, which is about one quarter of the area of alpine ice cover in North America, but only 0.2% of the total on Earth. The number of glaciers, although difficult to establish, is approximately 15,000, of which about 1,000 are in Alberta. Nearly 70% of the total glacierized area in B.C. and Alberta is in the Coast Mountains, a series of northwest-trending ranges bordering the Pacific coast and extending about 1,000 km from the B.C.–Washington border on the south to the B.C.–Yukon border on the north (Figure 1). The highest peaks in the Coast Mountains are in the southern part of the mountain system, culminating in Mount Waddington (4,016 m asl). The southern part of the St. Elias Mountains extends into northern B.C. along its border with Alaska, and peaks in that area exceed 4,000 m asl, the highest being Mount Fairweather (4,663 m asl).



Canadian Rockies and Coast Mountains of Canada, Figure 1 Relief map of western Canada, showing major mountain systems and ranges. Blue shading shows present-day ice cover.

Ice cover is greater in the northern and southern Coast Mountains than in the central part of the system, where lower elevations limit the size and number of glaciers. Overall elevations are greater in the southern Coast Mountains than in the northern Coast Mountains. More extensive ice cover in the northern Coast Mountains results from the decrease in the glaciation limit from south to north due to lower mean temperatures and locally greater precipitation (Østrem, 1966). As a consequence, 36% of the total glacierized area in B.C. and Alberta is in the northern Coast Mountains, 26% in the southern Coast Mountains, and 7% in the central part. The B.C. portion of the St. Elias Mountains has about 12% of the total ice cover.

The glaciation limit generally rises to the east across B.C. due to the more continental environment and generally lower amounts of precipitation in the interior ranges than along the coast (Østrem, 1966). The total glacierized area in the B.C. interior ranges and Alberta Rocky Mountains thus is much less than in the Coast Mountains – glaciers in the Rocky Mountains represent 8.7% of the total area of ice cover; those in the southern B.C. interior, 7.5%; and those in the mountains of the northern interior, 2.3%. Approximately 60 small glaciers on Vancouver Island have a combined area of only 20 km^2.

Most glaciers are remote and not easily accessible except by helicopter, but some are close to roads or established hiking trails. Notable among these are Athabasca and Saskatchewan glaciers in the Alberta Rocky Mountains; Illecillewaet Glacier in the Selkirk Mountains of eastern B.C.; Hudson Bay Glacier near Smithers, B.C.; Helm, Sphinx, and Sentinel glaciers in the southern Coast

Mountains, and Salmon Glacier in the northern Coast Mountains. Athabasca Glacier, located along the Icefields Parkway in Jasper National Park, is the most visited glacier in North America (Figure 2). It flows from the Columbia Icefield, which has an area of nearly 325 km^2 and feeds six major glaciers. Athabasca Glacier is presently about 6 km long, has an area of about 6 km^2, and a maximum thickness of about 300 m.

Mapping British Columbia and Alberta glaciers

Western Canadian glaciers were mapped at scales of 1:50,000 and 1:250,000 as part of the National Topographic Survey (NTS) completed during the second half of the twentieth century. No single date can be associated with the areal extent of the glaciers depicted on NTS maps. Glaciers in B.C. were mapped at 1:20,000-scale during the initial Terrain Resources Inventory Management (TRIM) program between 1981 and 1989. The total glacier cover, estimated from aerial photographs acquired for TRIM mapping, is about 28,500 km^2 (Schiefer et al., 2007). Glacier cover in the Alberta Rocky Mountains for the same period was approximately 1,050 km^2. Some small glaciers have subsequently disappeared, and others have disintegrated into multiple smaller ice masses.

Links between climate and glaciers

A prominent feature of British Columbia's climate is the regular occurrence of mid-latitude cyclones during winter. These systems originate in the North Pacific Ocean, track eastward across the coast, and deliver large amounts of snow to the mountains of B.C. A high-pressure center commonly forms off western North America during summer and steers storm systems along more northerly tracks. Summer is thus typically warm and dry in southern B.C. and Alberta (Moore et al., 2009). The interior ranges of B.C. and the Canadian Rockies experience frequent convective storms during summer, and snow can fall during these storms at high elevations.

The strongest links between regional climate and glacier mass balance in B.C. are during winter when the atmosphere is most active. Wintertime circulation is strongly influenced by the Pacific North American Pattern (PNA), a recurring pattern of high-and low-pressure centers (Wallace and Gutzler, 1981) that can either direct or divert winter storms across southern and middle latitudes of B.C. A persistent ridge of high pressure over B.C. during the strong phase of the PNA favors reduced snowfall. In contrast, cool, wet conditions characterize the weak phase of the PNA, especially in maritime locations of southern B.C. and the U.S. Pacific Northwest (Moore, 1996; Moore and McKendry, 1996).

PNA-like atmospheric patterns are linked to large sea-surface temperature anomalies in the equatorial Pacific or in the North Pacific. These temperature anomalies are associated with the El Niño-Southern Oscillation (ENSO) and the Pacific Decadal Oscillation (PDO). ENSO events typically last 1–2 years and recur every 2–7 years, whereas PDO events tend to last for periods of one to several decades (Mantua et al., 1997). Both El Niño conditions and the warm phase of the PDO favor higher-than-average sea surface temperatures along the west coast of North America and lower-than-average sea-surface temperatures in the central North Pacific. In contrast, cool sea surface temperatures are common during La Niña events and the cold phase of the PDO.

Canadian Rockies and Coast Mountains of Canada, Figure 2 Athabasca Glacier, the most visited glacier in North America. The glacier has retreated more than 1.5 km since the middle 1800s.

Glacier mass balance and frontal variations

Mountain glaciers respond to climate over a range of temporal scales. At annual timescales, for example, glaciers may gain mass if winter accumulation outpaces melting during summer. A persistent imbalance between accumulation and ablation will eventually cause glaciers to adjust their thickness, length, or area to reach a new equilibrium with climate. Adjustments in length and area can take decades or centuries, whereas changes in thickness occur over timescales of years.

Detailed glacier mass balance studies in western Canada began at the start of the International Hydrologic Decade in 1965. Early researchers chose glaciers along a west–east transect through southern B.C. and westernmost Alberta to examine links between climate and mass balance from maritime (Sentinel and Helm glaciers) to continental (Peyto and Ram River glaciers) environments (Østrem, 1966). Berendon Glacier in the northern Coast Mountains was added after 1965 to establish a north–south transect. Only Place and Peyto glaciers, however, have mass balance records longer than 30 years.

Yarnal (1984) showed that mass balance changes at Sentinel and Peyto glaciers are partly controlled by recurring synoptic features during the accumulation and ablation seasons, determined from charts of the geopotential surface (500 hPa). Both glaciers gain mass during periods of cyclonic activity in winter and under synoptic conditions that favor cloudy conditions. Similar synoptic mass balance relations were shown by Walters and Meier (1989), who analyzed a longer and more complete data set for other North Pacific glaciers (South Cascade, Sentinel, Place, Peyto, Wolverine, and Gulkana glaciers). They suggested that wintertime mass balance variability can be largely explained by changes in atmospheric circulation similar to those controlled by the PNA.

The mass balance of western Canadian glaciers is strongly affected by winter precipitation (Hodge et al., 1998; Bitz and Battisti, 1999). In addition to the direct influence of precipitation on accumulation, winter precipitation can also influence summer ablation (Moore et al., 2009): years with heavy snowfall can delay exposure of ice in the ablation season, thus maintaining a high surface albedo and reducing melt during summer (Young, 1981; Moore and Demuth, 2001). Weather and synoptic conditions during summer influence the balance of glaciers in the interior ranges and Rocky Mountains (Letréguilly, 1988; Bitz and Battisti, 1999).

The average winter balance at Peyto Glacier averaged 1.51 m water equivalent (we) per year from 1965 to 1976, but decreased to 1.01 m we per year over the period 1977–1999 interval, following a Pacific climate shift in 1976 (Watson and Luckman 2004; Moore et al., 2009). Place Glacier and glaciers in the U.S. Pacific Northwest experienced similar declines in winter mass balance following 1976, in concert with a shift in climate involving the warm phase of the PDO and more frequent El Niño conditions (McCabe and Fountain, 1995; Moore and Demuth, 2001).

Historical glacier changes and links to climate

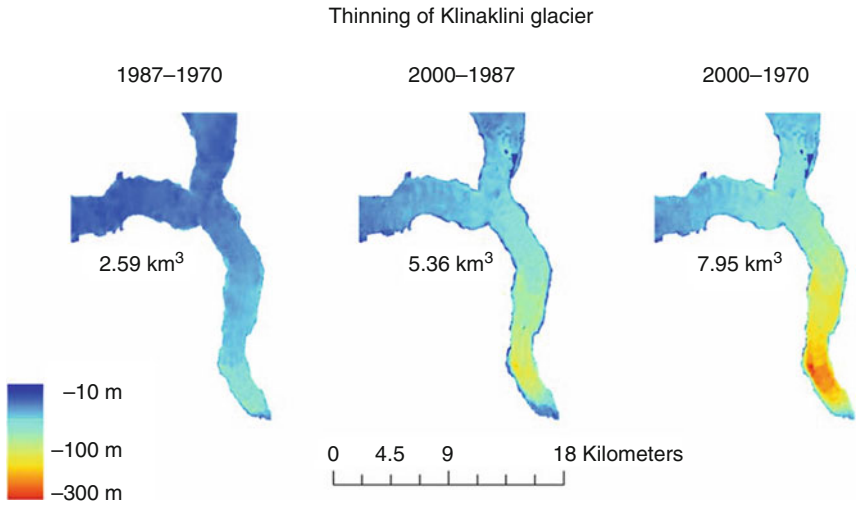
Glaciers in B.C. and Alberta remained near their Little Ice Age positions until the early twentieth century, when climate abruptly warmed in western North America (Jones et al., 1999; Menounos, 2006; Koch et al., 2009). Athabasca Glacier in the Rocky Mountains retreated only about 200 m between 1844 and 1906, but receded over 1 km during the next 75 years and lost nearly half its volume (Luckman et al., 1999). Likewise, Helm Glacier in the southern Coast Mountains and Illecillewaet Glacier in Columbia Mountains retreated about 200 m in the late 1800s, followed by about 1 km of retreat between 1900 and 1988 (Osborn and Luckman, 1988; Koch et al., 2009).

Fluctuations of glaciers in B.C. and Alberta also mirror changes in climate on decadal timescales. Most glaciers rapidly retreated during the period 1920–1950. Glacier recession slowed after 1950, and in some cases glaciers advanced during the 1960s and 1970s. After about 1980, glaciers resumed their retreat, a trend that has continued to the present (Koch et al., 2009; Moore et al., 2009). Periods of glacier recession coincide with positive phases of the PDO, when the climate of B.C. was relatively warm and dry. The minor advances of the 1960s and 1970s occurred during a negative, cool phase of the PDO. Rates of glacier retreat in the southern Coast Mountains were highest (30 m a^{-1}) between about 1920 and 1950 (Menounos et al., 2005; Koch et al., 2009). Illecillewaet Glacier in eastern B.C. retreated 20–40 m a^{-1} between 1900 and 1960, but only about 6 m a^{-1} between 1960 and 1980 (Osborn and Luckman, 1988).

Analysis of 2005 Landsat satellite imagery shows that the total glacierized area in B.C. and Alberta decreased 10.8% (±2.9%) and 25.4 (±3.4%), respectively, over the preceding 20-year period (Bolch et al., 2010). The average annual retreat rate of 0.55% a^{-1} is comparable to late twentieth century rates reported for other mountain regions, including the European Alps and the Himalayas.

Areal changes in ice cover during the past 3 decades

The Coast and St. Elias Mountains have the greatest glacierized area and show the greatest total ice loss – about 2,400 km^2 between 1985 and 2000. Regions with less ice cover, however, have the highest relative areal ice losses – 24% in the northern interior ranges and 25.4% in the Alberta Rocky Mountains, compared with 7.7% and 10.3% in the northern and southern Coast Mountains, respectively. These losses are only part of the total reduction in ice cover since the Little Ice Age. For example, in Garibaldi Provincial Park, ice cover was 16% less in 2005 than in 1987, but was 49% less in 2005 than in the eighteenth century (Koch et al., 2009). Many valley glaciers have retreated more than 1 km since



Canadian Rockies and Coast Mountains of Canada, Figure 3 Elevation change of Klinklini Glacier between 1970 and 2000. Colors denote elevation loss in the ablation zone of the glacier over three periods. Changes in the glacier surface were obtained by differencing digital elevation models produced from the National Topographic Database maps (1970), Terrain Resource Inventory Maps (1987), and Shuttle Radar Topographic Mission imagery (2000).

1900, based on visible trim lines. Small glaciers have experienced the highest percentage areal losses and, in some cases, have disappeared. Conversely, many small cirque glaciers in sheltered topographic locations experienced relatively little reduction in area (DeBeer and Sharp, 2007, 2009).

Volume losses

Geodetic methods and area-volume scaling provide volume loss estimates for glaciers in B.C. and Alberta (Schiefer et al., 2007; Bolch et al., 2010). In the case of small glaciers, terminus retreat explains much of the volume loss; for large glaciers, downwasting in the ablation zone dominates mass loss. The total estimated ice loss in B.C. between 1985 and 2000, based on the TRIM and the Shuttle Radar Topographic Mission (SRTM) digital elevation models, is 22.5 ($\pm$5.5) km^3 a^{-1}, which corresponds to an average thinning rate of 0.78 $\pm$ 0.19 m a^{-1}. Thinning rates are highest where ice cover is greatest (i.e., the Coast and St. Elias Mountains) and lowest in the B.C. interior and the northern Rocky Mountains (Figure 3).

Summary

There are about 15,000 glaciers, covering a total area of 26,000 km^2, in British Columbia and western Alberta. About 36% of the ice cover is in the northern Coast Mountains, 26% is in the southern Coast Mountains, and 12% is in the B.C. portion of the St. Elias Mountains; the remainder is in the central part of the Coast Mountains.

The mass balance of western Canadian glaciers is strongly affected by winter precipitation, although weather and synoptic conditions during summer influence the summer balance of glaciers in the interior ranges and Rocky Mountains. Wintertime circulation in British Columbia is controlled by the Pacific North American Pattern (PNA). A persistent ridge of high pressure over B.C. during the strong phase of the PNA favors reduced snowfall. In contrast, cool, wet conditions typify the weak phase of the PNA, especially in maritime locations of southern B.C. PNA-like atmospheric patterns are linked to large sea-surface temperature anomalies in the equatorial Pacific or in the North Pacific, which in turn are associated with the El Niño-Southern Oscillation (ENSO) and the Pacific Decadal Oscillation (PDO).

Most glaciers in British Columbia and Alberta retreated between 1920 and 1950. Glacier recession slowed after 1950, and in some cases glaciers advanced during the 1960s and 1970s. After about 1980, glaciers continued their retreat, a trend that has continued to the present. Periods of glacier recession coincide with positive phases of the PDO. The minor advances of the 1960s and 1970s occurred during a negative, cool phase of the PDO.

Glacier cover in the Coast and St. Elias Mountains decreased by about 2,400 km^2 between 1985 and 2000. The average annual loss in ice volume over this period is 22.5 ($\pm$5.5) km^3 a^{-1}, which corresponds to an average thinning rate of 0.78 $\pm$ 0.19 m a^{-1}.

Definition

The Cascade Mountains, USA, is a major mountain range of western North America. It extends for about 1120 km in the north–south direction from northern California through Oregon and Washington State, and for a short distance into British Columbia, Canada. The Cascades derive their name from the cascades (waterfalls) of the Columbia River. The Cascade Mountains include both nonvolcanic mountains, including the rugged spires of the North Cascades and the notable volcanoes known as the High Cascades. Major peaks in Cascade Mountains in California are Lassen Peak and Mount Shasta; in Oregon are Mount Hood and Mount Jefferson and in Washington State are Mount Adams, Mount Baker, Mount St Helens, and Mount Rainier.

The Cascade Mountains are part of the Pacific Ring of Fire, the ring of volcanoes and associated mountains around the Pacific Ocean. The most active volcanoes in the USA, excluding Alaska and Hawaii, are found in the Cascade Range, e.g., Mount Rainier (4,392 m), Mount Shasta (4,317 m), and Mount Adams (3,751 m). Mount Rainier is the highest Peak in the Cascade Mountain USA. Mount St Helens in Washington (2,549 m), which had been dormant since 1857, erupted violently in 1980 and 1982. Minor eruptions of Mount St. Helens have also occurred, most recently in 2006.

The core of the Cascade Mountains is formed by old crystalline rocks but above their crest line are many volcanic cones, whose lava flows have covered much of the lower slopes. Because of the Cascade Mountain's proximity to the Pacific Ocean, these mountains receive good

precipitation, especially on the western slopes, with annual accumulations of up to 3,800 mm in some areas. It is not uncommon for some places in the Cascades to have over 5,500 mm of snow accumulation, such as at Lake Helen (near Lassen Peak), one of the snowiest places in the world. Most of the High Cascades are therefore white with snow and ice year round. However, the annual rainfall drops to 200 mm on the eastern foothills due to a rain shadow effect.

CASCADE SYSTEM

Rijan B. Kayastha
Himalayan Cryosphere, Climate and Disaster Research Center (HiCCDRC), Kathmandu University, Dhulikhel, Kavre, Kathmandu, Nepal

Definition

Cascade system is defined as a system in which the flow of energy and/or matter from one element passes to next element in the series. The concept of cascade system is used in the distributed hydrological modeling for simulating runoff from a basin. In this concept, a basin is divided into number of sub-basins say, Tank 1, Tank 2, Tank 3, . . ., Tank n, from upstream to downstream as shown in Figure 1. The inflow on the starting tank, Tank 1, in the upstream end of the basin will be rainfall and after evapotranspiration, infiltration, and other initial losses, the remaining water (outflow of Tank 1) will be inflow to the lower tank, Tank 2. Similarly, outflow of the Tank 2 will be will become the inflow to Tank 3 in the series and so on. This process will continue to the lowermost tank of the basin which will give the actual runoff from the basin.

Synonyms

High magnitude floods; Superfloods

Definition

The term "catastrophic flooding" is generally used to describe the occurrence of exceptional or rare high magnitude floods.

The term catastrophic flooding has its origins in the diluvial theory of the biblical flood and derives from the thinking that catastrophic events shaped the Earth's surface. Floods can be attributed catastrophic status on the basis of their impacts on channel morphology and/or sedimentology or the amount of sediment that they transport. Catastrophic floods create substantial monetary and human losses in the areas in which they occur. Whether a flood is catastrophic or not can depend on the timescale over which the impacts of the flood are considered; for example, an event may appear catastrophic over a short timescale but over a longer timescale may be one of a number of similar events and therefore be relatively "non-catastrophic" (Wolman and Miller, 1960; Wolman and Gerson, 1978; Maizels and Russell, 1990a, b; Russell, 2004). Preservation of erosional landforms and sedimentary evidence of floods over geological timescales is likely to reflect truly catastrophic events and the conditions appropriate for their impacts to be preserved (Russell, 2004). If considered over shorter timescales a flood could be defined as catastrophic if it results in irreversible changes in fluvial systems.

The largest known catastrophic floods are associated with deglaciation as well as high-intensity rainfall. In glaciated environments, catastrophic processes associated with high-energy flows (such as *Ice-Dammed Lakes*, *jökulhlaups/glacier lake outburst floods (GLOFs), etc.*, see entries *Hydrology of Jökulhlaups*; *Glacier Lake Outburst Floods*.) can cause substantial landscape change. The main causes of catastrophic flooding in glaciated terrain comprise rainfall, melting of ice, and natural or man-made dam failure, which generate sudden and large inputs of water to flood routeways (e.g., Mayer and Nash, 1987; Evans and Clague, 1994; Tweed and Russell, 1999; Clague and Evans, 2000; Martini et al., 2002). The Channeled Scablands of Washington, USA, are believed to have been shaped by catastrophic flooding from the drainage of proglacial lakes during the late *Pleistocene Epoch* (Baker, 1981).

Definition

"Catastrophic rock slope failure" is the sudden failure and downslope movement of a large mass of intact rock. The failed rock mass rapidly disintegrates and may flow a long distance at speeds up to 100 m s^{-1} before coming to rest, in some instances kilometers beyond the source. The mobility of the streaming debris is enhanced as it travels over snow and ice. Catastrophic rock slope failures and other types of landslides are common in mountains around the world, but are particularly numerous in high glacierized ranges where glaciers have eroded steep slopes and where recent glacier retreat has left unstable slopes unsupported. Thaw of alpine permafrost in a warming climate has also been implicated in many landslides in glacierized mountains. We describe the interplay between catastrophic rock slope failures and glaciers in the Karakoram Himalaya and western North America, two areas with some of the highest relief and largest alpine glaciers on Earth, and thirdly in the European Alps, with one of the most detail records.

Introduction

Rock slope failures in glacierized mountains may generate rock avalanches that affect mountain glaciers (Figure 1). The runout and emplacement geometry of rock avalanches are affected when they travel over ice (Evans and Clague, 1988; Deline, 2009), and substantial modifications of glacier activity, mass balance, and sedimentation can follow (Huggel, 2008; Hewitt, 2009). If the landslides descend over glaciers into ice-free valleys, they can develop even greater mobility and can, if they reach inhabited areas, result in singular catastrophes (Pflaker and Ericksen, 1978; Hauser, 2002;

Catastrophic Rock Slope Failures and Mountain Glaciers, Figure 1 Rock avalanche onto the accumulation zone of a glacier in the Southern Alps of New Zealand.

Huggel et al., 2008). Rock avalanches occurring in ice-free areas below glaciers can affect ice-margin and proglacial sedimentation, even terminal fluctuations. When landslides dam valleys at or near glacier termini, lakes may cause the ice to float (Hewitt, 2001; Deline, 2005b).

Rock avalanches occur in almost all mountain ranges (Table 1), but most reported examples are in presently or formerly glacierized mountain valleys. Many detachment zones are on slopes over-steepened by glacial erosion. Glacial retreat and debuttressing may be important factors in destabilizing such slopes (Evans and Clague, 1993;

Investigations are revealing a much higher incidence of rock avalanches in glacierized mountains than formerly realized and impacts there have been underestimated (McSaveney, 2002; Deline, 2009). As such, they must be considered an important factor in denudation, sedimentation, and landscape evolution in these mountains.

Our topic involves new and challenging notions for the relations between mass movements and mountain glaciers. Hitherto, studies of the phenomenon have focused mainly on modern events, commonly treated as singular cases (Voight, 1978). These studies have elucidated the processes involved, but the broader implications of regional concentrations of events received little attention until recently.

Rockslide-rock avalanches

Catastrophic rock slope failures are referred to as *rockslide-rock avalanches* (Mudge, 1965), *rock avalanches* (Eisbacher and Clague, 1984), and *sturzstroms* (Heim, 1932; Hsü, 1975, 1978; Hutchinson, 1988). They are characterized by sudden failures of large (10^6–10^{10} m^3) intact masses of rock, followed by rapid runout and emplacement of relatively thin sheets of crushed and pulverized debris. Maximum runout distances are commonly five to ten times total fall height. The debris generally travels at velocities exceeding 100 km h^{-1}, in some instances more than 250 km h^{-1}. When the speed falls below a threshold, the debris comes to an abrupt halt through frictional "freezing" (Hewitt et al., 2008).

The majority of known rock avalanches are in glacierized mountains, but those actually falling on glaciers must be greatly underestimated, mainly because they are unlikely to be recognizable after a few decades. Burial of landslide debris by snow in glacier accumulation zones, or its dispersal by ice movement and ablation as described below, greatly reduce the chances that their legacy will be recognized (McSaveney, 2002). Because most occur in rugged, often uninhabited terrain that is difficult of access, many modern events must have been missed, at least prior to satellite imaging. Most catastrophic rock slope failures are triggered in earthquakes or severe weather, further reducing the chances of direct observation. And dozens of surviving rock-avalanche deposits have been misidentified as moraines or till (Heim, 1932; Porter and Orombelli, 1980; Hewitt, 1999; Blikra et al., 2006; Deline and Kirkbride, 2009). Misidentification is an understandable mistake in rugged environments with many different sources of coarse, poorly stratified, or massive debris.

Landslide–glacier interactions

The impact of a landslide on a glacier depends partly on the size and character of the rock slope failure, partly on its location relative to the glacier, and partly on the behavior of the rock avalanche from inception to cessation of flow. The size of the rock avalanche relative to that of the glacier, the steepness and relief of the rock-avalanche path, the orientation of path relative to that of the glacier, and the steepness of the glacier bed and surface are important factors.

Several distinct contexts and some sub-types can be recognized. First are rock avalanches that occur entirely on ice and do not reach beyond the margins of the glacier. Important sub-categories are events largely restricted to the glacier's accumulation area (Figure 1) and those affecting mainly the ablation zone (Figure 2). Second are rock avalanches that originate in glacierized basins and travel onto ice-free valley floors (Figure 3). A rare variant of this group is rock avalanches that significantly erode the glaciers onto which they fall, producing highly mobile, mixed flows of debris, and ice that travel far beyond the glacier terminus. An example is the disastrous 2002 Kolka-Karmadon event in the Russian Caucasus (Haeberli et al., 2004; Huggel et al., 2005). An avalanche of rock and ice fell onto Kolka Glacier, eroding almost all its ice. A massive flow of rock and ice continued 20 km down valley, where it came to rest at the entrance to a gorge. There, it transformed into a mudflow that traveled for another 15 km. The rock-ice avalanche killed about 140 people and caused massive destruction. Third are rock avalanches that originate on slopes of ice-free valleys and travel over the termini of active glaciers. In addition, rock avalanches that originate and are wholly emplaced in ice-free valleys may affect up-valley glacier behavior (Figure 4). This article deals mainly with the first group of events, where landslide material is emplaced on active ice, but in terms of natural hazards the second and third types are more dangerous (Figure 5).

An important contextual variant, not dealt with here, is glacierized volcanoes. The cataclysmic eruption of Mt. St. Helens in 1980 triggered a huge rock avalanche and lahars, and indicated something of the scale and diversity of mass movements that occur on glacier-clad volcanoes during eruptions (Waitt et al., 1983).

Significant processes and developments

Glacier effects on rock-avalanche movement

From a study of 17 examples, Evans and Clague (1988) concluded that travel over glaciers tends to increase rock-avalanche mobility. Snow and ice surfaces over which the debris travels are typically flat or gently sloping, allowing unobstructed flow, and frictional resistance is much lower than in situations where the landslide travels over rock or sediment surfaces. During landslides in 1986 at Bualtar Glacier in the Karakoram Himalaya, rapid melting of ice by the frictionally heated debris helped to remove surface irregularities (Hewitt, 1988). These conditions also mean the debris sheets on glaciers are characteristically thin; average thicknesses are generally 1–3 m, and large areas of bare or nearly bare ice may occur within the sheet (Figure 6).

Channeling by lateral moraines or in glacial troughs increases the runout distances of rock avalanches by

Catastrophic Rock Slope Failures and Mountain Glaciers, Figure 2 Rock-avalanche deposit on Black Rapids Glacier, Alaska. The deposit has a volume of about 10×10^6 m^3 and averages about 2 m in thickness. The rock avalanche was triggered by a magnitude-7.9 earthquake in November 2002. (Photo: J. J. Clague, 2007.)

limiting or preventing lateral spreading (Evans et al., 1989). For instance, downwasting of the Brenva Glacier since 1988 had converted its moraines into ramparts that channeled the 1997 rock avalanche. In contrast, most deposition in the 1920 rock avalanche occurred outside the moraines because the advance of the glacier that started in 1913 had raised its surface above the moraine crests (Deline, 2009).

Observations of what happens in accumulation zones of glaciers during rock avalanches are few because the landslide material is soon buried under new snow. Many high-elevation landslides occurred during the 1964 and 2005 earthquakes in Alaska; observations after these events suggest that soft snow, ploughed up and melted by the landslide, may affect its movement (Post, 1967; McSaveney, 1978; Harp et al., 2003; Jibson et al., 2006). Debris typically moves away from the main body of the rock avalanche in linear tongues, sometimes anchored by large blocks of rock (Figure 7). Some rock avalanches, such as at Brenva Glacier in 1997, erode through the firn of the accumulation zone and incorporate large amounts of ice. At Kolka-Karmadon in 2002, a large part of the glacier was removed (Huggel, 2008).

Effects of rock avalanches on glacier movement and supraglacial debris

A landslide onto the accumulation zone of a glacier may have some, as yet undetermined, effect on glacier flow. Clearer and more significant consequences for glacier behavior and the fate of the landslide debris are in the ablation zone where the debris is continuously exposed. Deline (2009, 1073) has identified two types of supraglacial units derived from rock avalanches in his work on Miage Glacier, the main debris-covered glacier on the Mont Blanc massif. One type is flow-parallel stripes derived from rock avalanches and rock falls in the accumulation zone that have subsequently been transported englacially. A straight stripe is associated with a short englacial transport path, and a curved stripe results from longer englacial transport. However, it is unlikely debris transported from the accumulation zone will, when it reemerges, be ablated out as a more or less continuous and pure sheet of rock-avalanche debris. Rather, it will undergo irregular and gradual emergence at the surface over a long period with a degree of modification that is greater than with earlier emergence. The second type comprises irregular sheets of rock-avalanche and rock-fall deposits emplaced on bare ice in the ablation zone and subsequently transported entirely supraglacially.

Whatever the origin of the debris, it is progressively modified as it is transported down the glacier. The original form of the debris sheet is distorted by glacier flow that occurs at typical rates of tens to hundreds of meters per year. Surface features common to rock-avalanche deposits in other environments, including ridges transverse and parallel to rock-avalanche flow may be preserved for decades, but become less distinct with time. Even thin layers of rock debris insulate the underlying ice surface, leading to rapid and significant elevation of the debris sheet above the surrounding bare ice. Debris-draped ice plateaus may develop at rates of several meters per year and reach heights of many tens of meters as they move down valley toward the glacier terminus (Figure 8). Observations in the Karakoram, described below, indicate a limit as to how high the protected ice will become,

Catastrophic Rock Slope Failures and Mountain Glaciers, Figure 3 Rock-avalanche debris (*foreground*) blocks the Hunza and Hispar valleys, Central Karakoram. The rock avalanche originated on the rock walls of Ultar Peak (7,388 m asl) and traveled down the glacier in the background. (Photo: K. Hewitt, 2005.)

probably as a result of compensating flow displacement at depth (Hewitt, 2009). Eventually, debris adjusts to surface irregularities by sliding into depressions or moulins.

The fabric and thickness of the debris change as a result of these processes. In glaciers with tributaries, crevasse fields, icefalls, and changes of direction, there is ample opportunity for redistribution and modification of the debris. With time, it becomes difficult to distinguish rock-avalanche debris from other supraglacial materials. The impacts on glacial transport and ablation are likely to be significant, but techniques hardly exist to even identify the phenomenon, let alone the scale of the impacts.

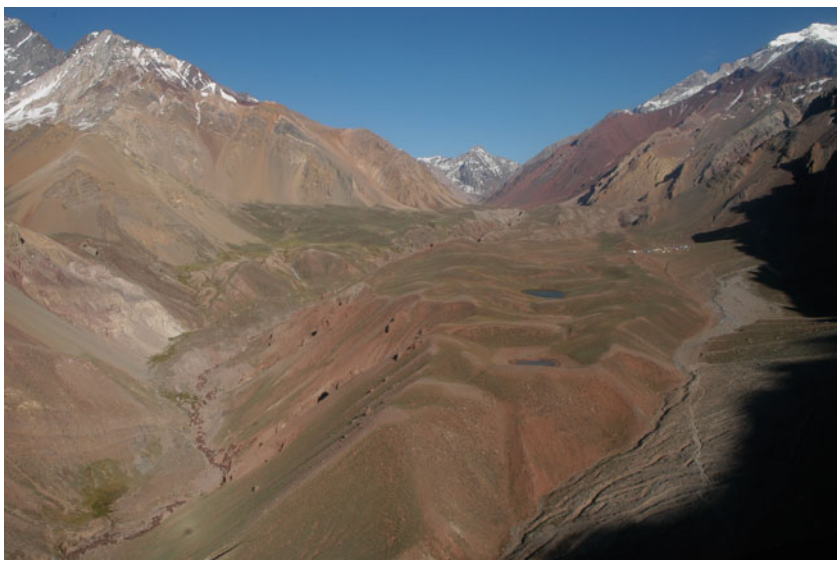
When a rock avalanche blankets part or all of the ablation zone with debris, it initiates a series of disturbances that affect mass balance and ice dynamics. A source of positive mass balance – a large area of insulated glacier ice – becomes a moving "accumulation" anomaly localized in the ablation zone. Ice thickening and accelerated movement may lead to overriding of ice-free margins and advance of the glacier terminus. A consequence is that the normal relations between accumulation and ablation zones are compromised, and the glacier may respond in a different manner from other glaciers in the region. Fluctuations of Brenva Glacier, Italy, over the past century have been associated with repeated burial and reduced ablation under rock-avalanche debris (Valbusa, 1921; d'Agata et al., 2005; Deline, 2005a). The 1920 rock avalanche augmented the debris cover in the ablation zone, causing the glacier to advance 490 m between 1920 and 1941; in contrast, neighboring glaciers retreated from the mid-1920s onward. Bualtar and Aling glaciers in the Karakoram continued advancing for almost 15 years after being blanked by rock-avalanche debris, while surrounding glaciers retreated (Hewitt, 2009). These two also are examples of glaciers that have surged following rock avalanches (Gardner and Hewitt, 1989). Unlike typical surges, however, the advances may continue long after the surge.

Landslide debris alters sedimentation at the glacier margin. Ice-margin and proglacial fluvial sedimentation may, over the course of a disturbance episode, exceed normal rates by one or two orders of magnitude. Most of the rock-avalanche material is dispersed to the glacier margin and forefield within a few decades or centuries. In contrast, rock avalanches emplaced on ice-free ground may resist removal for millennia, even tens of millennia (Voight, 1978; Hewitt, 2002). A consequence is that many lateral and end moraines may include a substantial legacy of reworked and transported rock-avalanche debris. They may even be, as Deline (2009, 1082) suggests ". . . long-term archives of rock-avalanche activity." In some cases, moraines may consist entirely of rock-avalanche debris, in which case they carry no climatic implications. The distal flank of one of Brenva Glacier's lateral moraines has a pronounced concave slope that differs from the typical rectilinear distal slope of a dump moraine; it is attributed to successive deposits of Holocene rock avalanches. Finally, certain morainic complexes extend farther down valley than neighboring ones and lack ordered concentric moraines. They record glacier advances driven, not by climate, but by rock avalanches. Examples have been described in the Barpu-Bualtar basin, Pakistan (Hewitt, 2009) and at Triolet Glacier, Italy (Deline, 2009; Deline and Kirkbride, 2009).

Glaciers affected by rock avalanches also have significant contributions from smaller, but far more frequent rock fall. Patches or tongues of rock-fall debris are common on these glaciers. The two need to be considered together when assessing the role of rock-wall processes on long-term denudation in glacierized terrain (Deline, 2009).

The large amounts of fine debris emplaced during rock avalanches are readily flushed away by on-ice processes, making it progressively more difficult to distinguish the residual coarse fraction from rock-fall material. Nevertheless, it is now evident that in many glaciated mountains, moraines may include a substantial legacy of reworked

Catastrophic Rock Slope Failures and Mountain Glaciers, Figure 4 The Bhurt rock avalanche in the Western Karakoram crossed the Karambar valley from a source behind the camera. Rock-avalanche debris blocks the valley of the tributary Bhurt Glacier (*upper background*); almost all sediment from the glacier is trapped behind the debris barrier. (Photo: K. Hewitt, 1998.)



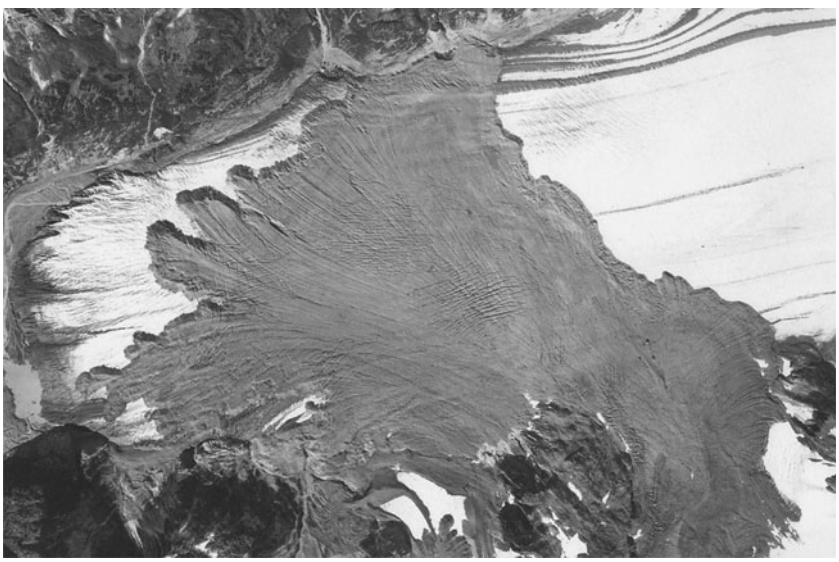
Catastrophic Rock Slope Failures and Mountain Glaciers, Figure 5 Up to 200 m of debris filling the valley in the foreground originated as a rock avalanche from Mount Aconcagua (6,962 m asl; *top right background*). The landslide traveled over Horcones Glacier and incorporated large quantities of ice, snow, and additional debris to become an extremely large (>3 km ^{3}) and very mobile mass flow. The landslide traveled another 15 km down the valley below the photograph to dam the main valley where the Trans-Andean Highway is located today. (Photo: K. Hewitt, 2006.)

and transported rock-avalanche debris produced by the same events that left intact, unmodified deposits at the glacier margins (Hewitt, 2002).

Effects of recent glacier retreat on slope stability

Thinning and retreat of alpine glaciers appear to be responsible for some catastrophic rock slope failures in glacierized mountains (Evans and Clague 1994, 1999; Holm et al., 2004). Many marginally stable slopes that were buttressed by glacier ice during the Little Ice Age failed after they became deglaciated in the twentieth century. An ancillary factor that may have contributed to such failures is steepening of rock slopes by cirque and valley glaciers during the Little Ice Age.

Catastrophic Rock Slope Failures and Mountain Glaciers, Figure 6 The boulder surface of the 1986 rock avalanche on Bualtar Glacier, Karakoram Himalaya. (Photo: K. Hewitt, 1987.)



Catastrophic Rock Slope Failures and Mountain Glaciers, Figure 7 Aerial photograph of the deposit of the 1964 Sherman Glacier rock avalanche, taken in August 1967. Note the digitate margin of the debris sheet; lobes of debris ploughed through snow ahead of the main body of debris.

These effects are most pronounced in mountain ranges with the greatest ice cover (Himalaya, St. Elias Mountains, and Coast Mountains) because it is there that ice losses in the twentieth century have been largest. An extreme example is Glacier Bay, Alaska, which until the end of the eighteenth century was completely occupied by glacier ice. Since then, the bay has become deglaciated, with the loss of over 1,000 km^2 of ice. The ice loss is so great that the land is rising due to isostatic rebound (Larson et al., 2005).

Other mechanisms besides debuttressing can cause or trigger landslides. Temperatures in high glacierized mountains are normally below freezing. They may rise rapidly, however, during warm spells, melting snow and ice. The water generated by this melting can infiltrate fractures in marginally stable rock masses (Davies et al., 2001). When

Catastrophic Rock Slope Failures and Mountain Glaciers, Figure 8 Thin sheet of rock-avalanche debris overlying an ice platform in the ablation zone of Black Rapids Glacier. The debris sheet, which is 2 m thick, insulates the underlying ice. In the 7 years since the rock avalanche, the bare glacier surface adjacent to the debris sheet has downwasted nearly 20 m, leaving the elevated platform of debris-covered ice. (Photo: J.J. Clague.)

temperatures fall below freezing, water within the fractures may freeze or the fractures may be sealed by freezing at the surface. In either case, pore water pressures rise, producing extensional forces on an already weak rock mass. A related process is thawing of permafrost beneath high-elevation rock slopes (Gruber et al., 2004; Fischer et al., 2006; Gruber and Haeberli, 2007; Noetzli and Gruber, 2009). The lowest elevation of alpine permafrost has risen in most or all mountains in the twentieth century due to global warming (Zhang et al., 2006). Thawing has lowered the strength of rock with fractures or other structural discontinuities, because water in the fractures melts.

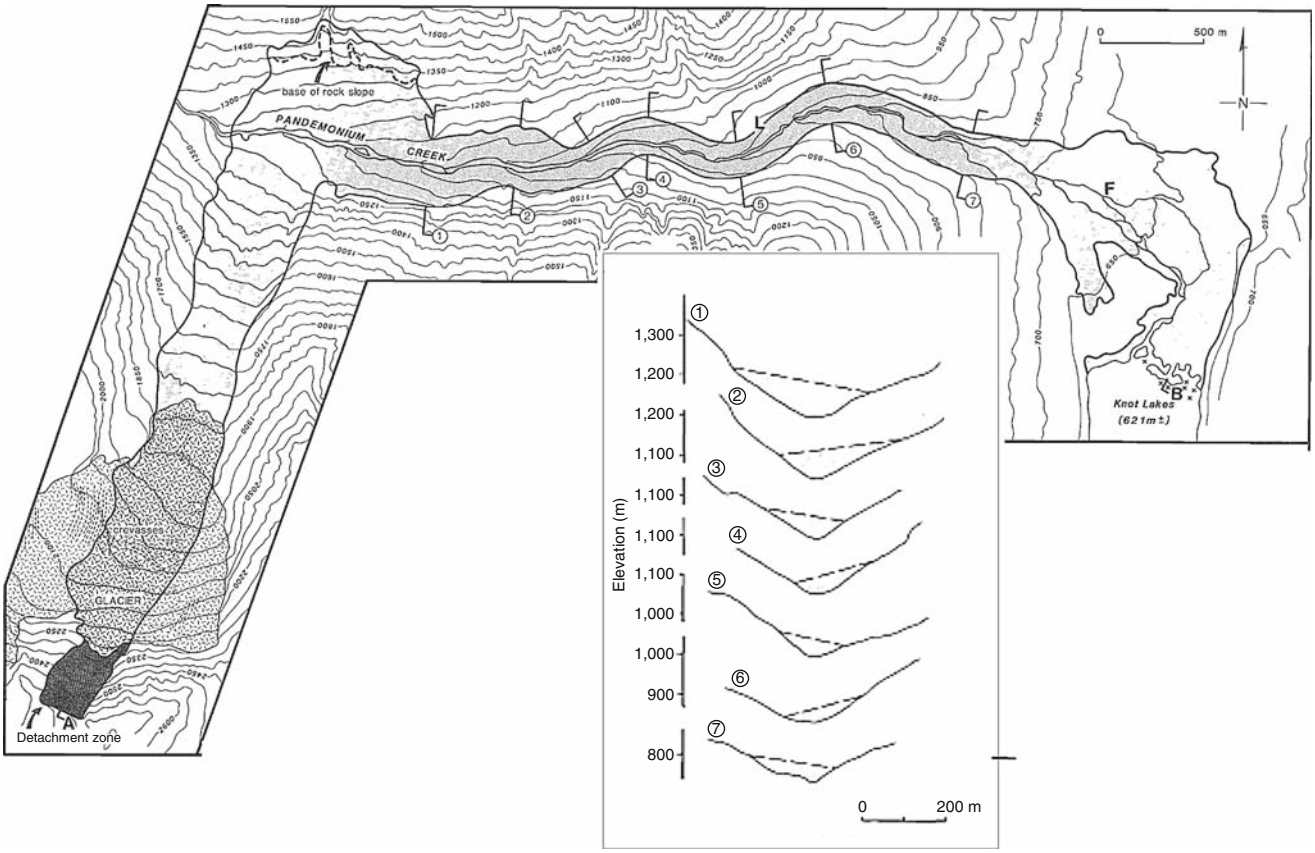
Illustrative of these processes is the unusually large number of rock falls that happened in the European Alps during the exceptionally warm summer of 2003. The rock falls posed a significant hazard to climbers and attracted the attention of scientists and the public. Larger landslides have also occurred more recently, for example in 2004 at Thurwieser Peak in the central Italian Alps and in 2007 at Monte Rosa in the northwestern Italian Alps, both areas visited by large numbers of tourists.

Examples from western North America

The Canadian and Alaskan parts of the North American Cordillera have supported glaciers for at least 10 million years, and during the Pleistocene much of this region repeatedly was enveloped by the Cordilleran ice sheet (Clague, 1989). This recurrent and repeated glaciation has left a strong imprint on the physiography of the region: local relief is great, steep slopes are common, and classic glacial landforms, including U-shaped valleys, fiords, cirques, and arêtes, abound. Glaciers remain common within the Cordillera, covering approximately 125,000 km^2 of region.

Pandemonium Creek

In 1959, a rock spur became detached from the glacially debuttressed headwall of a cirque near Pandemonium Creek in the southern Coast Mountains of British Columbia (Evans et al., 1989). Approximately 5×10^6 m^3 of blocky, gneissic quartz diorite debris traveled across a small glacier and then 9 km along a highly irregular path, descending a vertical distance of 2 km to the valley of South Atnarko River (Figure 9). The high mobility of the rock avalanche is manifested by super-elevation in valley bends, two runups, and two right-angle changes in flow direction. This mobility is due, in part, to peculiarities in the path of the landslide (lateral moraines, for example, funneled and accelerated the debris) and, in part, to travel over a glacier below the detachment zone. Although most of the debris came to rest on the upper part of a fan at the mouth of Pandemonium Creek, one lobe traversed the fan and entered Knot Lakes, where it generated displacement waves that destroyed trees along the shore. Runup and superelevation data indicate that the debris was moving between 81 and 100 m s^{-1} as it entered the runup zone at Pandemonium Creek and 21–38 m s^{-1} in Pandemonium valley to the east. The Pandemonium Creek landslide is similar in many respects to much larger, highly mobile rock avalanches involving glacier ice in other parts of the world, for example, Huascaran, Peru (Pflaker and Ericksen, 1978). It is illustrative of the extreme mobility of relatively small rock avalanches that interact with glaciers.



Catastrophic Rock Slope Failures and Mountain Glaciers, Figure 9 Topography, longitudinal profile, and cross-sections of the 1959 Pandemonium Creek rock avalanche, British Columbia. (Adapted from Evans et al., 1989, Figures 4 and 10.)

Mount Munday

Sometime between May 25 and July 10, 1997, a large rock avalanche occurred on the south flank of Mount Munday (3,367 m asl) in the British Columbia Coast Mountains (Evans and Clague, 1998). The site is 6.5 km southeast of Mount Waddington (4,019 m asl), the highest peak in the Coast Mountains. About 3.2×10^6 m^3 of debris flowed across and down the Ice Valley Glacier, forming a spectacular tongue-shaped deposit covering 220 ha of the glacier surface (Figure 7). The landslide involved highly resistant gneissic rocks that form a number of high peaks in the area. Failure was controlled by the foliation and by a steeply dipping planar fault surface that has a more southerly strike and cuts across the foliation at a lower dip angle.

The detached rock mass first traveled in a southwest direction across Ice Valley Glacier. It ran up the opposing slope to a height of about 100 m above the glacier surface and was deflected about 90° downglacier in a northwest direction, in a manner similar to a bobsled. Below the bobsled bend, the debris traveled up to 2.6 km over the snow-covered glacier surface on a slope of only 6°. Ridges of snow were pushed up at the margins of the debris. At the distal limit of the debris, a lobe approximately half the width of the main debris sheet moved a distance of 900 m on a slope of 5°.

The geometry of the rock-avalanche path below the bobsled bed indicates a coefficient of kinetic friction of approximately 0.11 (6°) for the interface between the debris and snow. Clearly defined, overlapping flow lines were evident in the debris following the rock avalanche. In places along the travel path, debris was thin or absent, exposing the glacier surface beneath.

Glaciers in the Mount Waddington area have thinned and retreated due to atmospheric warming, and glacier ice loss is likely a factor in the Mount Munday event. The immediate trigger of the failure may be related to the exceptional precipitation in southwest British Columbia during the first half of 1997 and a pronounced period of warm weather in the days before the failure.

Examples from the European Alps

A recent inventory of rock avalanches and rock falls in the Alps includes 301 events, of which about half are dated and most are historic (Schoeneich et al., 2008). Few of the landslides are known from glacierized environments, partly because the deposits in these environments typically are not preserved. However, since 1997 five rock

avalanches have descended in part or totally on glaciers in the western Alps – Brenva Glacier (1997), Punta Thurwieser (2004), the west face of Les Drus (2005), and the east face of Monte Rosa (2006, 2007). Research on the Italian side of the Mont Blanc massif suggests that many others occurred during the Holocene (Haeberli et al., 2002; Ravanel and Deline, 2008; Deline, 2009).

Brenva Glacier

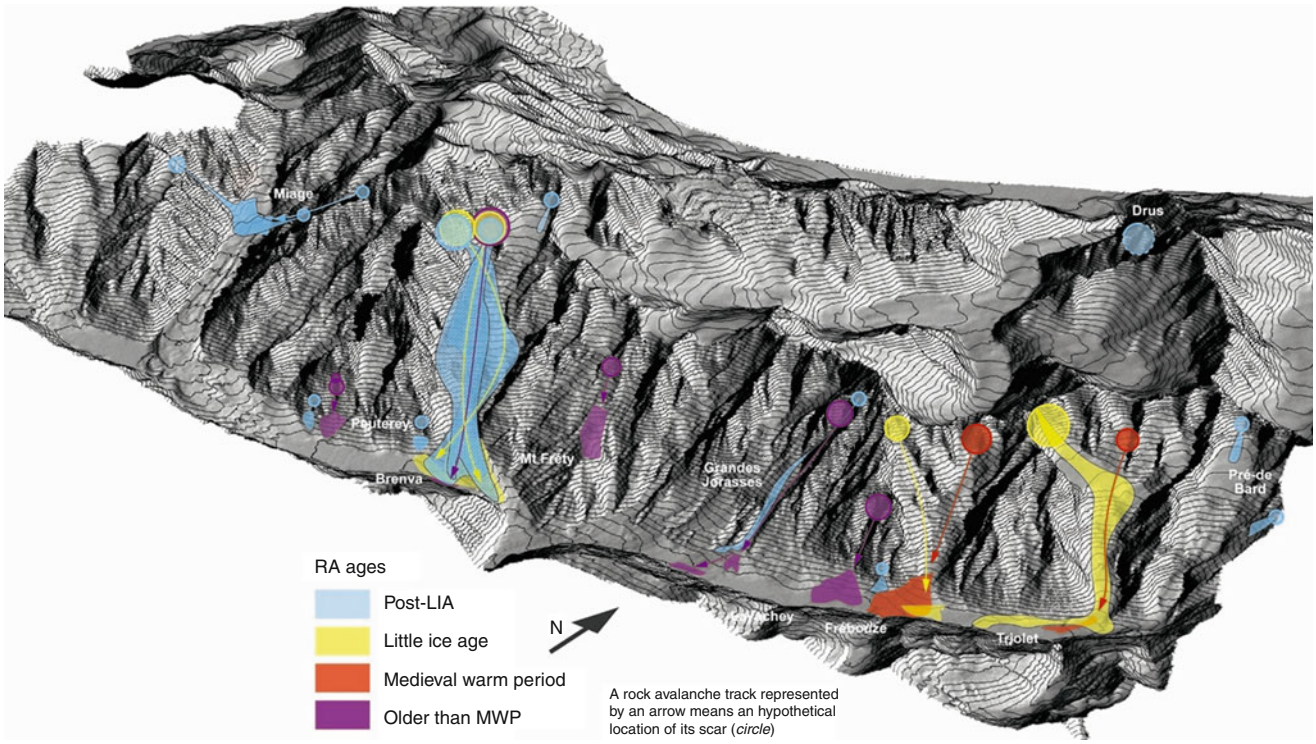
Small rock falls occur regularly on the steep slopes bordering Brenva Glacier. In addition, two large rock avalanches have occurred during the twentieth century (Figures 10 and 11), and several others in the late Holocene. In January 1997, part of Eperon de la Brenva collapsed, mobilizing 2×10^6 m^3 of rock debris and $>4.5 \times 10^6$ m^3 of ice and snow. The avalanche of rock, ice, and snow traveled 5,750 m horizontally and 2,325 m vertically before coming to rest. On reaching the lower part of the glacier, it spread in two directions: one lobe overflowed the south lateral moraine, whereas the main lobe was channeled by the lateral moraines and reached the glacier terminus.

In November 1920, four separate rock masses detached from the east face of the Grand Pilier d'Angle. The total volume of failed rock is in the range $2.4–3.6 \times 10^6$ m^3; an additional $7.6–9.9 \times 10^6$ m^3 of ice was mobilized in the four events. Maximal horizontal and vertical displacements were 5,150 m and 2,660 m, respectively (Figure 11).

Based on observations of these historic events, the strong asymmetry of the south lateral moraine of Brenva Glacier probably is the result of numerous rock avalanches onto the glacier during the Holocene. Thus far, however, only four Holocene rock avalanches prior to the twentieth century have been identified – AD 1767 (Deline, 2005a), early fourteenth century, after AD 426–615, and 2750–2350 calendar years BP (Deline, 2005b).

Examples from the Karakoram Himalaya

More than 320 rock avalanches have been identified in the Karakoram Himalaya, and at least 29 of them spread in part or whole over glaciers. Most events in the inventory are prehistoric, but 11 rock avalanches descended onto glaciers between 1986 and 2009, and one is reported from the nineteenth century (Table 2). For reasons noted earlier, these numbers are underestimates. If recent reports are at all representative, as many as 4,000 rock avalanches may have traveled over glaciers in the Karakoram, Nanga Parbat, and Hindu Raj ranges in the Holocene. The glaciers have a total area of some 18,000 km^2. By comparison, surveys of postglacial rock avalanches at lower elevations and in ice-free areas suggest much lower incidences – 1,000–1,500 Holocene events over an area of some 80,000 km^2. Yet, even these rates are among the highest global concentrations yet known. These lower areas may also have experienced more frequent rock



Catastrophic Rock Slope Failures and Mountain Glaciers, Figure 10 Late Holocene rock avalanches on the Italian side of the Mont Blanc massif. Most of the rock avalanches traveled onto glaciers.

Rock avalanche	River	Glacier	Volume (10^6 m^3)	Area (km^2)	Comment
Ghorsit	Hushe/Shyok	Charakusa	300	2.5+	Prehistoric, partly covered terminus
Lokpar	Hushe/Shyok	Aling	20	3.0	1992; surge of Lokpar and Aling terminus
Masherbrum	Hushe/Shyok	Masherbrum	2	1.5	Late 1980s
Unnamed	Shyok	Unnamed	600+	>30	Prehistoric; from small glacier basins
Tsok	Dumordo	Unnamed	150	8	Descent over small tributary below Panmah Glacier
Naltar Lakes	Naltar	Kuto	300	14	Dams outflow of glacier
Baltit-Sumayar	Hunza	Ultar	400	8	Dammed ice-free Hunza and Hispar valleys
Yashbandan-Barut	Hunza	Pasu and Ghulkin	>250	21	Covered termini of two glaciers
Bligim Platt I	Hunza	Batura	5	3	Covered outer moraines
Bilgim Platt II	Hunza	Batura	3	2	Covered outer moraines
Shikarjerab	Hunza	Unnamed	12	>8	Prehistoric
Qalandar Uwin	Karambar	Chhateboi	>600	>15	Prehistoric
North Te-Rong	Nubra	North Te-Rong	?	5	2002
Buldar Basin	Nanga Parbat	Kappen	11	2.3	2003
Astor basin	Nanga Parbat	Chhichi	1.5	0.5	2005?

avalanches in late-glacial time, as glaciers that covered almost the entire region thinned and retreated. If so, the evidence for this activity has been largely removed from the landscape.

Bualtar and Aling glaciers, central Karakoram

In August 1986, three rock avalanches descended from the same rock wall onto the ablation zone of Bualtar Glacier. By 2005, the landslide debris had been transported about 9 km down valley, about one-third of the distance in glacier surges (see below). During this 20-year period, the landslide debris was fully reworked. The average debris thickness was reduced from about 7 to 8 m in 1986 to about 2 m in 2005, and the debris became less readily distinguishable from supraglacial debris generated by snow avalanches and rock fall, which are widely present on

Catastrophic Rock Slope Failures and Mountain Glaciers, Figure 12 A rock avalanche descended onto the Lokpar tributary glacier (*upper left*) in 1992. The following year the glacier surged into the main Aling Glacier which rapidly advanced 2.5 km. (Photo: K. Hewitt, 1999.)

Karakoram glaciers. Nevertheless, throughout this time, the debris sheet remained much thicker than debris anywhere else on Bualtar Glacier before 1986, and thicker than most debris covers on glaciers examined elsewhere in the region. As a result, it reduced ablation to a much greater extent, and a large area of thickened ice persisted beneath the rock avalanche material. The debris cover had a positive impact on mass balance, equivalent to a 20% increase in annual accumulation (Hewitt, 2009). The area of thickened ice moved along with debris through the ablation zone, and within 10 years it was equivalent to the mass transferred in the surges.

The 1986 Bualtar rock avalanches represent a fivefold increase in supraglacial debris on the glacier. Rock-avalanche debris carried to the margins of the glacier within 30 years of the failures will equal almost 500 years of normal supraglacial transport by the glacier. Similarly, the events represent a doubling of average rate of denudation during this period.

A few months after the rock avalanches, in January 1987, Bualtar Glacier surged at and below the debris sheet (Gardner and Hewitt, 1989). Over the summer, a wave of fast-moving ice traveled down the valley from the vicinity of the rock avalanches. Measured ice velocities were between 7 and 11 m day^{-1}, an order of magnitude higher than pre-surge rates (<0.8 m day^{-1}). A second surge of similar scale occurred in 1989. During the two surges, ice overtopped lateral moraines that had been ice-free for at least a few decades. Ice and meltwater undercut the glacier margins and triggered landslides and debris flows. Meltwater that had ponded at the sides of the glacier escaped in a series of small outburst floods.

The surges initially did not affect the terminus, but over the next 5 years the glacier advanced some 2.5 km and it continued to advance more slowly for another 10 years. It reached to within a kilometer of the Hispar River, farther than at any time since the 1920s (Mason, 1930).

A rock avalanche appears to have been responsible for another glacier surge in the Karakoram. The rock avalanche descended onto Lokpar Glacier, a tributary of Aling Glacier (Figure 12). Shortly thereafter, Lopkar Glacier surged, in turn causing Aling Glacier to advance some 3 km. In other recent cases, glaciers affected by rock avalanches did not surge, but their rates of flow increased and they thickened down valley (Hewitt, 2009).

Concluding remarks

Rock avalanche–glacier interactions involve mutual disturbance of two different Earth surface process systems. The behavior and deposits of one process system cannot be understood without reference to the other. Glacier behavior, landforms, and sedimentary deposits are affected by landslides throughout an extended period of debris transport, disturbed mass balance, and sedimentation. Each period has a distinctive character and sequence, and spatial relations are organized and lagged accordingly.

Definition

The catchment glacier represents the superficial area of a glacier from where the glaciers receive and release the snow/ice material in different form and maintain the equilibrium of a glacier. The catchment of a glacier may be formed by single or more ice body, slowly moving on the downward slope and from a huge glacier reservoir system. All processes by which snow or ice are added or removed from or to a glacier are considered on its catchment basis.

CAUCASUS MOUNTAINS

Chris R. Stokes
Department of Geography, Durham University,
Durham, UK

The Caucasus Mountains are aligned west-northwest to east-southeast between 40–44°N and 40–49°E and span the borders of Russia, Georgia, Armenia, and Azerbaijan. They consist of two separate mountain systems: the Greater Caucasus extends for ~1,300 km between the Black Sea and the Caspian Sea, while the Lesser Caucasus runs parallel but approximately 100 km to the south. The Greater Caucasus contains several peaks above 5,000 m, the highest of which is Elbrus at 5,642 m (18,506 ft). The mountains originate from collision between the Arabian plate to the south and the Eurasian plate to the north and the region is tectonically active, with numerous small earthquakes.

In addition to altitudinal variations in climate, the Caucasus Mountains are characterized by strong longitudinal gradients that produce a maritime climate in the west and a more continental climate in the east. Trends in *Precipitation* (qv), for example, reveal that westernmost areas typically receive around three to four times as much as eastern areas (Horvath and Field, 1975). The southern slopes are also characterized by higher temperatures and precipitation, which can be up to 3,000–4,000 mm a^{-1} in the southwest (Volodicheva, 2002). Much of this precipitation falls as *Snow* (qv), especially on windward slopes of the western Greater Caucasus, which are subjected to moist air masses sourced from the Black Sea. The high snowfall and steep slopes (>25°) result in one of the highest levels of *avalanche* activity in the whole of Russia (Seliverstov et al., 2008).

Glaciers (*Glacier*, qv) cover large parts of the Caucasus, particularly on north-facing slopes of the central Caucasus, with estimates ranging from 1,400 (Bazhev, 1989) to 1,805 km^2 (Horvath and Field, 1975). There are over 2,000 glaciers, mainly classed as small, *mountain*, or *Cirque Glaciers* (qv); but the highest summits can be covered by larger *ice fields* drained by several glaciers, for example, Elbrus, which is covered by a 123-km^2 ice field (Volodicheva, 2002).

The most recent glacier advances are associated with the "Little Ice Age" and maximum positions have been dated to AD 1680, 1750, and 1850 (Volodicheva, 2002). Glaciers have subsequently retreated from these positions (probably by as much as 30%) and widespread *Terminus* (qv) retreat has been documented between 1972 and 2000 (Bedford and Barry, 1995; Stokes et al., 2006). Analysis of the mass balance (*Glacier Mass Balance*, qv) of Djankuat Glacier, one of ten *Benchmark Glacier* selected by the *World Glacier Monitoring Service* (*WGMS* (*World Glacier Monitoring Service*), qv) because of its continued measurement since 1967, indicate that this retreat is being driven by increased summer temperatures, with no compensating increase in winter precipitation (Shahgedanova et al., 2005). Furthermore, glacier retreat appears to be associated with expansion of supraglacial debris (*Supra-Glacial Debris Entrainments*, qv) cover and ice-contact/*Proglacial Lakes* (qv) (Stokes et al., 2007), which may increase the likelihood of glacier-related hazards and debris flows. Unfortunately, such hazards are relatively common in this region and have led to major loss of life. On September 20, 2002, for example, a catastrophic ice-debris flow, including almost complete mobilization of the Kolka Glacier, traveled 19 km down the Genaldon Valley, North Ossetia, and killed over 100 people (Evans et al., 2009).

CHARACTERISTICS OF SNOW AND GLACIER FED RIVERS IN MOUNTAINOUS REGIONS WITH SPECIAL REFERENCE TO HIMALAYAN BASINS

Akhouri Pramod Krishna
Department of Remote Sensing, Birla Institute of Technology (BIT), Deemed University, Ranchi, Jharkhand, India

Definition

Snow and glacier fed rivers of the Himalaya usually originate from the high mountains with their morphogenetic regions in perennial high snow fields and glaciers.

Introduction

Interactions between the processes that control the snow and glacier-melt contribution to runoff vary considerably between different climatic regions. In mid- and high-latitude mountain ranges, for example, seasonal snow cover exerts a strong influence on runoff variability, whereas glaciers are the dominant source of water during the dry season at low latitudes (Hock and Rees, 2006). In mountainous regions, snow- and glacier-fed rivers usually have their origins in the high snow fields. Upper morphogenetic regions of such rivers have their sources in perennial high snow fields and glaciers (Krishna, 2005). Meltwater contributions from snow cover, glaciers, and permafrost (permanently frozen ground) play an important role for generating the innumerable streams that feed the perennial river systems of the high mountain regions, e.g., Himalayan region. Himalayan glacier-fed rivers supply water to one third of the world's population. Since such rivers and their tributaries are fed perennially by snow cover and glacier ice, the extent of snow-covered areas has great bearing on their discharge and runoff (Krishna, 1996). Glaciers act as buffers and regulate the runoff water supply from high mountains to the plains during both dry and wet spells, which are inherent phenomena in a tropical environment. Estimated total volume of water stored globally in ice is 700 times greater than the volume of the annual river runoff (Hall and Martinec, 1985). Their hydrological implications are significant due to snow-fed origins in addition to their glacial meltwater regime and fluctuating rainfall they receive through different altitudinal zones. Snow- and glacier-fed rivers may not only be good indicators of climate change, but also may be suitable testing grounds for examining ecological concepts (Brittain and Milner, 2002).

Central Asia with an estimated total ice cover of 114,800 km^2 has as its dominant mountain range the Himalaya (WGMS, 2009). With 15% of its area covered by glaciers, the Himalaya constitutes the largest glacier system in the world outside Antarctica and Greenland (cf. Racoviteanu et al., 2008). Whereas in comparison, there are over 100,000 glaciers in Alaska, although overall ice cover is only 5% of this state (Anonymous, 2002). Himalayan glaciers form the largest body of ice outside the polar caps (Jain, 2008). Himalayan ranges are home to some of the longest glaciers in the world such as Siachen, Bara Shigri, Gangotri, Zemu, Milam, and Kedarnath. Ice mass covering the Himalayan-Hindu Kush mountain range is the third largest in the world, after the polar icecaps. Snow and glacier together are the source of largest rivers of Asia. These glacial masses store precipitation in the form of snow and ice, regulating water distribution and providing continuous flows during the dry months (World Bank, 2009). Runoff from rain-fed rivers may change in the future such that a reduction in snowmelt water may put the dry-season flow of these rivers relatively under more stress than the present situation (IPCC, 2000). River flow from glacier areas in the Himalaya is influenced both by intra-annual variations in precipitation and energy availability, and by longer-term changes in storage of water as glacier ice. High specific discharge from ice melt often dominates flow for considerable distances downstream, particularly where other sources of runoff are limited, providing a major water resource (Rees and Collins, 2005). Snow-fed basins are more sensitive in terms of reduction in water availability due to a compound effect of increase in evaporation and decrease in melt. For a complex type of basin, the decrease in melt from seasonal snow may be counterbalanced by increase in melt from glaciers (Singh and Bengtsson, 2005).

Himalayan glaciers feed many significant rivers of Asia ensuring a year-round water supply to hundreds of millions of people in the Indian subcontinent and China (Taylor, 2005). These glaciers, which release an estimated 8.6 million cubic meters of water annually, have nourished seven great rivers of Asia – Ganga, Indus, Brahmaputra, Salween, Mekong, Yangtze, and Huang Ho. Ancient civilizations sprang up and thrived along the shores of these rivers (Gopal Raj, 2007). Swiss and French Alps, Rocky Mountains, Colorado and across the US, Europe, and Antarctica have provided clear indications of rise in temperature during the twentieth century. Former Soviet Union except in eastern Siberia, the Baltic Republics, some locations in Caucasus, and low elevations in Central Asia show a rising trend. The rise in temperature has been felt almost in every region. An increase or decrease in the river discharge is one of the strongest evidences for climate change (Joshi, 2009). As glacier water flows dwindle, the energy potential of hydroelectric power

may decrease, causing problems for industry, while reduced irrigation means lower crop production. Heavy snowfall is very beneficial as with the onset of summers, snow starts melting. Thus, snow-fed rivers become replete with water as more of water is discharged. In case this diminishing trend of glaciers and hydrological disruptions continue, regime of snow-fed rivers in the region may be adversely affected. For suitable planning of micro and mini hydroloelectric power stations, there is a need to take up snow and glacier-melt run-off studies of snow- and glacier-fed river catchments (Kulkarni et al., 1999; Singh and Jain, 2002).

As per a recent WWF report on "Overview of Glaciers, Glacier Retreat and Subsequent Impacts in Nepal, India and China," rate of retreat of Himalayan glaciers are accelerating. The report suggested that three of Nepal's snow-fed rivers had declining trends in discharge. In case of China, the report stated that Qinhai Plateau's wetlands had declining lake water levels, lake shrinkage, absence of water flow in rivers and streams, and the degradation of swamp wetlands. In India, several glaciers are receding, which eventually result in water shortages for hundreds of millions of people who rely on glacier-dependent rivers in China, India, and Nepal.

Physical characteristics

According to Braddock (1998), glaciers contribute to flows throughout the year, but most melt occurs during the warmer spring and summer seasons. Glacier-fed rivers reach their peak discharge during hot summer weather. As the seasonal snow resource is depleted, the glacier surface is exposed to melt. The amount of melt generated is largely dependent on the prevailing synoptic situation of the period. Glaciers have three main influences: they contribute to river flows, delay the peak seasonal flow, and reduce the year-to-year variability of flow. Systematic and sustained studies of hydrometeorological processes of snow and glacial regime are necessary for evaluating changes in the hydrology of mountain rivers due to glacier recession and climate change (Thayyen et al., 2007).

Discharge regimes

The alpine and high mountainous areas of the world play an important and distinctive role in the hydrological processes of the planet and in the regional hydrology of all continents (Verbunt et al., 2003). One of the most important tasks related to snow and glacier hydrology in mountainous regions is river-flow forecasting. Snow is more convenient than rain for river-flow forecasting as water is retained in a basin for weeks or months before being released (Hall and Martinec, 1985). Such delays allow the forecasters more time for evaluating the hydrometeorological situation and getting more collateral inputs acquired through remote sensing data, etc. Remote sensing data may help in avoiding discharge forecasting failures particularly in the years which deviate from the usual run-off patterns, especially during snowmelt seasons. Better forecast possibilities in case of snow- and glacier-fed rivers lead to benefits in terms of various utility projects downstream, namely, power generation, irrigation, flood control and drinking water supply, etc. Impact of glaciers and snow cover on river hydrology are often not considered in water resources management policies at lower reaches of the glacier-fed rivers due to lack of information on hydrological processes of snow/glacier regime (Thayyen et al., 2007). Estimation of the snow and glacier contribution in the annual runoff of various Himalayan rivers is necessary for the development and efficient management of water resources, which include flood forecasting, reservoir operation, design of hydraulic structures, etc. (Kumar et al., 2007).

Snow cover built up in the higher altitudinal regions during the winter months melts in the spring and on a seasonal basis contributes the largest volume of water to river flow and to groundwater recharge in particular areas (Bandyopadhyay et al., 1997). Snowmelt runoff from mountains is the primary input to river discharge and is the major source of water for the populations of adjacent lowlands (Price and Barry, 1997). Seventy percent of the world's freshwater is frozen in glaciers, which buffer ecosystems against climate variability by releasing water during dry seasons or years. In tropical areas, glaciers melt year-round, contributing continuously to streamflow and often providing the only source of water for humans and wildlife during dry parts of the year (WWF, 2009). According to Braddock (1998), many rivers of the South Island are sourced from the glacierized catchments of the Southern Alps. Those that drain into hydro storage lakes rely on the regular flows from these catchments, ensuring close to full lake levels for the coming winter peak electricity demand. During summer, glaciers act to supplement flows with water when it is otherwise scarce. In winter, a large proportion of precipitation falls as snow, contributing to storage rather than directly to runoff, thereby reducing flows. In effect, glaciers influence the amount and timing of river flows throughout the year. At an annual scale, the water balance can be used to estimate the meltwater quantity to river flows.

For a better management of water resources, the information on water stored in a basin in the form of snow is of immense use (Singh et al., 2000; Singh et al., 1997). On a short term, fast-melting glaciers provide a bounty for some rivers, as more ice turns to water. But when the glaciers shrink too much, summer stream flows are expected to drop off (Cornwall, 2006). Glaciers are very sensitive to climate change. Their size, life span, and history of growth and retreat all depend strongly on climate conditions (Thapa, 2004). Availability of water from snow-fed rivers may increase in the short term but decrease in the long term. Runoff from rain-fed rivers may change in the future, although a reduction in snowmelt water would result in a decrease in dry-season flow of these rivers. Larger populations and increasing demands in the agricultural, industrial, and hydropower

sectors will put additional stress on water resources. Global Warming is melting glaciers in every region of the world, putting millions of people at risk from floods, droughts, and lack of drinking water. Pressure will be most acute on drier river basins and those subject to low seasonal flows. Hydrological changes in island and coastal drainage basins are expected to be small, apart from those associated with sea-level rise. Heavy snowfall proves fortuitous for the rivers, especially snow-fed ones which would have abundant water during summers when the snow melts, and boosts hydropower generation. Glaciers exert a direct influence on the hydrologic cycle by slowing the passage of water through the cycle. Like lakes and groundwater reservoirs, glaciers are excellent natural storehouses, releasing water when it is needed most (Anonymous, 2008). "Himalayan catchment" is one of the three distinct glacio-hydrologic regimes of the Himalaya. Other two are the winter snow dominated Alpine catchment and cold-arid region of the Ladakh (Thayyen and Gergan, 2009). At the foot of the Himalayas, vast plains receive much of their fresh water from thousands of glaciers high up in the mountains (Harris, 2007).

Geomorphology

Glacial landforms commonly found around high snow fields and glaciers constitute a variety of erosional features, namely, moraines, eskers, drumlins, braided streams, etc. Braided glacial rivers exhibit a highly predictable annual flow pulse caused by the freeze–thaw cycle onto which summer dale discharge fluctuations and unpredictable spates induced by rainfall are superimposed (Rothlisberger and Lang, 1987). Glaciers and subsurface aquifers are the main water sources that interact over time and space to produce a dynamic riverscape made of contrasting glacial water fed channels and groundwater-fed channels (Brown et al., 2003). The mountainous topography causes great spatial variations of all processes of snow cover formation and ablation. The main controlling factors are precipitation, air temperature, albedo, and the heating balance equation and all with more or less strong dependence on altitude (Verbunt et al., 2003).

Rivers of fluvio-glacial origin release large amounts of meltwater in summer months. Glaciers exert tremendous forces on the rocks over which they slowly flow. This action grinds the rocks to a fine silt known as glacial or rock flour. This means that one could begin with relatively dilute glacial water at the toe of an ice mass, then flow downstream with the associated suspended flour, dissolving the major constituents within, and quickly end up with water relatively high in dissolved salts (Ahearn, 2002). Thus, glaciers contribute a huge quantity of sediment and dissolved salts to the glacier-fed rivers every year. Meltwater transports glacially eroded material to the outwash plain, an alluvial plain at the edge of retreating glaciers. Discharge often occurs in surges with wide channels and vast quantities of water. These rivers usually flow in high-energy environment rendering them capable of eroding and transporting. Glaciers feeding the rivers in the high mountains show glacio-fluvial erosional and depositional features such as zones of ablation and accumulation along with glacial moraine features (Krishna, 1999). Fowler and Archer (2005) have illustrated that summer runoff on the high-altitude glacier-fed catchments shows significant positive correlation with summer temperatures. Winter precipitation is strongly correlated with summer runoff on the snow-fed catchments. However, temperature and runoff are negatively correlated on middle altitude (snow-fed) catchments. In middle altitude snow-fed catchments, Singh and Bengtsson (2005) have found that increased temperature results in increased evaporative loss and (since snow cover volume is limiting) reduced runoff.

Sediment transport and load

Magnitude of sediment transported by rivers has become a serious concern for the water resources planning (Jain et al., 2003). An attempt has also been made to quantify the suspended sediment load carried by the stream draining the Satopanth and Bhagirath Kharak Glaciers in Ganges basin in the Indian Himalayas (Chauhan and Hasnain, 1993). The suspended sediment concentration exhibits diurnal variation, an increase in discharge leading to a rise in the suspended load. Relationship between suspended sediment load and discharge allows an assessment of sediment transport and yield. In fluvial processes associated with snow- and glacier-fed rivers, sediment transport relates to rivers/streams, periglacial flows, flash floods, and glacial lake outburst floods (GLOF). Such rivers carry sediments ranging in size from sand, gravel extending even upto cobbles and boulders. Morphogenetic regions of snow- and glacier-fed rivers generally have erosional and depositional glacial-periglacial features present in the area. Fluvio-glacial characteristics of the snow- and glacier-fed rivers over their entire catchments are important to understand. As per IPCC Special Report (2001), Himalayas play a crucial role in the provision of water to continental monsoon Asia. Increased temperature and increased seasonal variability in precipitation may lead to accelerated recession of glaciers and increasing danger from glacial lake outburst floods. A reduction in flow of snow-fed rivers, accompanied by increases in peak flows and sediment yields, would have major impacts on hydropower generation, urban water supply, and agriculture.

Chemical characteristics

Chemical characteristics of meltwaters discharged from glaciers can be distinguished in terms of chemical activity from other aqueous systems (Chauhan and Hasnain, 1993). They further state that the data available on the geochemistry of meltwaters show that apparent rate of denudation in glaciarized basins is highly significant. Based

on studies on a significant Himalayan glacier, Hasnain et al. (1989) reported that meltwaters from the glacial surface had low solute content. Whereas after passing through the glacier, waters were found to be chemically enriched. Variations of solute concentration in meltwaters at the snout were related to their discharge.

Anderson et al. (1997) found that sediment yields were high from glaciers, which suggested that water flux, rather than physical erosion, exerted the primary control on chemical erosion by glaciers. They further stated that although glaciers did not influence total chemical denudation rates at a given runoff, they might yield compositionally distinctive chemical fluxes to the oceans. As such, geology of the area is a primary control on stream chemistry. Some of the findings state that clear water tributaries of snow-fed rivers are characterized by low temperatures, high dissolved oxygen concentrations, low total dissolved solids, and water rich in calcium and bicarbonate. Dilution of dissolved salts takes place due to factors like (i) high specific run-offs and (ii) seasonal variations. Conversely, glacially fed tributaries have a slightly higher dissolved load and in order of magnitude, greater turbidity and suspended sediment loads (Maurer and Scott, 1992).

Biological characteristics

Hydrological flow-paths and the connectivity of chemical weathering environments with sources of oxygen are key controls on the redox potential of the environments that microbes colonize (Tranter et al., 2005). The subglacial environment, comprising sediment and water beneath glaciers and debris-rich ice accreted to the glacier sole, was historically considered to be devoid of life, and subglacial geochemical activity was explained exclusively in terms of abiotic processes. However, this view has been superseded with the discovery of microbial communities in the refrozen lake water above an Antarctic subglacial lake and at the beds of alpine and high Arctic glaciers (Bhatia et al., 2006).

Understanding riverscape dynamics is of particular importance because the relative proportion, life span, and spatial arrangement of these contrasting water bodies control biodiversity and bioproduction within the braided band (Malard et al., 2006). Based on studies on glaciers in Switzerland by Sharp et al. (1999), it is suggested that bacterial populations found in subglacial meltwaters and basal ice are comparable to those in the active layer of permafrost and orders of magnitude larger than those found in ice cores from large ice sheets. Populations increase with sediment concentration, and 5–24% of the bacteria are dividing or have just divided, suggesting that the populations are active. These findings (1) support inferences from recent studies of basal ice and meltwater chemistry that microbially mediated redox reactions may be important at glacier beds, (2) challenge the view that chemical weathering in glacial environments arises from purely inorganic reactions, and (3) raise the possibilities that redox reactions are a major source of protons consumed in subglacial weathering and that these reactions may be the dominant proton source beneath ice sheets where meltwaters are isolated from an atmospheric source of CO_2.

Glacier and Nival systems: variations downstream

Glacier-fed (more properly, glacionival) rivers play a central hydrologic role in many regions, including much of North America, Europe, and the Indian subcontinent; they are typically spatially interspersed with nival rivers, and a growing body of evidence suggests that the two types of fluvial system can respond quite differently to climatic variability (Fleming, 2004). Nival ecosystems comprise of moraines, eternal snow, and glaciers. Nival systems, especially glaciers, play the important role in formation of a river drain and climatic conditions of a region.

Dery et al. (2009) found that runoff from pluvial, nival, and glacial catchments differ in the timing and the quantity of flow. They have further stated that the flows in rain-dominated rivers in western Canada peak during fall and winter and are low during summer. In contrast, high flows in nival and glacial rivers occur in spring and summer with low flows during winter. Nival rivers show a more pronounced and narrower peak in river discharge driven by snowmelt, whereas glacial rivers have an extended period of high flows with an attenuated recession following snow and glacial melt. Accordingly, cumulative annual discharge rises more steadily in rain-dominated rivers than in nival or glacial rivers.

Growing interest in the differential responses of glacial and nival rivers to climatic forcing, and in ecological distinctions between the two streamflow regimes, suggests the need for a better comparative understanding of how the annual hydrologic cycle differs with presence or absence of catchment glacial cover (Fleming, 2005). A nival-glacial system is an environmental system characterized by the dominant role of snow cover and ice, where moisture and energy exchanges may have central importance and in all processes that affect the evolution of the system and its interaction with the environment (Il'yina, 1991). Annual peak flow generally occurs in a certain month in pluvial rivers, whereas this happens between some other periods for nival and glacial rivers.

Summary

Snow- and glacier-fed rivers particularly emanating from high mountains are of significance to understand their characteristics. This is owing to the fact that such rivers receive significant discharge from the snow and glacier covered morphogenetic regions giving them a perennial character. Thus they carry runoff, from such regions which are considered rich frozen deposit of water, downstream fulfilling various needs of the regions through which they travel. Glacier and nival regimes together leads to distinct nature of seasonal hydrological discharge as a result of meltwater from the catchment. Understanding of detailed characteristics of rivers of such origins may facilitate forecasting of seasonal run-off pattern, appropriate discharge

forecasts for hydroelectric power generation, irrigation, drinking water supplies, and many allied types of requirements and prevention against floods, flash floods, and other forms of channel disturbances downstream. In addition, global climate-change investigations are also being facilitated a lot through various hydrological and glaciofluvial indicators in the morphogenetic regions. Present day approach to detail snow- and glacier-fed rivers tend to consider their physical, chemical, and biological characteristics as well. Inherent natural processes with respect to high mountain catchment areas of snow- and glacier-fed rivers are necessarily referred to in terms of fluvio-glacial and hydrological characteristics. This may lead to better understanding of conceptual and practical aspects of the genesis as well as utility and services being provided by snow- and glacier-fed rivers.

CHEMICAL COMPOSITION OF SNOW, ICE, AND GLACIERS

Amanda M. Grannas
Department of Chemistry, Villanova University, Villanova, PA, USA

Incorporation of chemicals in snow/ice

Snow is formed by the condensation of water vapor onto an ice forming nucleus (IFN) or by riming, a process whereby supercooled liquid droplets freeze onto growing ice crystals. IFN and cloud condensation nuclei can thus introduce impurities to snow. Supercooled liquid droplets can also scavenge gas phase and aerosol species from the atmosphere, which will eventually be incorporated into the snow. Rimed snow generally has higher impurity concentrations than snow formed solely by vapor condensation. Snow crystals can scavenge aerosol and gas phase species from the atmosphere during precipitation. Gases can also be taken up or emitted from freshly fallen snow. Further discussion of snow physical properties can be found in the section *Physical Properties of Snow*.

Postdepositional metamorphism is an important factor in both the physical characteristics and chemical composition of snow. Sublimation/condensation can alter individual snow grain characteristics and cause changes to snowpack such as porosity, specific snow surface area, hardness, density, etc. (*Physical Properties of Snow*, qv). These physical processes have the ability to release/trap dissolved species. As snowpack begins to melt, wet metamorphism can have significant impacts on the chemical composition of the snow. More highly water soluble species, such as acids and ions, have a higher affinity for the liquid

phase and can be readily removed during the first stages of snowmelt. There is evidence, however, for the preferential elution of some ions (e.g., SO_4^{2-}, Ca^{2+}, Mg^{2+}, K^+, Na^+) before others (NO_3^-, NH_4^+, Cl^-, F^-). Nonpolar organic molecules can also be found in meltwater, but are less easily removed by percolation. Although particulate material can be incorporated into percolating water, such entrainment rarely occurs in the early stages of melt and particulates may remain in the snow until the final stages of melting. An extensive discussion of snow physics, particularly as related to chemistry occurring in snow, can be found in the recent review of Dominé et al. (2008).

Both glaciers and ice cores represent important archives of environmental information. Where summer melting is absent, accumulation of snow (subsequently transformed into ice) allows for the preservation of chemical, isotopic, and insoluble composition signatures from the atmosphere in oftentimes well-defined stratigraphic sequences. High snow accumulation sites result in thicker layers that can allow for determination of variability of inputs on seasonal timescales, while low accumulation sites can provide longer sequences, but with arguably less-resolved information.

Inorganic species

Snow and ice contain a number of inorganic species. The dominant contributors depend in part on the proximity to continental and oceanic inputs. Dominant ions include H^+, Na^+, Ca^{2+}, Mg^{2+}, NH_4^+, Cl^-, NO_3^-, SO_4^{2-}, and carboxylic acids. Greenland ice contains significantly more NH_4^+ and carboxylic acids as compared to Antarctica, likely due to the larger input from continental biosphere sources. The reviews of Delmas (1992) and Legrand and Mayewski (1997) discuss the chemical composition of polar ice cores, including inorganic species, dust, and gases, and the environmental information that can be obtained by careful analysis of ice core inputs. Snowfall composition in the high Arctic has shown that the major ions present are Ca^{2+}, Na^+, H^+, NH_4^+, SO_4^{2-}, Cl^-, and NO_3^-. Organic acids are also present, although in smaller quantities (about 2% of the ionic balance). Seasonal differences are evident in many species, influenced both by anthropogenic sources as well as localized snowpack chemistry.

Metals can also be found in snow and ice. Evidence of atmospheric metal emission increases from anthropogenic activities, as compared to preindustrial levels, is apparent in Greenland ice cores. Increase in Zn, Cu, Cd, and Pb (in some cases several orders of magnitude) is observed when comparing post-1950 ice to preindustrial levels. Heavy metal records in Antarctic ice cores are also available for select sites. Heavy metal and metalloid records from an East Antarctic ice core date back 672,000 years, one of the longest records available to date. Deciphering ice core records of heavy metals can be challenging, however, due to the low concentrations present in polar ice, and the potential for contamination during the drilling process. Careful decontamination procedures allow for reliable records to be obtained. Mercury is also found in polar snow and ice, as well as glacial ice, and is deserving of special attention due to its toxicity and propensity to bioaccumulate (in organomercury forms). Steffen et al. (2008) discuss the existing polar atmospheric and snow/ice measurements of mercury and review its cycling in the environment, particularly as related to active snow chemistry that can alter the oxidation state and chemistry of this particular metal.

Organic species

Snow is an efficient scavenger of organic chemicals from the atmosphere, more efficient than rain in some cases. Snow can remove both particle-bound and gas phase organics from the atmosphere. A general measure of the organic carbon content of snow/ice can be determined by total organic carbon (TOC) measurements. These have been reported for snow and ice in a variety of sites, including the high Arctic, Greenland, Antarctica, and midlatitude sites with widely ranging values (from <10 to $>3{,}000$ μg C L^{-1}). Organics can exist in both the dissolved and particulate phases, so it is important to distinguish dissolved and particulate fractions. Recent measurements have focused on the water soluble component of organic carbon (WSOC) in air and surface snow at Summit, Greenland. Large firn air concentrations of gas phase WSOC suggested that the snowpack was a source for this material, consisting mainly of formic and acetic acids. Despite recent work aimed at better understanding the relative contributions of dissolved and particulate organic carbon to the total organic carbon pool, the fraction of organic carbon that is distributed between the aqueous and particulate phases is still not well understood.

Organic carbon present in snow and ice can be of both natural and anthropogenic origin, and can be from primary or secondary sources. Only recently has the complex nature of organic matter in snow and ice been fully appreciated. Previous work has quantified small molecules like hydrocarbons, formaldehyde, and methanesulfonic acid in snow, firn, and ice. Other species present in snow and ice include black carbon, carboxylic acids, and anthropogenic materials such as PAHs, pesticides, and industrial chemicals. Higher molecular weight materials are also present in snow and ice. Biogenic materials such as lignin, humic, and fulvic acids and larger polycarboxylic acids have been identified in snow and ice from a variety of locations, including Antarctica. A recent review (Grannas et al., 2007) discusses much of the available literature describing organic matter incorporation into snowpack and the nature of organic materials found in polar snow.

Biological inputs are important in snow and ice as well. Bacteria can act as effective ice nucleation sites, thus becoming incorporated into ice and snow crystals during formation. Recent investigations indicate that snow, glaciers, and ice sheets are biologically active, containing algae, bacteria, viruses, and other organisms. In some

cases, the microorganisms present have the ability to degrade organic compounds found in snow/ice (e.g., propionate, acetate, and formate) and could play a role in both snow chemistry and the carbon cycle as a whole. Additionally, microbial sequestration of nutrients from the atmosphere can play a major role in annual fluxes of, for example, nitrogen from glacier surfaces. It could be the case that snow, ice, and glacial environments should be considered as a separate ecosystem in their own right.

Release of chemicals from snow, ice, and glaciers

Melting snow, ice, and glaciers can lead to release of chemicals in short and concentrated pulses delivering nutrients and contaminants to terrestrial and aquatic environments, possibly affecting ecosystem health. Although much is known about the fate of inorganic species during snowmelt, release of organic contaminants from melting snow is less well studied. Several factors will affect the behavior of organic materials during melt including solubility, vapor pressure, Henry's law equilibria, association with the dissolved phase or particles, etc.

Snow/ice may also release species to the gas phase from chemical processes occurring in the condensed phase. Examples of such releases include nitrogen oxides, formaldehyde, acetaldehyde and acetone, small carboxylic acids, molecular halogens, organohalogens, etc. These processes are seemingly ubiquitous, having been observed in the Arctic, Antarctic, and midlatitudes. The sources of these emissions are discussed in further depth in Chemical Processes in Snow and Ice.

Summary

The chemical composition of snow, ice, and glaciers is an important area of continuing research. It is important to better understand the potential effects of chemical transfer upon snowmelt, as the release of nutrients and contaminants to surrounding terrestrial and aquatic areas could play an important role in ecosystem health. Additionally, the presence of various inorganic and organic species (both soluble and insoluble) as well as trapped gases in glacial and polar ice cores can serve as an important record of past atmospheric and climatic histories. Advanced analytical techniques are continually being developed to better characterize the oftentimes low concentrations of a variety of species at higher resolution than previously available. As these techniques develop, better glaciochemical records will become available, allowing for a better understanding of past climate and potentially help us better understand the potential impacts of future climate change scenarios.

CHEMICAL AND MICROBE RECORDS IN SNOW AND ICE

Liu Yongqin
Laboratory of Tibetan Environment Changes and Land Surface Proceses (TEL), Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Haidian District, Beijing, China

Definition

Microbe records in snow and ice. Microbe is an organism that is microscopic. Microbes include bacteria, algae, fungi, archaea, and protists. Microbe records in snow and ice mostly focus on the bacteria and algae.

Chemical records in snow and ice. Chemical ions and anions, such as Ca^{2+}, Mg^{2+}, K^{+}, Na^{+}, NH_4^{+}, SO_4^{2-}, NO_3^{-}, Cl^{-}, in the snow and ice are frequently analyzed. They are found closely connected with climatic and environment change.

Introduction

Snow falling on polar and high altitude regions carries lots of biotic and abiotic material. Ice is formed from accumulated snow as a result of compression and immured these materials. Chemical records in snow and ice from polar ice sheets or mountain glacier provide information about natural and anthropogenic atmospheric content, atmospheric circulation, and aerosol and contaminant transport and deposition. Chemical analyses of ice cores have been

made to reconstruct high-resolution paleoclimate and environmental change (Mayewski et al., 1997; Thompson et al., 1997, 2000; Kang et al., 2002; Yao et al., 2004).

Despite the wealth of information about chemical records in snow and ice, little information exists on the microorganisms. Snow is a significant climatic and ecological system that covers ca. 35% of the Earth's surface permanently or for varying times during the year (Miteva, 2007). Snow ecological systems are dynamic nutrient and microbial reservoirs (Jones, 1999). Microbes play important roles in snow ecology (Hoham and Duval, 2001). Snow algae serve as primary producers that sustain heterotrophic communities on the glaciers (Yoshimura et al., 1997; Hoham and Duval, 2001; Painter et al., 2001; Takeuchi, 2001; Stibal et al., 2006). Diverse bacteria habiting in snow were recovered by culture and unculture method. Early in 1933, snow samples were collected in the south polar region in the course of the Byrd Antarctic Expedition II. *Bacillus mesentericus*, *B. subtilis*, *B. tumescens*, *Achromobacter delicatulum*, *A. liquidum*, *Micrococcus freudenreichii*, *Flavobacteriu devorans*, and unidentified *Bacillus* were obtained using cultivation methods (Darling and Siple, 1941). Employing molecular methods, Carpenter et al. (2000) obtained rRNA gene sequences related to *Thermus-Deinococcus*-like organisms, and report the low rates of bacterial DNA and protein synthesis in South Pole snow. In Arctic, Amato et al. (2007) report the bacterial concentrations are about 2×10^4 cells mL^{-1} in snow cover at Spitsbergen, Svalbard. They recovered that strains have the capacity to degrade organic compounds at moderate temperature, which suggests that bacteria were actively involved in the chemistry of the Arctic snow cover (Amato et al., 2007). In the low and mid latitudes, bacterial abundance in the snow at Mount Sonnblick, Austria, and in the Tyrolean Alps ranges from 10^3 to 10^5 cells mL^{-1}(Alfreider et al., 1996; Sattler et al., 2001). The snow bacterial biomass at the Tateyama Mountain, Japan, varied seasonally due to rapid bacterial growth during summer (Segawa et al., 2005).

The Tibetan Plateau (TP) contains the largest concentration of the world's snow and ice outside of Antarctica and Greenland. Abundant bacteria existed in snow at the world highest plateau. Bacterial diversity and cell abundance in the snow of the four glaciers (Guoqu, Zadang, East Rongbuk, and Palong No.4) located in different climatic zones of the TP were investigated through culture-independent molecular analysis of 16S rRNA gene clone library and flow cytometry approaches. Cell abundance ranged from 676 to 7.2×10^5 cells mL^{-1}. Most of them were similar to those in the Antarctica, and less than those in the Arctic and other high mountains. Snow bacteria at the northern glaciers were higher than that at the southern ones. Cell abundance were related with Ca^{2+} concentration (index of the input dust) but did not show obvious correlation with the concentration of total organic carbon and total nitrogen. The snow bacteria spatial variation was agreed with the snow chemistry in the TP. The ion concentrations in snow from the northern of the plateau are higher than that from the southern of the plateau. The spatial patterns of snow chemistry demonstrated that continental dust originates mainly from the deserts to the north, while monsoon sources of moisture exert greater influence on snow chemistry on the southern of the plateau (Xiao et al., 2002). The result suggested that snow bacteria could be a good index of climate and environment as other chemical parameters in the snow.

Unexpected high diverse bacteria dwelled in snow over the TP. Bacterial 16S rRNA gene sequences affiliated to 13 phyla and 82 genera. Fifteen common genera (genera *Acinetobacter, Acidovorax*, *Arthrobacter, Bacillus*, *Bradyrhizobium*, *Brevibacterium, Curvibacter*, *Hymenobacter, Kocuria, Ochrobactrum*, *Polaromonas*, *Pseudomonas, Ralstonia* , *Rhodoferax*, *Sphingomonas*) distributed widely in glaciers located at different regions of the plateau, implying that the same selective mechanism occurs at the plateau. The bacterial diversity in the snow at different glaciers was related to the surrounding environments. The Guoqu Glacier, to the north near the desert zone and with the lowest temperature, preserved more bacteria closely related to a cold environment and soil than the other glaciers. However, in the Palong No. 4 Glacier located in the south warm region around vegetation, most bacteria were phylogenetically related to plant-associated bacteria (Liu et al., 2009a).

Bacteria in snow over the TP were seasonal various. Under the influence of various atmospheric circulation and temperature, bacteria in snow varied seasonally with different manners at different regions. High bacterial abundances occurred during monsoon season at the East Rongbuk Glacier located in the southern of the TP, but exhibited during no-monsoon season at the Guoqu Glacier in the central of the TP. Bacterial diversity seasonal variation at the Guoqu Glacier was more distinct than that at the East Rongbuk (Liu et al., 2006, 2009b).

Glacier ice immures microbial life in extreme environment for hundreds of thousands of years. Microbe in ice core firstly drew biologists' attentions. Bacteria were recovered from the Vostok ice core in the Antarctic (Priscu et al., 1999; Christner et al., 2001), GISP2 ice core in the Arctic (Sheridan et al., 2003; Miteva et al., 2004; Miteva and Brenchley, 2005), Guliya ice core in TP (Christner et al., 2003), and ice cores in the Andes and New Zealand (Christner et al., 2000). The diversity, evolution, survival mechanism of microorganism, and in situ microbial activity were revealed (Christner et al., 2000; Priscu and Christner, 2003; Miteva, 2007).

During recent years, microbe in ice core attracted glaciologist's attention because glacier ice is a unique ecosystem preserving microbial life and past climate changes chronologically. In the TP, bacteria and chemical features in the ice cores were analyzed together to explore the relationship between microorganisms and climatic and environmental changes. In the 102-m-deep ice core from Malan glacier, microbial concentrations were negatively correlated to temperature in four different temperature

phases and positively correlated with mineral particle concentrations (Yao et al., 2006).

Vertical profile of bacterial DNA structures at different depths in the Puruogangri ice core (83.45 m) were investigated by the denaturing gradient gel electrophoresis (DGGE) DNA fingerprinting technique. DGGE profiles indicated that the bacterial species diversity in glacial ice is high, and indigenous species represented by common bands in all samples may grow on the glacial surface. Bacterial diversity was comparable to that of soil habitats and had a positive correlation with Ca^{2+} concentration. This suggested that the soil ecosystem was the main source of bacteria in this glacier. The low similarity indices (0–43%) were found between the ice-core samples, which corresponded to the episodic deposition under defined climatic conditions and low activity of microorganisms in glacial ice. The profile of bacterial species composition in glacial ice is a bioindicator of climatic changes (Zhang et al., 2006).

Annual bacterial abundances in ice deposited over the past 70 years and trapped within a core retrieved from Mt. Geladaindong were recovered. The bacterial abundance was lowest in 1938 and highest in 1997. Analyses of correlations between bacterial abundance and $\delta^{18}O$ and Ca^{2+} concentrations indicate that bacterial abundance correlates positively with both temperature and amount of dust transported onto the glacier. These correlations imply that both higher temperatures and more frequent dust deposition influence bacterial abundance in the Geladaindong ice core (Yao et al., 2008).

Summary

Chemical and microbe records in snow and ice contain plenty of information about climate, environment, and anthropogenic active. They were both good indicators of paleoclimatic and paleoenvironmental change. However, microbes in ice core need further work in the future.

CHEMICAL PROCESSES IN SNOW AND ICE

Amanda M. Grannas
Department of Chemistry, Villanova University, Villanova, PA, USA

Introduction

Recent studies have identified important chemical processes occurring in snow and ice in polar, alpine, and midlatitude regions that can influence the chemical composition of snow/ice and the surrounding environment. Many processes are photochemically driven and can significantly impact the composition of the atmosphere overlying these chemically active snowpacks. Observations include both ozone and mercury depletion in the lower atmosphere, driven by interactions between the atmosphere and photochemically active snow/ice. These processes may also impact the overall oxidizing capacity of the tropospheric boundary layer.

Photochemical processes in snow and ice

In the mid-1980s scientists made the shocking discovery of complete ozone removal from the marine boundary layer in the Arctic. Concentrations of ozone in the lowest portion of the atmosphere were occasionally significantly depleted from typical background levels of 40 ppb (parts per billion). It was found that the ozone depletion was inversely correlated with particle-phase bromine concentrations and subsequent studies have better elucidated the role of halogens in the ozone depletion chemistry. It is now apparent that chemistry occurring in the sunlit snowpack plays a key role in the cycling of photochemically active halogens (Br_2 and BrCl) by oxidation of seasalt (a review of halogen chemistry as related to ozone depletion events can be found in Simpson et al., 2007). Associated with the observed ozone depletion events are simultaneous atmospheric mercury depletion events (Steffen et al., 2008).

Many chemical processes are now known to occur in sunlit snow and ice. The chemistry occurring within this frozen medium can produce species such as NO_x, HONO, H_2O_2, HCHO, CH_3CHO and acetone, alkenes, molecular halogens, organic acids, and CO and can cause destruction of ozone within the snowpack interstitial air. The various locations of the measurement sites indicate that snow photochemistry may indeed be a ubiquitous process, as snowpack production of chemicals has been observed in both Arctic and Antarctic sites, as well as midlatitude areas. An extensive review of snow photochemistry can be found in Grannas et al. (2007).

The production of such varied species can have an important impact on the overlying atmosphere, as well as the surrounding ecosystem. Oxidation of sea-salt halogens in sunlit snow/ice is presumed to be the primary mechanism of halogen activation that leads to tropospheric ozone depletion events witnessed every spring in the Arctic (Simpson et al., 2007). Additionally, the observed snowpack source of H_2O_2, HCHO, and HONO can significantly impact the oxidant budget of the overlying atmosphere. Mercury cycling (an important toxic chemical that, depending on its form and oxidation state, can bioaccumulate) is also perturbed by snowpack photochemistry, as described in detail in the review of Steffen et al. (2008). This can have important ramifications for ecosystem health.

The impact of the physical nature of snow and ice on chemistry

Chemical processes occurring in snow and ice are impacted by the physical nature of the frozen medium.

It has been shown that a liquid-like (quasi-liquid or disordered) layer exists on the surface of pure ice and that this quasi-liquid layer is also found on the surface of ambient snow crystals and ice at environmentally relevant temperatures. Many processes can take place when freezing a solution that could impact the location and chemistry of dissolved species, including the formation of grain boundaries (the surface between two monocrystalline ice grains), veins (the linear intersections of grain boundaries), and nodes (the junction of veins). As liquid water freezes, solutes can be excluded from the ice phase into the quasi-liquid layer, grain boundaries, veins, or nodes, increasing their apparent aqueous concentration, known as the freeze concentration effect. Fast, nonequilibrium freezing can also cause solutes to become trapped in micropockets of highly concentrated solution. These processes lead to a chemically enriched liquid-like layer at the surface, grain boundaries, and interstitial pores of snow and ice that can impact the nature and rates of chemistry occurring in snow and ice.

As water freezes, anions and cations can become distributed unevenly between ice and solution, leading to a "freezing potential." H_3O^+ or OH^- then migrates to neutralize the potential, leading to highly variable pH in the liquid layer. This too can have an effect on chemical processes occurring in snow and ice. For example, Takenaka et al. (1996) found that the rate of reaction of nitrous acid with dissolved oxygen in laboratory experiments was accelerated 10^5 times upon freezing, due in large part to the freezing potential effect. Field measurements of nitrogen oxide production also support the idea that the pH of the snow will play a role in the release of chemicals from sunlit snowpack. It has been shown that HONO production ceased in alkaline snow. This is supported by the fact that HONO formation is highly dependent on pH of the quasi-liquid layer, with no HONO production at pH $\geq$ 5 (HONO pKa is 2.8 in solution).

It is thus apparent that the nature of the snow and ice, as well as its history (e.g., postdepositional metamorphism) can potentially impact the chemical processing of species (Physical Properties of Snow). This is discussed in further detail in the reviews of Grannas et al. (2007) and Dominé et al. (2008).

Summary

The ability of snow and ice to act as a chemically reactive medium is only a recently discovered phenomenon. The production of photochemically and oxidatively active species can have a number of impacts on the overlying atmosphere, including the initiation of ozone and mercury depletion events and alteration of the oxidizing capacity of the boundary layer. Both field and laboratory measurements have advanced the field significantly, yet our understanding of the fundamental behavior of solutes in snow and ice, partitioning of chemicals between air/snow/ice, and a molecular level understanding of many reaction mechanisms remain limited.

CIRCULATION AND MIXING IN ICE-COVERED LAKES

Lars Bengtsson
Department of Water Resources Engineering, Lund University, Lund, Sweden

Definition

Circulation is the water movement and mixing is the dispersion of particles. The circulation, as well as the dispersion in ice-free lakes is mainly caused by the wind. When a lake is ice covered, the wind does not act on the water surface, and the water movements are much determined by thermal processes and by the vertical movement of the ice cover.

Introduction

Knowledge about circulation processes in lakes is essential when planning for the use of a lake for water supply or receiving waters. The conditions controlling the dynamics of ice-covered lakes are different from those of an ice-free lake. The ice cover prevents heat losses to the atmosphere and direct generation of wind mixing. As in ice-free lakes, a river running through a lake induces currents. In an ice-free lake, the dynamics are dominated by the directly induced wind mixing. There are also oscillations caused by set-up of the water surface by the wind. Such oscillations occur also in ice-covered lakes. The wind causes the ice cover to oscillate, thereby causing back and forth movements of water mass. However, much of the mixing is caused by thermal processes. The thermal conditions and the heat fluxes are responsible for convection and mixing of different character. Heat accumulated in the sediments during summer is released to the water in ice-covered lakes. The heat flux is largest at shallow water, where the water is cold and lighter than the deep water. When the water gains heat from the sediment, it becomes warmer and denser and the water slides downwards generating a large convection cell. In the spring, when the snow is free from ice and the solar radiation can penetrate into the lake water and heat the water close to the ice, density instabilities arise, local convection takes place, and a top mixing layer develops. While the currents in ice-free lakes are typically 2% of the wind speed, that is 20 cm/s when the wind is 10 m/s, the currents in an ice-covered lake are very much lower. The oscillation movements may be 1 cm/s back and forth. The currents caused by thermal processes are of the order mm/s or even less. Still, these movements result in vertical mixing and changed temperature conditions in the course of the winter.

River through-flow

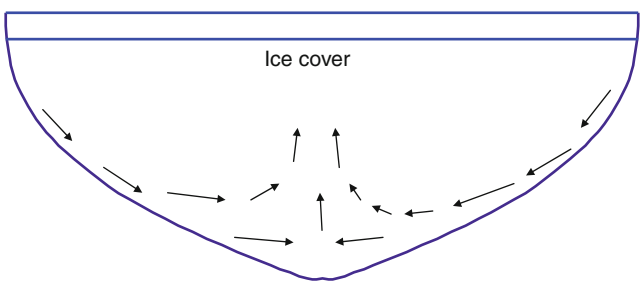
A river that runs through a lake generates currents, but after initial mixing near the inlet, the river water can be traced only if the river is large. In ice-covered lakes, it has been observed thinner ice on the right-hand side indicating upwelling of warm bottom water with secondary currents induced as an effect of the earth's rotation, but most studies show that the current is rather uniformly directed in the upper part of a cross section. When the river flow is large and the lake elongated like a fjord lake, a cold top layer, where the flow takes place, develops over a pronounced thermocline separating the cold layer from a warmer bottom layer. The dispersion (dispersion coefficient D) in this top layer can be determined as for a river (D = coef R U*), only that the friction velocity (U*) is related to the friction against the ice. The hydraulic radius (R) is the distance between the underside of the ice and the thermocline.

Oscillating currents induced by ice movement

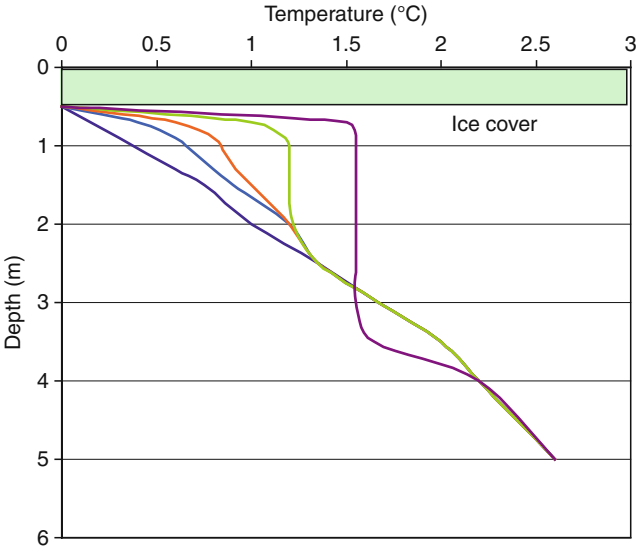
When a wind acts on the ice of a lake, the ice cover is tilted and oscillates. The water particles underneath are forced to move back and forth over very short distances, in the order of meters. The maximum velocities in lakes 1–10 km^2 seem to be 1–3 cm/s. The net movement is close to nil, although a slow horizontal circulation pattern can be induced. Although the net movement is close to nil, mixing occurs and particles are dispersed. Dye experiments in Swedish lakes, where the oscillation period is about 20 min, have shown that the horizontal dispersion coefficient is in the range 10–200 cm^2/s. It can be stated that some kind of oscillatory currents are always present in ice-covered lakes and they significantly contribute to the horizontal mixing.

Currents induced by heat released from the sediments

Water that gains heat from the sediment near the shores moves slowly along the bottom towards the deeper parts of the lake, generating large convective circulation cells as shown in Figure 1. As compensation for the downward movement along the bottom, there is an upward movement in the central part. The convective velocities can be crudely estimated from mathematical model experiments and from crude dye measurements. The velocities involved seem to be well below 1 mm/s. Instead of considering the physics of convective motion, it is instead possible to determine a vertical mixing coefficient from the change over time of the vertical temperature profile. The thermal vertical diffusivity is well below 0.1 cm^2/s. Detailed measurements in the Karelian Lake Vendyurskoe reveal that the diffusion coefficients increase from the ice downwards, being molecular at the top 20 cm and increasing linearly to six times the molecular ($7*10^{-3}$ cm^2/s) value at 2 m below the ice. The bottom water is mixed due to the convection induced by the heat flow from the sediments. However, once the water has reached the temperature of maximum density, 4°C, the water does not take part in the mixing process; the convection takes place above this 4°C water. The bottom water in subbasins of a lake may be isolated from the water in the main basin and remain stagnant for many months.



Circulation and Mixing in Ice-Covered Lakes, Figure 1 The principle of large-scale convective circulation generated by heat flux from sediment to water.



Circulation and Mixing in Ice-Covered Lakes,
Figure 2 Convective mixing during 5 consecutive days (the first day being the lower line with linearly increasing temperature with depth, the last day being the top line with constant temperature between 0.5 m and 3.5 m) in Lake Vendyurskoe due to penetration of solar radiation through the ice. Ice thickness 0.5 m.

Convective solar radiation induced mixing

When the solar radiation is able to penetrate through the ice, the water below the ice gains heat and becomes denser than the water further down. Convective mixing is initiated as the warm water sinks. A mixed layer may develop down to considerable depths, but it is depended on the extinction coefficient of the lake water and to how far the shortwave radiation reaches. The mixed layer deepens rather fast, maybe 0.5 m/day. An example of deepening of the mixed layer is shown in Figure 2. The convective vertical velocity involved in the mixing process is about 1 mm/s.

Summary

Although a lake is ice covered, there are mixing and slow currents below the ice. Currents are generated by rivers through flow, by oscillation of the ice cover, and by heat released from the sediments. There is intense convection below the ice in late spring, when the ice is free from snow and some solar radiation can penetrate the ice. The net currents are of the order mm/s, but still important for the vertical mixing and the development of the temperature profile.

Definition

Cirque glacier. Small glacier found in half-open, semicircular shaped niches, or hollows located on mountainsides or in upper part of valleys. The French term *cirque* originates from the Latin word *circus* meaning *circle*.

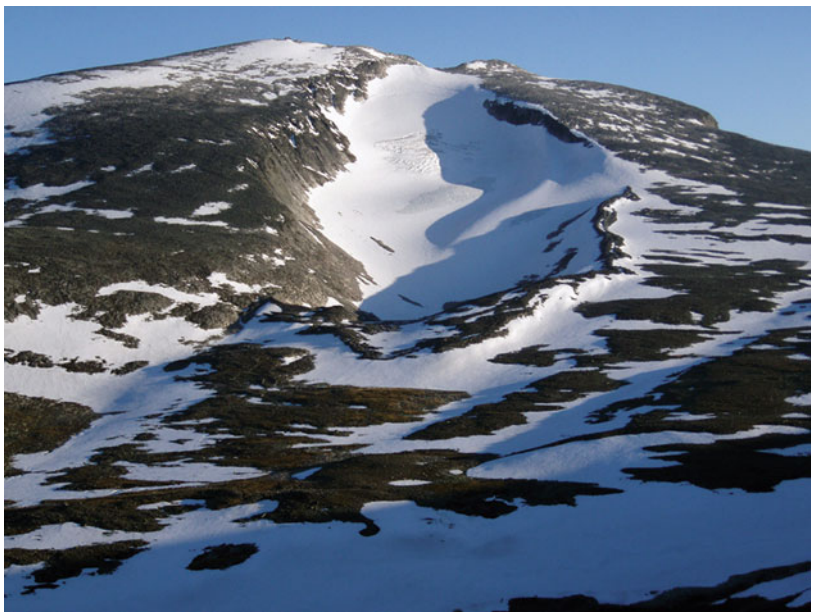
Introduction

Cirque glaciers are among the most frequent types of glacier found on Earth, and typically observed in any Alpine landscape where climate condition allows glacier formation. *Cirque glacier* is a true hybrid concept referring both to the landform it creates through erosion and evacuation of rocks and sediments (Glacial Erosion: Glaciological Variables Controlling Glacial Erosion; Glacial Geomorphology and Landforms Evolution), and to the ice body occupying it in the first place. In certain areas of the world such as the Himalayas and the Andes, cirque glaciers represent vital water reservoirs that are critical for agriculture and human living conditions. Because of their small size and volume they are extremely sensitive to changing climate conditions, which is emphasized by the fact that cirque glaciers worldwide are receding at an unprecedented rate (e.g., Oerlemans, 2005; Haeberlie et al., 2007), suggesting that they are among the most vulnerable parts of the now ever-diminishing Cryosphere (Cryosphere).

Morphology and size

The shape of any cirque glacier is to a large extent determined by the surrounding topography, which not only constrains the morphology, but also directs the flow and movement of the ice mass (cf. Lewis, 1960). Because cirques (i.e., the landform) come in such a wide variety of forms, the glaciers hosting these hollows also exist in many shapes. Evans (2007) offers a rigid classification of different types of cirques, divided into five grades (ranging from premature to mature). He also demonstrates that the length and the width of cirques in Wales and the English Lake District are positively correlated to the overall size of the cirque, which suggests that the glaciers tend to increase in size and volume with cirque enlargement. As the cirque evolves, the more sheltered the glacier occupying it will be by steepening sidewalls and headwall, which outline its basin. Through this slow process, certain positive feedbacks will be amplified such as added accumulation through wind-drifted snow, snow avalanching, and net shading. An example of a cirque glacier is shown in Figure 1.

Another aspect that influences the morphology of a cirque glacier is its thermal regime, which to some extent also controls its erosional capacity. Glaciers are by convention defined as being either temperate, polythermal, or polar (the old classification would be temperate, subpolar, and polar (Ahlmann, 1935). The thermal regime of an ice body is usually different in the accumulation area (usually the upper part, but not exclusively) and the ablation area (Glaciology, Glacier Mass Balance). In polythermal glaciers, which usually are warm based in the upper part and cold based in the lower part, the erosional efficiency would be highest in the upper part (e.g., Richardson and



Cirque Glaciers, Figure 1 A small cirque glacier in the mountain massif called Snøhetta (2,286 m) located in central Norway. The glacier, which appears to be of a polythermal character, has been steadily retreating for the last 10 years. The ice-cored moraine damming up a small proglacial lake has yet to be breached, but erosion along proximal sides of the moraines indicates that this is bound to happen in near future. The age of the moraine is uncertain, but it shows that the cirque glacier has been considerably larger than at present. The author took the picture in 2007.

Holmlund, 1996). The frequently observed low-relief base of cirques agrees well with such an erosional system. Since cirque glaciers are found within all three classes of thermal regimes, so their shapes also vary significantly, which simply adds to the complexity of the glacier morphology (Polythermal Glaciers).

It should be kept in mind when relating glacier physics to cirque geometry that the development of a mature cirque arguably takes several 100,000 years (e.g., Benn and Evans, 1998). This implies that reoccurring cirque glaciers of different thermal regimes have eroded the same cirque over the period in question, including non-glacial processes.

In a slightly outdated, but comprehensive glacier inventory from 1973, covering Northern Norway and Sweden, most of the 1,491 registered glaciers are categorized as cirque glaciers (Østrem et al., 1973). They are often smaller than 0.5 km^2 and certainly smaller than 3 km^2. A more up-to-date survey carried out for southwestern Greenland shows similar numbers (Weidicke et al., 1992). Out of 1,473 mapped mountain glaciers, the majority is labeled as cirque glaciers. They are on average 1 km^2, with a mass volume of around 0.1 km^3 and a corresponding thickness of 20–50 m (see also Østrem et al., 1988).

Inception and decay of cirque glaciers

A cirque glacier may develop from a perennial snowfield, ice apron, or glacieret that is already established in concave, often steep, mountainsides. Leeward sides and shaded areas are favored places for cirque glacier inception.

Separating perennial snowfields from cirque glaciers are, however, not straightforward, although in theory it is simple, that is, when the ice mass starts to deform it is per se a glacier. Benn and Ballantyne (1994) suggest, for instance, that the threshold boundary separating a snowfield from becoming a glacier is related to the length measured from the headwall to the terminus of the snowfield, which is set to be 30–70 m. Whenever exceeding this threshold limit, the overlying pressure will be big enough to trigger the existing ice mass to start flowing. The average temperature of the snowfield is critical to this approach because colder temperatures will slow the annual process of transforming snow to ice, and it will also increase the pressure required to instigate and sustain deformation (cf. Paterson, 1994). Once a glacier is established, it will quickly start to erode the substratum (Formation and Deformation of Basal Ice).

A cirque glacier that expands beyond the outer limit of the rock basin can develop, often by coalescing with other advancing cirque glaciers, into a valley glacier – a process that can be reversed.

How fast can cirque glaciers develop? In theory, this will depend solely on climate conditions promoting growth, that is, temperature, precipitation, and prevailing wind direction. Few empirical studies currently exist that addresses this question, perhaps because most glaciers currently are receding. One option for obtaining estimates on cirque glacier development is by reconstructing the behavior of paleoglaciers.

A thoroughly studied cirque glacier system, once located on a small island in Western Norway, might shed light on this issue. At this site (called Kråkenes) a small, but temperate glacier (0.14 km^2) formed due to the transient cooling of the North Atlantic realm referred to as the Younger Dryas, which existed from 12,900 to 11,700 calendar years BP (cf. Rasmussen et al., 2006). The reconstruction of this glacier is based on exceptionally well-dated downstream lake sediments that efficiently track its inception and subsequent decay. According to a novel study carried out by Jostein Bakke and coworkers the glacier formed within 90 years and disappeared in 55 years (Bakke et al., 2009).

Modern observations of receding cirque glaciers indicate that the recession rate can be even faster than what the paleodata predicts for the Lateglacial–Holocene transition. At South Georgia (54°S, 34°W), Hodges Glacier was still present in 1982 with a size of 0.19 km^2, even producing a terminal moraine at the time (Gordon and Timmis, 1992). By 2008, it had completely disappeared (author's observation, unpublished). The initial size of the glacier, as it starts to retreat will obviously impact the time it takes to melt it completely. A massive loss of cirque glaciers is nevertheless to be expected for the coming century, as global temperatures keep getting warmer. However, as valley glaciers diminish and tributary glaciers become separated from their main glacier trunk, a significant number of glaciers will be reclassified as cirque glaciers.

A molder of landscapes

Glaciers erode through physical processes such as abrasion, abrading, and plucking, and chemically through meltwater interaction (Subglacial Weathering; Mechanical Weathering; Hydrochemical Characteristics of Snow, Ice, and Glaciers). The erosional capacity of cirque glaciers is obvious from the many empty cirques, Alpine horns, and arêtes, but they are also responsible for shaping mountain ranges with peaks rising above the regional equilibrium line altitude (ELA) (Equilibrium-Line Altitude (ELA)). The influence and significance of mountain glaciers, and particularly cirque glacier, as chief landscape molders led Mitchell and Montgomery (2006) to launch the concept of "glacial buzzsaw," arguing that the formation of glaciers on mountain ranges that gradually elevates, due to tectonic movements, will constantly lower the range as long as it keeps rising. Their case study area was the Cascade Range in central Washington, USA. In a long-term perspective with climates significantly warmer than present day, this theory might be less valid, but for average Quaternary (<3 million years) conditions (cf. Porter, 1989) there is

abundant empirical work to support it (Oskin and Burbank, 2005; Mitchell and Montgomery, 2006 and references therein; Foster et al., 2008).

Climatic indicator

Of all glaciers used as indicators of climate change, cirque glaciers are probably the optimal ones to use. Due to their small size and volume, their response time to positive or negative changes in mass balance is rapidly manifested, often within a couple of years. This implies that a sustained negative mass balance, lasting no less than a decade, will rapidly lead to a reduction in size and vice versa. In the European Alps, cirque glaciers (including other types of mountain glaciers) have since 1850 lost more than 50% of their volume, and the rate of melting keeps increasing toward present with an ongoing loss of 2–3% a^{-1} (Haeberlie et al., 2007).

If moraines have been deposited, that later can be mapped, the accumulation area ratio (AAR) can be invoked in order to estimate the corresponding ELA (Andrews, 1975; Osmaston, 2005). Given that the moraines can be properly dated, either directly or indirectly, they can be used as proxies for past climate change.

Because downstream lakes are extremely efficient in trapping suspended sediments (Suspended Sediment Dynamics), they currently represent the only possibility to produce continuous glacier reconstructions. The fact that most cirque glaciers have such defined catchments is an advantage for reconstructions utilizing lake sediments precisely because it reduces the risk of unwanted "sediment pollution" by extraglacial sediment sources (cf. Paasche et al., 2007). Another advantage with using cirque glaciers for the purpose of reconstructing past climate conditions is that they very rarely surges, which otherwise would seriously hamper the quality of the reconstruction.

Summary

Cirque glaciers are small and extremely responsive to changing climate conditions. Currently, such glaciers are in a global state of demise. Because of their swift response to changing climate conditions, they are preferred for continuous reconstructions of past glacier activity. Cirque glaciers erode the hollows they occupy, which tends to be enlarged through time. In a long perspective, they are probably among the most important molders of mountain ranges such as the Alps, the Himalayas, and the Andes.

CLIMATE CHANGE AND GLACIERS

Arun B. Shrestha
International Centre for Integrated Mountain Development (ICIMOD), Kathmandu, Nepal

Definition

Ablation area: The area of a glacier where more glacier mass is lost than gained.
Accumulation area: Area of a glacier where more mass is gained than lost.
Climate: Climate in a narrow sense is usually defined as the "average weather," or more rigorously, as the statistical description in terms of the mean and variability of relevant quantities over a period of time ranging from months to thousands or millions of years. The classical period is 30 years, as defined by the World Meteorological Organization (WMO). These quantities are most often surface variables such as temperature, precipitation, and wind. Climate in a wider sense is the state, including a statistical description, of the climate system.
Climate change: IPCC definition – Climate change refers to a statistically significant variation in either the mean state of the climate or in its variability, persisting for an extended period (typically decades or longer). Climate change may be due to natural internal processes or external forcings, or to persistent anthropogenic changes in the composition of the atmosphere or in land use.
UNFCC Definition: A change of climate which is attributed directly or indirectly to human activity that alters the composition of the global atmosphere and which is in addition to natural climate variability observed over comparable time periods.
Glacial retreat (advance): When the position of a mountain glacier's terminus is farther upvalley (downvalley) than before. Glacial retreat occurs when a glacier ablates more (less) ice at its terminus than it transports into that region.
Glacier: A mass of ice that originates on land, usually having an area larger than one tenth of a square kilometer; many believe that a glacier must show some type of movement; others believe that a glacier can show evidence of past or present movement.
Mass balance: Difference between accumulation and ablation of a glacier in a given time interval.

Glaciers and climate

Glaciers can form anywhere in the world where snow deposited during the cold/humid season does not entirely melt during the warm/dry times. The seasonal snow, as it accumulates, gradually becomes denser and transforms into perennial firn (rounded, well-bonded snow that is older than 1 year) and finally, after the voids connecting the grains are closed off, into ice. The ice from such accumulation area flows under the influence of its own weight and the surface topography down to the lower altitudes, where it melts. The lower areas where temperatures are high and where melting occurs are termed as ablation areas. Accumulation and ablation areas are separated by equilibrium line, where the balance between gain and loss of ice mass is exactly zero.

The glacier-climate change response system is a complex chain of processes. Changes in atmospheric conditions (such as solar radiation, air temperature, precipitation, wind and cloudiness) influence the mass and energy balance at the glacier surface (Kuhn, 1981; Oerlemans, 2001). Air temperature plays a predominant role, as it is related to the radiation balance and turbulent heat exchanges, and also determines whether precipitation falls as snow or rain. Over time periods of years and decades, changes in energy and mass balance cause changes in volume and thickness, which in turn affect the flow of ice through internal deformation and basal sliding.

This dynamic relation eventually leads to changes in the size of the glacier more visually manifested by the retreat and advance of the glacier terminus. In simple terms, the glacial mass balance is directly linked with annual atmospheric conditions – with no delay – whereas the advance or retreat of glacier tongues is an indirect, delayed, and filtered signal of climate change.

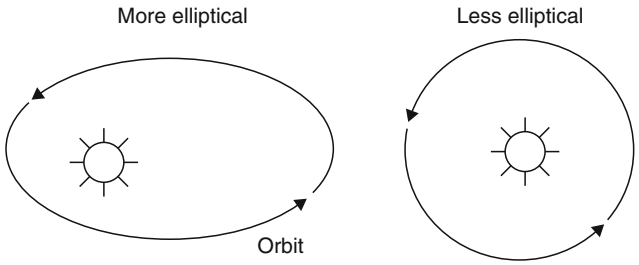
The climate of the specific location determines the nature of the glaciers. In humid-maritime climates the equilibrium line is at a relatively low altitude because for ablation to take place, warm temperatures and long melting seasons are necessary. The climatic regions are dominated by temperate glaciers with relatively rapid flow. The ice caps and valley glaciers of Patagonia and Iceland, the western Cordillera of North America, and the mountains of New Zealand and Norway are examples of this type of glaciers. In dry continental areas, on the other hand, such as northern Alaska, Arctic Canada, subarctic Russia, parts of Andes near Atacama Desert and many Central mountain chains, the equilibrium line is at relatively high elevation with cold temperatures and short melting seasons. These glaciers have low mass turnover.

Glaciations and climate change of the last 2.5 million years

Evidences from Europe, North America, and other parts of the world show clear sequences of expansion and contraction of glaciers and sheets in the last 2.5 million years. The fluctuations in the ice masses were better understood in proper time frame after studying deep-sea sediments. The large-scale fluctuations in the glaciers and ice sheets were clearly related to similar large-scale changes in the climate of the earth, mainly due to changes in the earth's orbital parameters with very regular cyclic behavior. Variations in Earth's eccentricity, axial tilt, and precession comprise the three dominant cycles, collectively known as Milankovitch Cycles for Milutin Milankovitch, the Serbian Astronomer who calculated the variations in the orbital forcings in 1914 while detained as a political prisoner.

Eccentricity is, simply, the measure of how elliptic is the Earth's orbit around the Sun (Figure 1). This constantly fluctuating, orbital shape ranges between more and less elliptical (0–5% ellipticity) on a cycle of about 100,000 years. These oscillations, from more elliptic to less elliptic, are of prime importance to glaciations in that it alters the distance from the Earth to the Sun, thus changing the distance the Sun's short wave radiation must travel to reach Earth, subsequently reducing or increasing the amount of radiation received at the Earth's surface in different seasons.

Axial tilt, the second of the three Milankovitch Cycles, is the inclination of the Earth's axis in relation to its plane of orbit around the Sun. Oscillations in the degree of Earth's axial tilt occur on a periodicity of 41,000 years from 21.5° to 24.5° (Figure 2). Today the Earth's axial tilt is about 23.5°, which largely accounts for our seasons. Because of the periodic variations of this angle the severity of the Earth's seasons changes. With less axial tilt the Sun's solar radiation is more evenly distributed between winter and summer. However, less tilt also increases the difference in radiation receipts between the equatorial and Polar Regions. One hypothesis for Earth's reaction to a smaller degree of axial tilt is that it would promote the growth of ice sheets. This response would be due to a warmer winter, in which warmer air would be able to hold more moisture, and subsequently produce a greater amount of snowfall. In addition, summer temperatures would be cooler, resulting in less melting of the winter's accumulation. At present, axial tilt is in the middle of its range.



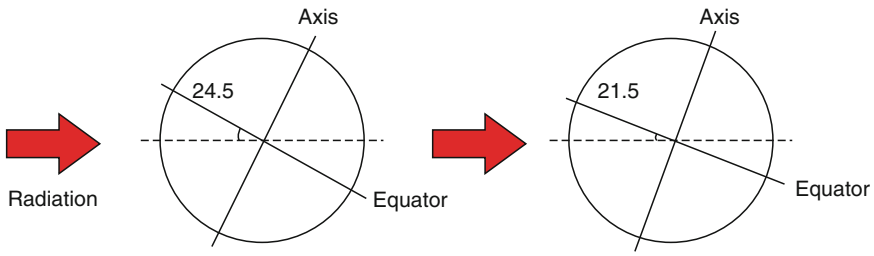
Climate Change and Glaciers, Figure 1 Eccentricity of the Earth's orbit.

The third and final of the Milankovitch Cycles is Earth's precession. Precession is the Earth's slow wobble as it spins on axis. This wobbling of the Earth on its axis can be likened to a top running down, and beginning to wobble back and forth on its axis. The precession of Earth wobbles from pointing at Polaris (North Star) to pointing at the star Vega (Figure 3). When this shift to the axis pointing at Vega occurs, Vega would then be considered the North Star. This top-like wobble, or precession, has a periodicity of 23,000 years. Due to this wobble a climatically significant alteration must take place. When the axis is tilted toward Vega the positions of the Northern Hemisphere winter and summer solstices will coincide with the aphelion and perihelion, respectively. This means that the Northern Hemisphere will experience winter when the Earth is furthest from the Sun and summer when the Earth is closest to the Sun. This coincidence will result in greater seasonal contrasts. At present, the Earth is at perihelion very close to the winter solstice.

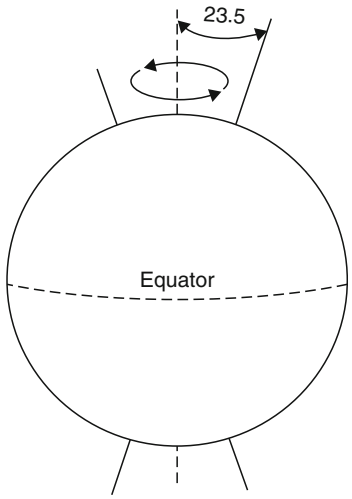
These variables are only important because the Earth has an asymmetric distribution of landmasses, with virtually all (except Antarctica) located in the Northern Hemisphere. Even when all of the orbital parameters favor glaciations, the increase in winter snowfall and decrease in summer melt would barely be enough to trigger glaciations, not to grow large ice sheets. Ice sheet growth requires the support of positive feedback loops, the most obvious of which is that snow and ice have a much lower albedo than ground and vegetation, thus ice masses tend to reflect more radiation back into space, thus cooling the climate and allowing glaciers to expand. The positive feedback also involves thickening of ice sheets which reduces the temperature at the surface.

Glaciations and climate change of past 21,000 years

The large extension of glaciers occurred about 21,000 years ago, in period known as last glacial maximum (LGM), when glaciers covered up to 30% of the land. Glacier fluctuations can be reconstructed back to that time using a variety of scientific techniques and this knowledge has become central to understanding the causes and possible future of contemporary glacier change. Historical reconstruction of glaciers in the Alps, Scandinavia, Alaska, the Canadian Rockies, Patagonia, the Tropics of



Climate Change and Glaciers, Figure 2 Changes in Earth's axial tilt.



Climate Change and Glaciers, Figure 3 Precession of the Earth's axis.

South America, Tibet, the Arctic, and Antarctica shows that the fluctuations in the state of the glaciers are largely consistent with the reconstruction of climatic and environmental changes provided by other indicators, such as ice-cores, tree-line shifts, pollen records, and lake sediments (Solomina et al., 2008). General warming during the transition from the Late Glacial period (between the Last Glacial Maximum and about 10,000 years ago) to the early Holocene (about 10,000 to 6,000 years ago) led to a drastic general glacier shrinkage with intermittent periods of expansion. About 11,000 to 10,000 years ago, this pronounced warming reduced the glaciers in most mountain areas to sizes comparable with conditions at the end of the twentieth century. In northern Europe and western North America, which were still influenced by the remnants of the great ice sheets, this process was delayed until about 6,000 to 4,000 years ago. Several early-Holocene re-advances, especially those in the North Atlantic and North Pacific as well as possibly in the Alps, cluster around an event about 8,000 years ago, and were likely triggered by changes in the ocean thermohaline circulation and subsequent cooling resulting from the outbursts of Lake Agassiz (Solomina et al., 2008). On a timescale of hundreds of years there were periods of synchronous glacier advance around the world – peaking in the late Holocene in the Northern Hemisphere, and in the early Holocene in the Southern Hemisphere (Koch and Clague, 2006). The difference in the amount of sunlight that reaches the Earth's surface in the two hemispheres (Solanki et al., 2004) accounts for these differences in long-term glacier evolution (Koch and Clague, 2006).

About 5,000 years ago, there was a period of increasing warming around Earth as recorded through pollen and other indicators. Glaciers in the tropics were rather small or even absent during this period, gradually re-advancing from about 4,000 years ago, probably as a result of increasing humidity (Abbott et al., 2003). During medieval times there was a general warming, at least as recorded in Europe. Starting about 1300 A.D. the climate began to deteriorate drastically. Circumstantial evidence suggests that the cooling was caused by decrease in the Sun's heat output. Vikings who had settled on Greenland vanished by the fifteenth century and the year 1645 A.D. was the coldest year modern Europeans have ever experienced. Thereafter the climate gradually warmed until the middle of the nineteenth century. The period from 1300 A.D. to 1820 A.D. has been called the "Little Ice Age." The moraines (accumulations of unsorted, unstratified mixtures of clay, silt, sand, gravel, and boulders deposited by the glaciers) that were formed during the so-called Little Ice Age (from the early fourteenth to the mid-nineteenth centuries) can be found in many regions of the world, although the timing is asynchronous.

There has been a general retreat of glaciers worldwide since their Holocene maximum extent, toward the end of the Little Ice Age, between the seventeenth and the second half of the nineteenth century, with intermittent periods of glacier re-advance in certain regions.

From the paleoclimatic evidences, it is clear that climate change and glacier fluctuations are closely connected phenomena.

Glacier response to climate change

There are two main ways that a body of snow or ice can lose mass: through melting (conversion of solid into liquid) or sublimation (conversion of solid into vapor). Both transformations require energy. It takes 8.5 times as much energy to convert a kilogram of ice into water vapor by sublimation as it does to convert the same kilogram into liquid water by melting. Therefore, if conditions allow the glacier surface to warm to 0°C, the amount of ablation that can be sustained by a given energy input increases dramatically. Sublimated water vapor is always carried away by the air, but the fate of meltwater has a strong effect on ablation by melting. Runoff from steep ice-cliffs, or through subglacial flow driven by water percolating through pores or fractures, will convert a high fraction of melting into ablation. If meltwater percolates into the glacier and re-freezes, the effect on ablation is more limited and indirect.

Lower altitude portions of a glacier can be warmed directly by year-round exposure to above-freezing air, but at higher altitudes absorption of sunlight ultimately supplies all the energy, which sustains ablation. However, the other terms in the energy balance directly or indirectly affect the amount of absorbed solar radiation which is available for ablation. These terms are sensitive to air temperature, atmospheric humidity, cloudiness, and wind. The daytime glacier surface temperature typically has to be greater than the air temperature in order to close the energy budget; in consequence, melting can occur even when the air temperature remains below freezing. Because melting is so much more

energetically efficient than sublimation, the main way that moderate changes in atmospheric conditions – including air temperature – affect ablation is through changing the number of hours during which melting occurs, and the amount of energy available for melting. In particular, through infrared and turbulent heating effects, an increase in air temperature forces the glacier surface to warm, and makes it easier for melting to occur.

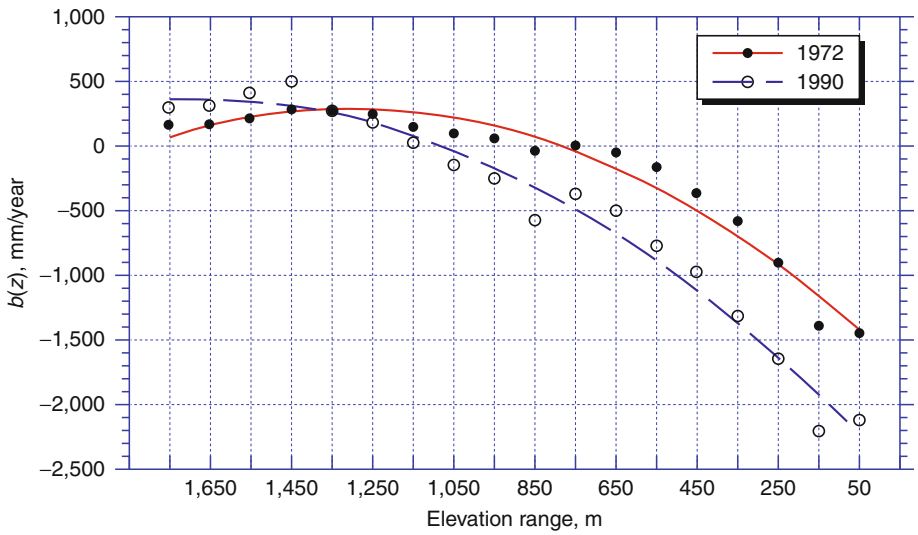
In addition to adding mass to a glacier, precipitation has an indirect effect on glacier mass balance by changing the amount of sunlight the glacier absorbs. This occurs because fresh snow is much more reflective than old snow or bare ice. The reflectivity effect can be almost ten times more important than the effect of mass directly added by precipitation. Because a thin layer of snow is just as reflective as a thick layer, the reflectivity effect depends more on the seasonal distribution of snowfall than the annual average amount.

A healthy glacier has an accumulation zone at high elevations and an ablation zone at lower elevations; ice flow from the accumulation zone continually feeds glacier tongues that penetrate into the ablation zone. The altitude separating the accumulation zone from the ablation zone is known as the equilibrium line altitude. Glaciers shrink when climate change causes the equilibrium line to rise, but they stop at a new equilibrium size with smaller accumulation zone. However, if the equilibrium line rises to the summit of the mountain, the accumulation zone disappears altogether and the glacier is doomed. This has happened on Chacaltaya and, according to limited recent observations (Mölg and Hardy, 2004), also on the summit glaciers of Kilimanjaro. Glacier AX010 in Shorong Himal, Nepal has its equilibrium line above the highest point on the glacier (Fujita et al., 2001).

Seasonal glacier-balance data, including winter balance, b_w, and summer balance, b_s, provide estimates of precipitation and summer temperature distributions in high-mountain and high-latitude areas where observational climatic data are both rare and biased. Very few long-term climatic stations exist above 3,000 m in altitude, and those that do grossly underestimate the actual precipitation as compared to observed glacier winter balances. Winter balance and precipitation also obey rather different spatial statistics. Unlike temperature, precipitation is not spatially homogeneous parameter, especially in mountainous environment. Winter balance, on the other hand, shows a higher autocorrelation at these distances, and drops to only about 0.5 at 2,000 km. This suggests that accumulation values are well correlated spatially, and are less influenced by local variations.

Another important measure of glacier–climate interactions is the vertical gradient in mass balance, d_b/d_z (Shumskiy, 1947; Meier and Post, 1962; Kuhn, 1980, 1984; Dyurgerov and Dwyer, 2001). While a good network of glaciers with long record of mass balance studies is lacking, Dyurgerov and Meier (2004) collected available data and found that d_b/d_z is getting steeper in recent years with warmer climate conditions (Figure 4). This is a result of glaciers losing mass at low altitudes due to higher temperatures. On the other hand, it is also due to glaciers gaining mass at high altitudes because of increasing snow accumulation that indicates intensification of precipitation in the higher altitude, although this might have some regional exceptions.

Apart from the change in the mass balance gradient, Dyurgerov and Meier (2004) also noted the increase in the equilibrium line altitude (ELA) and the decrease in ratio of glacier area above the ELA to the total glacier area



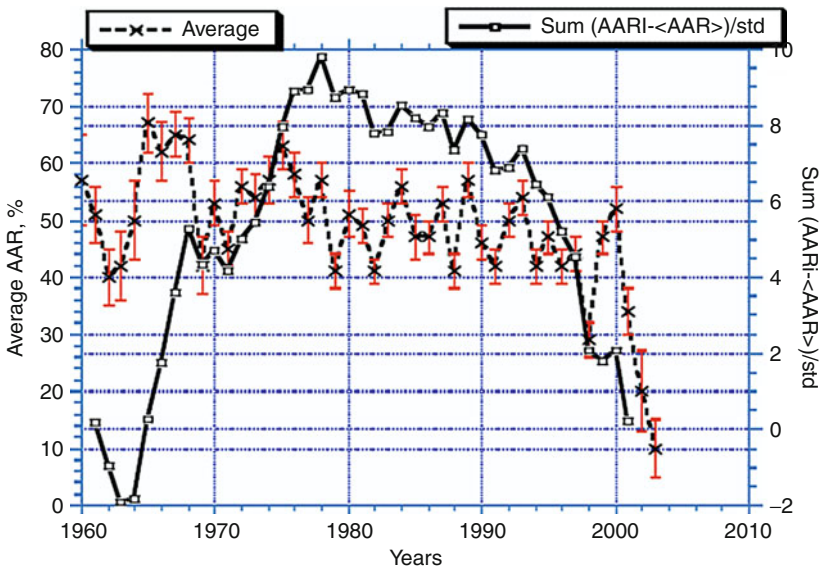
Climate Change and Glaciers, Figure 4 Change in mass balance gradient between cold and warm years; mass balance data have been averaged for 21 Northern Hemisphere glaciers and adjusted to the same elevation (Source: Dyurgerov and Meier, 2005).

(the accumulation-area ratio, AAR). One interesting indication of recent shifts in glacier mass balances is seen in the averaged AAR data plotted as standard departures (Figure 5); this shows an accelerated decrease in the AAR around the year 1977 and again in the early 1990s, in common with other evidence of increased glacier wastage. Except for debris covered glaciers, measurements of AAR can be made from satellite images, so this is an especially useful metric, particularly for glacial hydrological modeling.

The current increases in winter balances at high elevations have been especially rapid in the last decade, and have not been paralleled by appreciable increases in precipitation as measured at (lower altitude) climate stations. This also suggests a significant increase in the intensity of the hydrologic cycle at high elevations. The increase in b_w is even more remarkable considering the simultaneous decrease in glacier accumulation areas. An appropriate measure of this change in both major components of glacier mass balance is the glacier mass turnover, the average of the absolute values of b_w plus b_s (Meier, 1984). Another important measure is the sensitivity of mass balance to air temperature, db/dT. These observations show that both demonstrate changes in the recent warm decades of the twentieth century; these have not been predicted by, or used in, glacier-climate models. The spatialtemporal changes in glacier mass balances appear to be forced by changes in air temperature, which has increased globally. The study shows that an acceleration in volume wastage started in some regions as early as the 1970s (e.g., in Central Asia) and was completed by the end of the twentieth century in other regions (e.g., Arctic).

Glaciers: indicators of climate change

Glaciers have been considered to be excellent indicator of climate change (Oerlemans and Reichert, 2000; GTOS, 2008). Fluctuations of a glacier, which are not influenced by thick debris covers, calving or surge instabilities, are a reaction to climatic forcing. Thereby, the glacier length change (i.e., the advance or retreat) is the indirect, delayed, filtered but also enhanced signal to a change in climate, whereas the glacier mass balance (i.e., the change in thickness/volume) is the direct and undelayed response to the annual atmospheric conditions (Hoelzle and Haeberli, 1995). The mass balance variability of glaciers is well correlated with air temperature over distances of several hundred kilometers (Lliboutry, 1974; Schöner et al., 2000; Greene, 2005). However, the glacier mass balance change provides an integrative climatic signal, and the quantitative attribution of the forcing to individual meteorological parameters is not straight forward. The energy and mass balance at the glacier surface is influenced by changes in atmospheric conditions (e.g., solar radiation, air temperature, precipitation, wind, cloudiness). Air temperature thereby plays a predominant role as it is related to the radiation balance, turbulent heat exchange, and solid/liquid precipitation ratio (Kuhn, 1981; Ohmura, 2001). The climatic sensitivity of a glacier not only depends on regional climate variability but also on local topographic effects and the distribution of the glacier area with elevation, which can result in two adjacent glaciers featuring different specific mass balance responses (Kuhn et al., 1985). As a consequence, the glacier sensitivity to a climatic change is much related to the climate regime in which the ice is located. The mass balance of temperate glaciers



Climate Change and Glaciers, Figure 5 Annual variability and the change with time of the accumulation-area ratio <AAR> in terms of standardized cumulative departure. The data are averaged for all time series longer than 5 years; bars are standard errors. The time of <AAR> shifts to a decrease at the end of 1970s and again the early 1990s; data after 2001 are incomplete (Source: Dyurgerov and Meier, 2005).

in the mid-latitudes is mainly dependent on winter precipitation, summer temperature, and summer snow falls (temporally reducing the melt due to the increased albedo). In contrast, the glaciers in the low-latitudes, where ablation occurs throughout the year and multiple accumulation seasons exist, are strongly influenced by variations in atmospheric moisture content which affects incoming solar radiation, precipitation and albedo, atmospheric longwave emission, and sublimation (Wagnon et al., 2001; Kaser and Osmaston, 2002). In the Himalaya, influenced by the monsoon, most of the accumulation and ablation occurs during the summer (Ageta and Fujita, 1996; Fujita and Ageta, 2000). Cold glaciers in high altitude and the polar regions can receive accumulation in any season (Chinn 1985). As described in the text, strongly diverse mass balance characteristics also exist between glaciers under dry continental conditions and in maritime regions. As a consequence, analytical or numerical modeling is needed to quantify the above mentioned topographic effects as well as to attribute the glacier mass changes to individual meteorological or climate parameters (e.g., Kuhn, 1981; Oerlemans, 2001). Modeling is further needed in combination with measured and reconstructed glacier front variations, to compare the present mass changes with the (pre-) industrial variability (e.g., Haeberli and Holzhauser, 2003).

Recently, attempts have been made to relate the glacial dynamics with climate change. Differences in the climate sensitivity and response time of glaciers are taken into account. Oerlemans (2005) made an attempt to reconstruct past climate based on glacier length fluctuations data of 169 glaciers distributed around the world. The records are not spread equally over the globe. There is a strong bias toward the European Alps, where a wealth of documents exists and glacier monitoring was introduced relatively early. Fluctuations of some glaciers in Iceland and Scandinavia before 1800 have also been documented well (Sigurdsson, 1998; Østrem et al., 1976; Bogen et al., 1989).

The response of a glacier to climate change depends on its geometry and on the climatic setting. To unravel the climate signal contained in the glacier length records, Oerlemans (2005) discriminated glaciers with respect to the climate sensitivity c and to the response time t (the time a glacier needs to approach a new equilibrium state). Similar to other climate proxies, glacier length fluctuations are the product of variations in more than one meteorological parameter. Glacier mass balance depends mainly on air temperature, solar radiation, and precipitation. Extensive meteorological experiments on glaciers have shown that the primary source for melt energy is solar radiation but that fluctuations in the mass balance through the years are mainly due to temperature and precipitation (Greuell and Smeets, 2001).

Mass-balance modeling for a large number of glaciers has shown that a 25% increase in annual precipitation is typically needed to compensate for the mass loss due to a uniform 1 K warming (Oerlemans, 2001). These results, combined with evidence that precipitation anomalies normally have smaller spatial and temporal scales than those of temperature anomalies (Follard and Karl, 2001), indicate that glacier fluctuations over decades to centuries on a continental scale are primarily driven by temperature. Here, the climate sensitivity c is therefore defined as the decrease in equilibrium glacier length per degree temperature increase. The simplest approach that deals with lag effects is the response equation (Oerlemans, 2005):

$$\frac{\mathrm{d}L'(t)}{\mathrm{d}t} = -\frac{1}{\tau[cT'(t) + L'(t)]}$$

Here, t is time, L' is the glacier length with respect to a reference state, T' is a temperature perturbation (annual mean) with respect to a reference state, c is climate sensitivity, and τ is response time. The inverse model is now obtained by solving for T':

$$T'(t) = -\frac{1}{c\left[L'(t) + \tau\frac{\mathrm{d}L'(t)}{\mathrm{d}t}\right]}$$

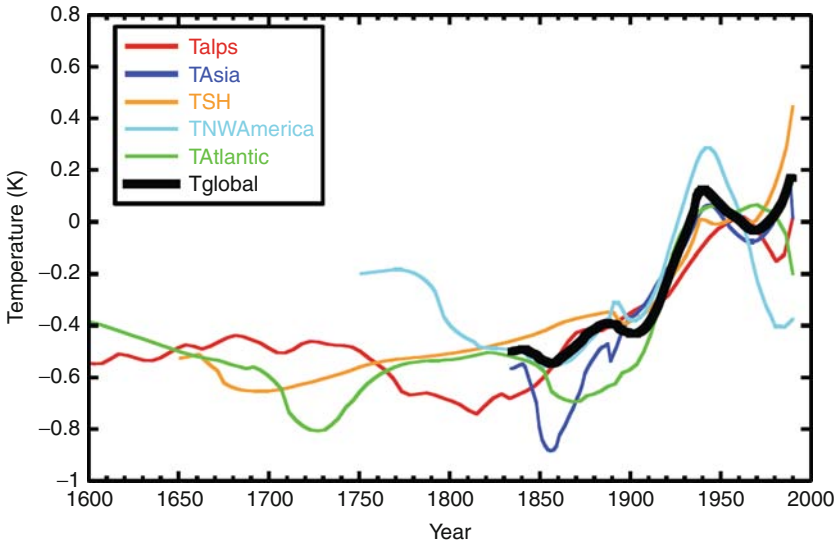
For any glacier length record, the corresponding temperature history can be obtained with above equation once the climate sensitivity and response time are known.

The temperature reconstruction obtained using this method is shown in Figure 6. The interpretation of the temperature curves before 1800 should be done with caution, because the number of records is small. From 1860 onward, most regions show a temperature increase. In the first half of the twentieth century the temperature rise is notably similar for all regions: about 0.5 K in 40 years. After 1945, the global mean temperature drops slightly until 1970, when it starts to rise again. For North America, the reconstruction shows a marked cooling after 1940. The global mean temperature shown in Figure 6 is a weighted mean for the period from 1834 to 1990.

The derived global temperature record is in broad agreement with other reconstructions and for the last part also with the instrumental record (Figure 7). However, the glacier reconstruction shows somewhat larger amplitude on the century timescale. Because glaciers need time to react and the number of records drops sharply after 1995, the warming seen in the instrumental record over the past 15 years is not yet reflected in the reconstruction. Temperature curves appear to be very similar for glaciers with low and high median elevation. Low and high glaciers are classified as glaciers with median elevation below and above 2,850 m, respectively. For this threshold, the number of glaciers in both classes is approximately equal. Although the evidence is not conclusive because only a limited altitudinal range is considered, the glacier record does not show any sign of a height dependence of the global warming signal.

Summary

Glacier are widely distributed over the globe and form where over longer time periods snow deposited during cold/humid season does not entirely melt during warm/dry seasons. The glacier-climate change response system



Climate Change and Glaciers, Figure 6 Temperature reconstruction for various regions. The black curve shows an estimated global mean value, obtained by giving weights of 0.5 to the Southern Hemisphere (SH), 0.1 to Northwest America, 0.15 to the Atlantic sector, 0.1 to the Alps, and 0.15 to Asia (Source: Oerlemans, 2005).

is a complex chain of processes. The dynamic relationship between climate and glacier leads to changes in the size of the glacier, which is visually evident by advance and retreat of glacial front. The terminus fluctuation closely represents the changes in the mass balance of glaciers. A healthy glacier has accumulation zone at high elevation and ablation zone at lower elevations. The equilibrium line separates the two zones. Glaciers shrink when climate change causes the equilibrium line to rise and stop at a new equilibrium size.

The relationships between glacier fluctuation and climate change existed throughout the history of the Earth. The correlation exists in varying timescales: from several years to several hundred thousand years. At time scales of tens of thousands to hundreds of thousands of years, glacial variations were caused by climate change, which in turn was due to solar variations and variations in orbital and axial parameters of the Earth.

The excellent relationship between glacier and climate provides the opportunity of using glacier fluctuations as indicators of climate change. Seasonal glacier-balance data, including winter balance and summer balance provides estimates of precipitation and summer temperature distributions in high-mountain and high-latitude areas where

observational climatic data are both rare and biased. Glacier mass balance provides an integrative climatic signal, which is very much dependent on the geometry of the glaciers.

CLIMATE VARIABILITY AND HIGH ALTITUDE TEMPERATURE AND PRECIPITATION

Mathias Vuille
Department of Atmospheric and Environmental Sciences, University at Albany, State University of New York, Albany, NY, USA

Definition

High altitude temperature and precipitation variability: It is the inherent characteristic of precipitation and temperature to change over time. Variability is measured as the temperature or precipitation deviations (anomalies) over a given period of time from a climate statistic (long-term mean) averaged over a reference period.

Introduction

Mountains give rise to very distinct climates at their highest peaks where glaciers exist, and this mountain climate varies in ways that is quite different from nearby low elevations. Mountain-induced dynamic and thermodynamic processes modify synoptic weather systems and create regional-scale atmospheric circulation regimes that generate distinct wind systems, cloudiness, Precipitation patterns, etc., and lead to a very unique mountain climate (e.g., Barry, 2008). However, climate variability at high altitude (including temperature and precipitation variability) is not nearly as well understood as similar variations at lower elevations. The remoteness and difficulty in accessing many high elevation sites, combined with the complications of operating automated weather stations (AWS) at high elevations, make long-term measurements very challenging. Furthermore, the complex topography of high elevation sites often leads to very site-specific measurements that are not always representative of a larger regional mountain environment.

Climate observations at high elevation

While some high elevation observatories, in particular in the Alps, have maintained climate records for over 100 years, most mountain regions of the world are difficult to access and essentially devoid of any high-altitude observations. New advances in instrumentation, satellite telemetry, and power supply through solar panels have made high elevation measurements more feasible in these regions over the past decade. For example, new and unique measurements have become available from remote glacier sites in the tropical Andean Glaciers, the Himalayas, and Mt. Kilimanjaro, thanks to the installation of such AWS – locations, where previously no climatic information existed (e.g., Hardy et al., 1998, 2003; Georges and Kaser, 2002; Moore and Semple, 2004; Mölg et al., 2009). Figure 1 shows an example from an AWS installed and operated by the University of Massachusetts, Amherst on the summit of Quelccaya ice cap in Peru (14°S) at 5,670 m above sea level. Still, to be truly useful for climate research it is imperative that these

Climate Variability and High Altitude Temperature and Precipitation, Figure 1 Automated weather station (AWS) on the summit of Quelccaya ice cap, located at 14°S in the eastern Peruvian Andes (Cordillera Vilcanota) at 5,670 m above sea level. Photo courtesy of Douglas R. Hardy.

AWS remain operational for several years and ideally decades to allow detection of trends and variability on interannual to decadal timescales (e.g., Bradley et al., 2004).

Characteristics of temperature and precipitation at high elevations

In the free atmosphere temperature decreases with height at a rate of about 6°C km^{-1} (Environmental Lapse Rate), although this rate varies by region, season, time of day, and by the type of air mass. Similarly the diurnal temperature range also decreases with elevation in the free atmosphere; an effect that can also be observed on mountain slopes and summits where mixing of slope air with the free atmosphere occurs (Barry, 2008). The comparison between near-surface observations at high elevations and measurements in the surrounding free atmosphere at the same elevation, however, is not straightforward (e.g., Pepin and Seidel, 2005) as temperature in the free

atmosphere is generally colder than its near-surface counterpart due to both latent and sensible heating of the atmosphere above elevated surfaces. Therefore, temperature lapse rates on a mountain slope may bear a close resemblance to the free atmospheric lapse rate or may be almost independent (Barry, 2008).

Precipitation distribution and amount are also strongly affected by mountain barriers; but in many mountain regions the exact mechanisms and impacts on Precipitation are still poorly understood due to paucity of data and problems related to accurate measurements of snowfall totals, in particular at exposed, windy, high-elevation sites (e.g., Falvey and Garreaud, 2007). In general, high elevations sites are affected by mountain-induced Orographic Uplift or convective instability that lead to regionally enhanced Precipitation. In typical convective patterns, common on tropical mountains, Precipitation is usually highest near the cloud base (generally at or below 1,500 m) and decreases significantly at higher elevations. The zone of maximum Precipitation tends to occur at higher elevations in drier climates. In mid-latitudes where Precipitation is derived primarily from advective situations, at least during the winter season, forced large-scale ascent over a barrier can lead to enhanced Precipitation even at 3,000 m or above on the windward side, due to both higher intensity and longer duration of Precipitation events (Barry, 2008). On the leeward side, however, the remaining moisture that spills over the mountain crest is usually insufficient to induce significant condensation and Precipitation amounts tend to be much lower than on the windward side.

Climate variability and change at high elevation

In many mountain ranges of the world both Precipitation and temperature vary on interannual timescales in response to changes in the large-scale circulation, forced by major modes of ocean–atmosphere interactions. In the Alps, for example, winter precipitation is sensitive to the phase of the North Atlantic Oscillation, with decreased snowfall and higher temperatures during its positive phase (e.g., Beniston, 1997, 2006). Similarly Precipitation in parts of the Rocky Mountains, the Cascades, and the Alaskan coastal range (Alaskan Glaciers) are influenced by the Pacific Decadal Oscillation, while snowfall amounts in the mountains of East Africa and the Himalayas are sensitive to the phase of the Indian Ocean dipole and the El Niño–Southern Oscillation (ENSO) phenomenon (e.g., Vuille et al., 2005; Chan et al., 2008). Temperature and snowfall variations in the tropical Andean Glaciers are also primarily a reflection of ENSO variability (Vuille et al., 2000; Garreaud et al., 2003), while the southern Andean Glaciers are more strongly influenced by the state of the Antarctic Oscillation (Gillett et al., 2006).

Superimposed on these natural climate variations, caused by ocean–atmosphere interactions, are long-term trends in temperature and Precipitation that have become discernible at many high-elevation sites over the past decades. There is clear evidence from many mountain ranges that the temperature increase over the past 100 years has been significantly amplified at high elevations when compared with low elevations or the global average temperature (e.g., Beniston et al., 1997; Diaz and Bradley, 1997), and that the warming is more closely related to an increase in daily minimum temperature than a change in the daily maximum (Diaz and Bradley, 1997; Beniston, 2006; Giambelluca et al., 2008).

The differential temperature trends with altitude are particularly apparent in the Alps and on the Tibetan Plateau. In the Alps many locations have seen an increase in minimum temperature of 2°C or more during the twentieth century (Beniston, 2006). Liu and Chen (2000) reported a significant warming on the Tibetan Plateau since the 1950s (0.16°C per decade), and especially during winter (0.32°C per decade). They observed an amplified warming at higher elevations, which was later attributed primarily to a strong elevation dependence of trends in minimum temperature (Liu et al., 2009). However, this dependence does not seem to hold for temperature extremes (You et al., 2008). In the mountains of the western United States (Rocky Mountains) the strongest warming (0.5–0.6°C between 1950 and 2000) seems to have occurred below 2,000 m (Diaz, 2005), although strong summertime warming at high elevations has lead to a significant reduction of alpine tundra (Diaz and Eischeid, 2007). In East Africa the lack of an adequate observational network has so far precluded a definite assessment of temperature changes at high altitudes. While some suggest that temperature has also increased significantly at highest elevations of the East African Mountains (e.g., Taylor et al., 2006), this has been questioned by others (e.g., Mölg et al., 2006). In the tropical Andean Glaciers the observed warming is stronger at higher elevation only on the eastern slope, while on the western side the strongest warming is recorded close to sea level (Vuille and Bradley, 2000; Vuille et al., 2003). This differential response may be related to changes in cloud cover and the lack of a seasonal snow cover at high elevations, which precludes an amplified warming due to a snow-albedo feedback (e.g., Pepin and Lundquist, 2008). Nonetheless, temperatures at high elevations in the tropical Andean Glaciers have increased by about 0.68°C over the past 70 years (Vuille et al., 2008), consistent with the observed increase in the freezing level height (altitude at which air temperature is close to 0°C) of about 1.43 m $year^{-1}$ between 1948 and 2000 (Diaz et al., 2003). Much of the warming in the high elevation tropics and hence the increase in freezing levels can be traced back to warmer tropical sea surface temperatures SST (Diaz and Graham, 1996; Diaz et al., 2003; Vuille et al., 2003). In the southern Andean Glaciers of central Chile the freezing level has also increased by 122 m during winter and 200 m during summer between 1975 and 2001 (Carrasco et al., 2005), leading to a rise in the glacier equilibrium line altitude (Snow Line) (Carrasco et al., 2008).

Projections of future climate change under different Greenhouse Gas emission scenarios suggest that in many locations higher elevations will continue to experience the strongest warming (Global Warming and its Effect on Snow/Ice/Glaciers). Fyfe and Flato (1999) report that the strongest twenty-first century warming in the Rocky Mountains will occur at the highest elevations. Similarly model projections in the tropical Andean Glaciers suggest that both surface and free-tropospheric temperature changes will be largest at higher elevations where glaciers are located (Bradley et al., 2006; Vuille et al., 2008; Urrutia and Vuille, 2009). Simulations with regional climate models in the Alps also project a significant warming of 4–6°C by the end of the twenty-first century, when compared to the 1961–1990 average. In general winters will be warmer and more humid in the Alps, while summers will also be warmer, but drier than today (see Beniston, 2006 and references therein). For the Tibetan Plateau Liu et al. (2009) project increases between 2.9°C (below 500 m) and 3.9°C (above 5,000 m) by the end of the twenty-first century.

While there is strong evidence for warming in most mountain regions, the picture for changes in Precipitation is much more mixed. In the northwestern Alps winter precipitation has increased significantly during the twentieth century (up to 30% in the last 100 years) but decreased by the same amount in the southeast (Schmidli et al., 2005; Schär and Frei, 2005). Vuille et al. (2003) found a positive Precipitation trend in the tropical Andean Glaciers north of about 10°S and a negative trend further south, but in general the trends were weak and statistically not significant. Bhutiyani et al. (2009) reported a significant decline in summer monsoon Precipitation over the northwestern Himalayas during the past 140 years, but found no change in the amount of winter Precipitation. In general changes in timing or amount of Precipitation are much more ambiguous and difficult to detect and there is no clear evidence of significant changes in Precipitation patterns in most mountain regions. Nonetheless Precipitation characteristics at high elevation will change significantly over the next 100 years as the increase in temperature will lead to more Precipitation falling in the form of rain. For roughly every °C rise in temperature the snow/rain transition will rise by about 150 m (e.g., Beniston, 2003).

Summary

Temperature and Precipitation variability are still poorly understood at many high elevation sites due to the lack of an adequate long-term monitoring network, but studies on mountain-induced dynamic and thermodynamic processes have advanced our understanding of climate variability at high altitude. In many mountain ranges of the world large-scale ocean-atmosphere interactions are the main driver for observed variability in both Precipitation and temperature. Over the past 100 years long-term warming trends (Global Warming and its Effect on Snow/Ice/Glaciers) have been superimposed on this natural variability and become increasingly evident at most high altitude sites. In many mountain regions of the world high altitudes appear to experience a stronger warming than the surrounding lowlands. Projections of future climate change in the twenty-first century suggest continued warming and rising freezing levels, combined with altered Precipitation patterns in many high altitude locals.

CLOUDBURST

Vijay Kumar
National Institute of Hydrology,
Roorkee, India

Cloudbursts have no strict meteorological definition. The term usually signifies a sudden, heavy fall of rain over a small area in a short period of time. Cloudburst represents cumulonimbus convection in conditions of marked moist thermodynamic instability and deep, rapid dynamic lifting by steep orography. The phenomenon occurs due to sudden upward drift of moisture-laden clouds as a tall vertical column termed "Cumulonimbus clouds." The ascending moisture-laden clouds become heavier and at certain point they produce violent rainstorm within a short interval. Orographic lifting of moist unstable air releases convective available potential energy necessary for a cloudburst (Das et al., 2006).

A cloudburst is a devastating weather phenomenon representing sudden burst of highly concentrated rain associated with thunderstorm over a small geographical area, generally not exceeding 20–30 km^2. Cloudbursts are generally accompanied by lightening, thunder, and strong gusts of winds. Rain from a cloudburst is usually of the shower type with a fall rate equal to or greater than 100 mm/h. During a cloudburst, more than 20 mm of rain may fall in a few minutes. The hard rain characteristic of a cloudburst is caused by a phenomenon known as langmuir precipitation in which drops of rain fuse together to create large drops as they fall, falling ever more quickly as they grow.

Cloudbursts in India occur when monsoon clouds associated with low-pressure area travel northward from the Bay of Bengal across the Ganges plains onto the Himalayas and "burst" in heavy downpours (Das et al., 2006). Cloudbursts are common to all hilly areas but the states of Himachal Pradesh and Uttaranchal are most affected due to topographical conditions. Most of the damages to properties, communication system, and human casualties are as a result of flash floods. Prediction of cloudbursts is challenging and requires high-resolution numerical models and meso-scale observations, high-performance computers, and Doppler weather radar (Das et al., 2006).

COHESION

P. Pradeep Kumar
Department of Atmospheric and Space Sciences, Pune University, Pune, Maharashtra, India

Definition

Cohesion means cling together or sticking together. The force holding the molecules of the same substance is cohesion. The cohesion of molecules gives the phenomena of surface tension, which is responsible for the spherical shape of the cloud or rain drops as they fall through the air. Cohesion is important for fluid flow. Cohesion is important for snow avalanches.

COLD-BASED GLACIERS

Reginald D. Lorrain[1], Sean J. Fitzsimons[2]
[1]Département des Sciences de la Terre et de l'Environnement, Université Libre de Bruxelles, Bruxelles, Belgium
[2]Department of Geography, University of Otago, Dunedin, New Zealand

Definition and synonyms

Cold-based glaciers are glaciers with their basal part entirely below the pressure melting point and therefore sometimes called "dry-based glaciers" (through lack of liquid water). Floating ice bodies are not considered in this entry.

Antonyms are respectively warm-based glaciers and wet-based glaciers.

This terminology emphasizes the importance of basal conditions of glaciers. In a happy turn of phrase, Knight (1999, p. 78) justifies this point of view telling that the basal part is the "business end" of glaciers because, among other factors, the rheology of the basal ice layer which accommodates the bulk of movement in many glaciers is critical to glacier dynamics and the basal ice acts as an agent of glacier impact on the landscape. In fact, as we will see below, nearly always, it is possible to equate cold-based glaciers with cold glaciers (and warm-based glaciers with warm – or temperate – glaciers). But this dichotomy is too simple an approach because very often, different parts of the same glacier can fall into one or the other category. That is the reason why these transitional forms are referred to as polythermal glaciers. The twofold classification also leads to another oversimplification implying that there is no liquid water at all at the base of cold-based glaciers so that they are firmly frozen to their bed. As a result, they are thought to be ineffective agents of erosion and, after retreat, leaving nearly no evidence of their former existence in the landscape. Very large surfaces are thought to have been protected from glacial erosion because of the cold-based Pleistocene ice caps and ice sheets (Kleman and Hatterstrand, 1999; Sugden and John, 1976). This has been suggested by many observations of relatively fragile landforms as tors which are widespread in formerly glaciated regions. In fact, even if such observations are undeniable, the conclusion of the general absence of basal motion and, hence, of erosion by cold-based glaciers is questionable.

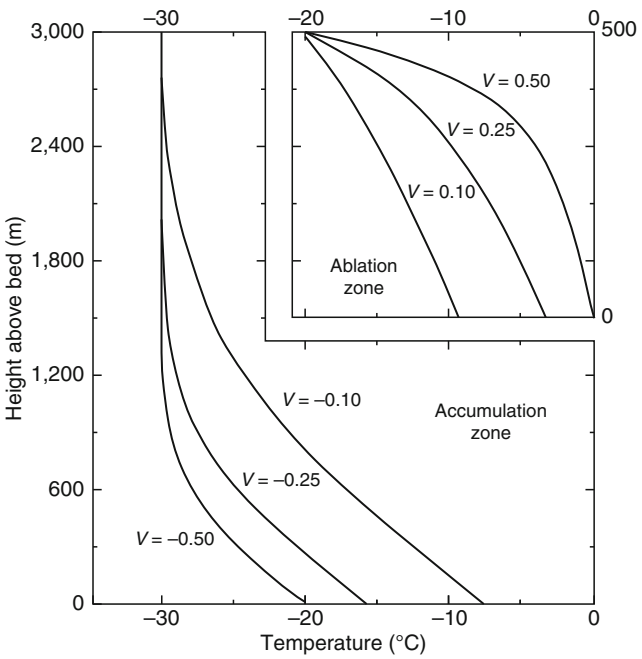
Basal thermal regime

Vertical temperature profiles in glaciers show that below an upper layer of 10–15 m thick affected by seasonal variations and eventually refreezing of percolating meltwater, there is a general increase in temperature with depth. This situation results from internal and basal heating. But, where the bed is below the melting point, the basal temperature is mainly governed by the geothermal heat flux and only secondarily by friction heat. This means that, if the ice mass

is stagnant, the steady state temperature distribution is determined as soon as the temperature gradient and the near surface temperature (below the depth of 10–15 m) are known. Because any heat flux is proportional to the temperature gradient, this heat flux determines the temperature gradient that must develop throughout the ice mass (Hooke, 1977). For a typical geothermal flux of 50 mW m^{-2} (Paterson, 1994), the gradient is 0.021 K m^{-1} since the thermal conductivity of ice is 2.39 W m^{-1} K^{-1} (at −20°C). For a 100 m ice thickness, this means that, if the near surface temperature is −20°C, the basal temperature will be −17.9°C.

Now, if the ice mass is moving, the effects of vertical and horizontal velocities have to be taken into account. Hooke (1977) has calculated temperature profiles for realistic combinations of ice thickness and vertical velocity, reproduced in Figure 1. It is clearly visible that the basal temperature increases markedly with increasing vertical velocity in the ablation zone while it is the contrary in the accumulation zone.

Considering the effect of horizontal velocity, Hooke (1977) indicates that temperature gradients in the horizontal direction are generally so small that very little warming or cooling of the ice occurs. But, because the velocity decreases with depth, there is shear deformation in the horizontal direction which produces heat. The rate of deformation increases with temperature so that in cold glaciers, the shear is particularly concentrated close to the bed. The frictional heat released is added to the geothermal heat with the result that the temperature gradient at the bed is that much higher. With the typical basal shear stresses of about 0.5 bars given by Hooke, it appears that for producing an amount of heat comparable to the geothermal heat, the horizontal velocity must be several tens of meters per year. However such velocities are far to be reached everywhere. Moreover, horizontal velocities increase from the highest places of the accumulation areas to the equilibrium lines and than decrease from these to the margins.



Cold-Based Glaciers, Figure 1 Illustrative temperature profiles [v = vertical velocity at glacier surface (in m a^{-1}) and is positive upwards]. In the ablation zone (*upper right*), v is upward. In the accumulation zone (*lower left*), v is downward; horizontal conduction and advection and internal heat generation is ignored in all cases. Vertical velocity is assumed to decrease linearly with depth. After Figure 3 in Hooke (1977).

From the considerations developed above, one can easily understand that at the places where they are cold-based, glaciers are at subfreezing temperature from top to bottom except in certain cases for a surface layer of about 10–15 m thick where the temperature can reach the melting point seasonally. It is also obvious that they can only exist in regions where the mean annual temperature is markedly negative, that is, in high latitude and high altitude areas.

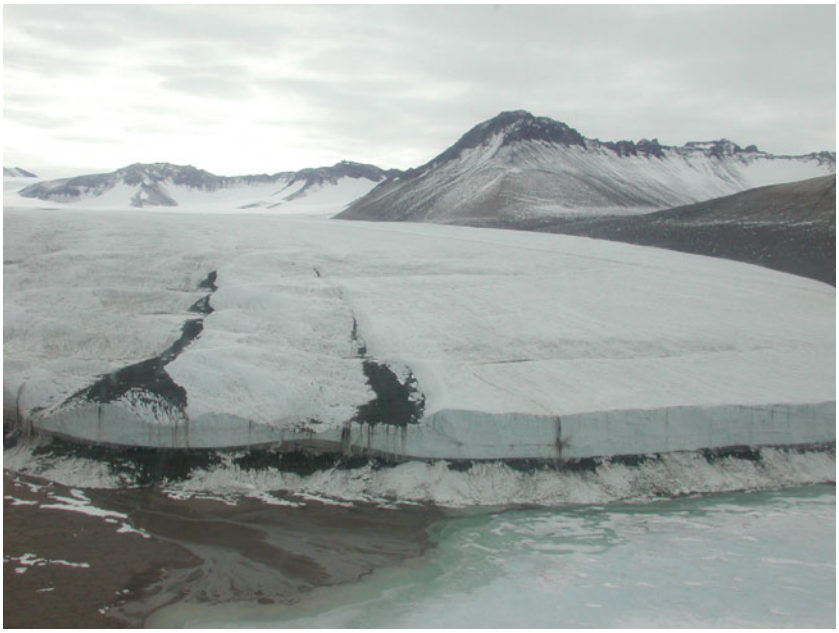
Now, as the temperature gradient above the glacier sole determines the amount of heat that can enter the glacier per unit time, there are three possible situations (Weertman, 1961):

1. More heat (from the geothermal flux and from frictional heating) is provided than can be conducted upwards through the glacier; then, the excess heat is consumed by melting ice at the base.
2. The heat amount provided is equal to that which can be conducted upwards through the glacier; there is thus a balance between melting and freezing.
3. The heat amount provided is smaller than the amount which can be removed through the glacier (even if latent heat is released locally by freezing of meltwater flowing in from an adjacent zone). In this case which is the only one relevant to our subject, the glacier is frozen to its bed and impedes (or reduces) sliding considerably so that the forward movement of the glacier is mainly due to internal flow.

From this threefold alternative, it appears clearly that different thermal zones can coexist at the base of glaciers (e.g., Robinson, 1984) and ice sheets, so explaining why they can be polythermal. The areal distribution of these zones is likely to change in the course of time as a result of climatic changes. Moreover, these changes can result in thickening or thinning of the glacier and in consequent changes in the velocity field. However, some glaciers are exclusively cold-based. A cold base is favored by smaller ice thickness, low surface temperature, low basal velocity, and low geothermal heat flux.

Glacier margin morphology

As remarkably analyzed by Chinn (1991), cold-based glaciers display a variety of margin forms which have in common a three-part structural sequence of: (1) white glacier ice, terminating at (2) an inner moraine, which is surrounded by (3) an outer apron structure (Figure 2).



Cold-Based Glaciers, Figure 2 Victoria Upper Glacier (Victoria Valley, Antarctica). This typical cold-based glacier is showing its terminal cliff, about 40 m high towering above the apron mainly formed by successive cliff collapses. Debris coming out at the upper part of the apron is progressively forming a shear moraine.

The forms and behavior of these margins result from the effects of internal zones of different viscosity and the fact that basal ice is frozen to the bed. Where the ice thins to nearly 20 m as it approaches to the glacier margin, the upper "semi rigid zone" (Chinn, 1991, p. 29) becomes grounded and basal debris is upwarded against this obstructing ice to appear at the surface as a shear moraine. A wedge of drifted snow and ice usually forms in the inflection between the glacier and the ground to form an kind of scree called "apron" (Chinn, 1991) around the glacier margin.

Sliding at subfreezing temperatures

As indicated above, ice masses with basal temperature below the pressure melting point are traditionally assumed to display neither sliding nor bed deformation even if Shreve (1984), theorizing on glacier sliding at subfreezing temperatures had already predicted nonzero sliding speeds.

It is highly significant in this respect that in the authoritative "The Physics of Glaciers," by Paterson (1994), there is only one page on sliding at sub-freezing temperatures out of 26 on glacier sliding. However, as pointed out by Waller (2001), there is growing field evidence that directly contradicts the generally accepted view. As far as contemporary glacial environments are concerned, this evidence has been first derived from field work conducted by, e.g., Echelmeyer and Wang (1987), Fitzsimons (1996), and Cuffey et al. (1999).

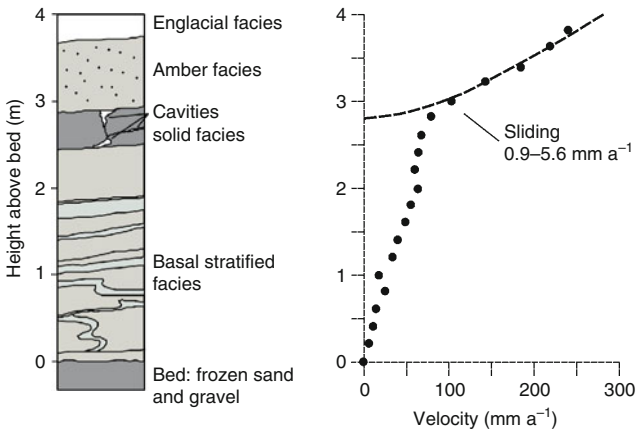
The first cited authors described observations they made in a tunnel at the base of the predominantly cold-based Urumqi Glacier n°1 in North-Western China. They found that 60–85% of the overall glacier motion occurred within the lowermost 1–2% of the glacier thickness, mainly through deformation of the subglacial sediments. The latter were displaying a 100-fold reduction in creep strength relative to clean ice at the same temperature (here $< -1.75°C$). A small but significant amount of basal sliding was measured at the ice–drift interface (0.5 mm day^{-1}) and basal sliding at an ice–rock interface was also detected. Among different conclusions, the authors suggested that cold-based glaciers are able to mobilize and entrain permafrozen, subglacial material *en masse*, due to transmission of basal shear stress across the ice–bed interface. Following Waller (2001), the greatest merit of Echelmeyer and Wang's work is that it demonstrates that the basal processes beneath a cold-based ice-mass may contribute in an extremely important way to its total surface motion, even though they are only accommodating flow rates of the order of up to a few meters per year. However, it should be noted that the basal temperature in this case is not very negative, which allows to suspect that liquid water could still be present, for instance in the case of high solute concentrations frequently found in water within sediments.

Fitzsimons (1996) has shown that several cold-based glaciers in the Dry Valleys of McMurdo (Antarctica) have prominent end moraines which contradict the previously accepted idea that these glaciers are geomorphologically inactive. They are thrust-block moraines consisting of blocks of lacustrine sediments often interbedded with ice. All previous explanations of the formation of thrust-block moraines depend on the presence of subglacial

meltwater and thus appear inappropriate for the cold-based glaciers in question, having basal temperature as low as −17°C. The author has proposed a model based on the presence of ice-marginal lakes. Transient wet-based conditions can occur as ice flows onto the unfrozen sediments of the lake bottom, creating conditions favorable for the entrainment of sediments and for ice accretion by water freezing. This model has been proved to be valid by an ice-composition study of the basal part of Suess Glacier (Taylor Valley) where stable isotope and gas composition have allowed discriminating between meteoric glacier ice and basal refrozen water from the adjacent lake (Lorrain et al., 1999).

Concerning the work of Cuffey et al. (1999), it showed that sliding is occurring at very cold (−17°C) ice–rock interface beneath Meserve Glacier situated in another of the Dry Valleys of McMurdo (Wright Valley, Antarctica). This observation is interpreted as manifestations of thin water films at ice–rock interfaces. These interfacial films can exist due to a reduction of the chemical potential of water very close to the surface of a foreign solid which depresses the melting point. It is to be noted that recent work by Samyn et al. (2005) have given some weight to this hypothesis thanks to gas composition analyses performed in the basal ice of another cold-based glacier of the dry Valleys. Their results point to the occurrence of water phase changes involving minute liquid water bodies present despite the ice temperature of −17°C. Coming back to the work of Cuffey et al. (1999), an interesting point is that cavities were observed in the lee of boulders on the bed and that the cavity roofs are striated. Displacement transducers were inserted 1and 30 mm above the bed just upstream of a prominent cavity. These markers moved downglacier at a rate more than an order of magnitude faster than due to shear strain and therefore measuring sliding (Cuffey et al., 1999). The markers showed a sliding rate of about 8 mm a^{-1}. Theoretical treatment based on Gilpin's (1979) interfacial film theory allowed the authors to explain the relatively rapid sliding of this cold glacier by the presence of very high solute content of unfrozen water within interfacial films at the ice–rock interface. In a later paper, Cuffey et al. (2000) reported on their investigations in the same tunnel and confirmed their previous interpretation, using compositional analyses (gas and stable isotopes) of the different types of ice observed at the base. They showed that active entrainment occurs at the bed. They were also able to calculate that, as the Dry Valleys have been cold and dry for at least 10^7 years, entrainment may have formed the U-shaped trough containing the glacier, assuming that the modern debris flux they measured is representative of long-term rates. Their general conclusion was: "The common assumption that cold-based glaciers are protective rather than erosional is not true in the absolute sense although it's accurate relative to temperate glaciers." (Cuffey et al., 2000, p. 354).

The Dry Valleys are particularly interesting in that context because they concentrate on a small territory a number of cold-based glaciers which are relatively accessible and, therefore have attracted many investigations. Examination of their basal zone has demonstrated a wide variety of types of basal ice (Fitzsimons, 2006). More specifically, it has shown that, in the case of glaciers that rest on unconsolidated sediments, the thickness, composition, and structure of basal ice are distinctly different from those confined to the valley sides, such as Meserve Glacier. Tunnels excavated into several of the former glaciers (Suess, Wright Lower, and Taylor glaciers) have provided an opportunity to closely examine the composition, structure, and behavior of basal ice (with temperature always lower than −16°C) and glacier beds. The configuration and composition of this basal ice show that, in several cases, no simple clear boundary does separate basal ice from a frozen substratum. In Suess Glacier for instance, the compound velocity profile (Figure 3) together with measurements of sliding demonstrate that the glacier bed is not a simple ice-substrate contact that can be adequately described by a power law like Glen's Law. Following Fitzsimons (2006), the measured velocity structure is the product of variability in the rheological behavior of ice with distinct physical and chemical composition. In other words, the zero-based velocity of cold-based glaciers is simplistic and in reality, the situation is likely to be much complicated. There is abundant evidence to suggest that deformation of the glacier substrate has resulted in both *en masse* entrainment of the glacier substrate and mixing of material from the glacier substrate with basal ice. Ultimately, the point of zero velocity in any glacier is governed by the thermal and mechanical processes which vary in space and time. Accordingly, where a glacier rests on an unconsolidated substrate, the base is likely to be a zone rather than a boundary. In the case of the cold-based Antarctic glaciers cited above, this zone has developed as a result of folding, faulting and shearing that has produced a complex mosaic of ice-rich sediment and debris-rich ice within which many structural characteristic of the



Cold-Based Glaciers, Figure 3 Ice composition, structure, and deformation at the base of Suess Glacier (Taylor Valley, Antarctica).

substrate are preserved after the material has been entrained (Fitzsimons, 2006).

Perspectives and conclusion

In a recent paper, Alley et al. (2008) have attracted attention on the fact that surface meltwaters that seasonally form lakes on top of the Greenland Ice sheet can drain catastrophically into the ice sheet, delivering heat rapidly to the bed. In a warming world, intensification of this phenomenon would deliver sufficient heat to thaw areas where the bed is currently frozen. Accelerations comprised between twofold and more than an order of magnitude could occur especially where extensive regions with soft sediments were to thaw. As such events would clearly influence future sea level change, we plead for an increasing research effort devoted to studying basal characteristics of the soft-bedded cold-based glaciers.

CONDENSATION NUCLEI

P. Pradeep Kumar
Department of Atmospheric and Space Sciences, Pune University, Pune, Maharashtra, India

Definition

Condensation nuclei are very small atmospheric particles in the range of 1 nm–0.1 μm on which water can condense at very high supersaturations. Atmospheric aerosols upon which water vapor can condense at lower supersaturations are called as Cloud Condensation Nuclei (CCN). Only a small fraction of aerosols serve as CCN (about 1% in continental air and about 10–20% in maritime air). Most of the CCN would be a mixture of soluble and insoluble components.

CONFLUENCE OF RIVERS

Anju Chaudhary
Water Resources System Division, National Institute of Hydrology, Roorkee, India

Definition

Confluence of rivers is defined as a meeting point of two or more rivers. In other words it usually refers to the point where a tributary joins a major river, called the mainstream. In general, downstream of the confluence, the river having the combined flow of rivers/streams is known as the main stream, but in some cases a new name is also given to the river after the meeting of two streams/rivers. Two examples of confluence of rivers are given below (Figures 1 and 2).

Confluence of Rivers, Figure 1 Confluence of Spiti river with Satluj river in the Himachal Pradesh (India).

Confluence of Rivers, Figure 2 Confluence of Alaknanda river with Bhagirathi river at Deoprayag in the Uttrakhand (India). This river is known as Ganga after confluence of Alaknanda and Bhagirathi rivers.

CONGELATION ICE

Pratima Pandey
Centre of Studies in Resources Engineering, Indian Institute of Technology Bombay, Mumbai, Maharashtra, India

Definition

Congelation ice forms as water freezes on the bottom of the ice cover, and the latent heat of crystallization is conducted upward through the ice and snow to the atmosphere. Formation of sea ice on the bottom of an established sea ice cover in the form of platelets, which coalesces to form solid ice, is also represented by congelation ice. Its growth rate is proportional to the rate at which energy is transferred from the bottom surface of the ice layer to the air above. Congelation ice is often referred to as *black ice* because it has a high optical depth that permits significant light transmission to the underlying water. It forms as a stable ice sheet with a smooth bottom surface.

CRACK

Pratima Pandey
Centre of Studies in Resources Engineering, Indian Institute of Technology, Bombay, Mumbai, Maharashtra, India

Definition

A crack is defined as a narrow rift/fracture in the ice. As ice expands, it causes stresses through its depth and across its breadth which results in crack of ice. Cracks are found in glaciers and floating ice in the sea. Wider cracks can be termed as "crevasses" in the glaciers.

CREEP

Christophe Lambiel[1], Reynald Delaloye[2], Isabelle Gärtner-Roer[3]

Definition

Creep is the slow deformation of rock, debris, soil, or ice.

Introduction

Regarding geomorphological processes, creep or flow, respectively, is one form of mass movement and may occur in bedrock (e.g., sagging, Sackung), debris (e.g., rock glacier), as well as soil (e.g., solifluction) (Dikau et al., 1996). In general, creep is driven by gravity and shows slow, plastic deformation with rates of mm, cm, and dm per year. Creep can be continuous or periodical (seasonal). In addition, creep is also defined for glacier movement. Regarding cryospheric processes, creep characteristics are detailed for ice (glacier) and ice–debris mixtures (rock glacier).

Creep of ice

Creep is the motion that results from ice crystal deformation and movement between individual ice crystals (Benn and Evans, 1998). Glacier ice deforms internally because it is subject to stress. The average shear stress within a glacier can be approximated as:

$$\tau = \rho_i g h \sin a$$

where ρ_i is the density of ice, g is the gravitational acceleration, h is the ice thickness, and a is the surface slope of ice. This equation indicates that the shear stress at the base of the glacier depends on the glacier thickness and on the slope. An increase in glacier thickness will increase the shear stress and thus increase the rate of movement. It also indicates that the deformation is maximal in the basal layers because shear stress is the highest.

The typical creep curve for glaciers, when polycrystalline ice is subject to a constant stress, displays an initial elastic deformation, followed by a primary creep in which the strain rate decreases continuously (Paterson, 1981). Then, a period of constant strain, which is called secondary or steady state creep, occurs. After this, the strain rate increases (tertiary creep). Most glaciers are thought to be in a permanent state of secondary creep.

Numerous laboratory studies have shown how the ice responds to stress. The law most often used is the Glen's flow law (Glen, 1955):

$$\varepsilon = A\tau^n$$

where ε represents the strain rate, A and n are constants, and τ is the shear stress. A correlates strongly with temperature. Thus, it signifies that the rate of deformation depends on shear stress and temperature. This explains the slower movement of cold ice, which is less plastic at lower temperatures. The flow law exponent n also varies, but is usually close to 3.

In reality, strain rates often differ from values predicted from laboratory experiments, especially because of orientation of crystals in the ice and of the presence of impurities in the form of dissolved ions, gas bubbles (which soften the ice) and rock particles, whose role on ice deformation is of great importance (Hubbard and Sharp, 1989; Benn and Evans, 1998).

Creep of ice-supersaturated permafrost

Rock glaciers are landforms resulting of the deformation of ice-supersaturated sediment (e.g., Barsch, 1996). By

definition, debris content in rock glaciers is important. In many cases, ice is present only in the pores between the particles, which reduces the cohesive strength.

Like glaciers, rock glaciers are thought to be in a permanent secondary creep (steady state creep) (Haeberli, 1985). It is generally assumed that the deformation rate of frozen sediment is strongly dependant on its external (slope gradient) and internal characteristics (ice content, particle size, etc.) and on its temperature. The presence of unfrozen water also influences the creep rate at temperatures close to the melting point (Barnes et al., 1971). Arenson (2002) showed in laboratory experiments that, for low stress conditions, creep is more influenced by the temperature than by the ice content and that creep rate may vary by an order of magnitude, even for small temperature changes, close to the melting point. Arenson and Springman (2005) confirmed that warm, ice-rich permafrost exhibits higher creep rate. However, if modelling the entire creep process is possible for ice, it is much more challenging for rock glaciers, since their internal structure is extremely heterogeneous (Haeberli et al., 2006).

A shear horizon was identified in some rock glaciers at various depths (e.g., Arenson et al., 2002). It was shown that a large part of total deformation occurs in this relatively thin layer. Thus, the surface movement of ice-supersaturated material is the addition of sliding in a shear horizon and internal deformation. Deformation at the base can be also possible (Roer et al., 2008).

Data on the internal deformation of rock glaciers is sparse, because of the high cost of boreholes. Thus, most of the information come from surface measurements, either by remote sensing (e.g., Kääb, 2005) or by terrestrial measurements (e.g., Lambiel and Delaloye, 2004). The strong dependency of rock glacier creep on permafrost temperature is illustrated by the velocity differences between arctic and alpine rock glaciers. Whereas cold arctic rock glaciers have velocities of some cm a^{-1} (Kääb et al., 2002), velocities of alpine rock glaciers are generally higher, typically between 20 cm and 1 m a^{-1} (e.g., Kääb et al., 2007; Lambiel et al., 2008).

Interannual variations of velocities of warm rock glaciers – which could be not frozen at their base – can be large, due to their dependency on external climatic factors, such as characteristics of the snow cover or summer temperatures (Delaloye et al., 2008), or seasonal snowmelt water refilling the rock glacier system (Ikeda et al., 2008). As observed since the beginning of the 1990s in the Alps, the increase of the ground surface temperatures leads to an increase in rock glacier creep (Kääb et al., 2007). Possibly in connection with this, recent observations of rock glaciers with velocities up to 4 m a^{-1} and in a destabilization phase have been reported (Roer et al., 2008).

Conclusion

Creep is a widely held process in cryosphere. With basal sliding, it is the major process of glacier advance and motion of perennially frozen sediments. As indicated by the Glen's flow law, temperature of the material is a critical parameter for creep. The effect of the ongoing warming on the deformation rates of ice-associated landforms is best expressed by the increasing velocities of rock glaciers.

CREVASSES

C. J. van der Veen
Department of Geography and Center for Remote Sensing of Ice Sheets, University of Kansas, Lawrence, KS, USA

Definition and introduction

Crevasses are intimidating fractures or cracks in the ice, a few tens to thousands of meters long and up to several meters wide and tens of meters deep, cutting through the surfaces of most glaciers. A crevasse may be covered or bridged by snow, thus masking its presence. Most explorers and glaciologists tend to consider these features as an impediment to safely traversing the glacier surface, especially those crevasses that have been bridged over and are all but invisible. On the other hand, it has been recognized that patterns of fracturing may provide information on how glaciers deform and move. Recent years have seen a modest resurgence of scientific studies on crevasse formation and propagation, motivated in part by efforts to better understand processes involved in iceberg calving and break up of ice shelves and floating ice tongues. Further, meltwater-driven crevasse propagation has been suggested as a mechanism by which surface meltwater can drain rapidly to the base of an ice sheet.

Opening criteria

As early as the mid-1800s, it was recognized that crevasses form as a result of tensional stresses. The earliest mathematical model was presented in 1843 at the Cambridge Philosophical Society by William Hopkins who argued that a fracture will form when the maximum tension is greater than the cohesive strength of the ice. While some studies relate first occurrence of crevasses to a critical strain rate, more complete compilations support the existence of a critical stress for crevasse formation. Strain rates are converted to stresses using the flow law for glacier ice, accounting for varying ice temperatures. A tensile stress between 90 and 320 kPa, altered by differences in crevasse spacing, is required for crevasses to occur. In a field of closely-spaced crevasses, a larger tensile stress is required for crevasse opening compared to a single crevasse due to the "blunting" effect that neighboring crevasses have on an individual one. Within the thin slabs of ice separating adjacent crevasses, no tensile stress can exist and there are no large stress concentrations near the crevasse tip that would otherwise promote downward propagation. This coupling between tensile stress and crevasse spacing may explain why in some places a few large crevasses exist while elsewhere crevasses occur in fields of smaller ones.

Penetration depth

For an air-filled crevasse at the glacier surface, the net longitudinal stress is the sum of the tensile stretching stress, which tends to open a crevasse, and the weight-induced lithostatic stress that causes the crevasse to close. In first approximation, the depth to which a crevasse will penetrate can be estimated from the depth at which the lithostatic stress balances the tensile stress such that the net longitudinal stress is zero. For a tensile stress of 150 kPa, this gives a depth of ca. 30 m. For individual crevasses, the penetration depth is greater because stress concentrations at the crevasse tip partly counter the lithostatic stress, thereby allowing the crevasse to extend deeper into the ice. Such stress concentrations become smaller in fields of crevasses and all but vanish if crevasses are closely spaced.

An expedient model to describe downward crevasse propagation that accounts for stress concentrations at crevasse tips is one based on linear elastic fracture mechanics (LEFM). This approach is based on the assumption that materials contain small cracks and flaws that may develop into large fractures through stress concentration near the crack tip. If the concentrated stresses are large enough to overcome the cohesion of the material, further crack growth is possible and under certain conditions, this process can become self-sustaining with crack growth leading to larger stress concentrations, allowing further growth, etc. Formally, this is described through the stress intensity factor, which is a measure for the concentrated stresses at the tip and that can be estimated from the geometry of the fracture (most notably its depth) and the net longitudinal stress acting on the fracture. Crack growth occurs where the stress intensity factor is larger than a critical value, called the fracture toughness, and will continue to the

depth at which the stress intensity factor equals the fracture toughness.

The LEFM approach to describing crevasse propagation on glaciers may be challenged for several reasons. First, ice is not a linear elastic material and viscous flow and deformation may affect the stress concentration at the crevasse tip. For surface crevasses that form in the upper firn layers, it is not clear how important this effect is. Second, initiation and growth of mature crevasses requires the presence of starter cracks of at least a few centimeters for tensile stresses typical of glaciers. Little is known about the origins and dimensions of these starter cracks. They may develop from millimeter-scale microfractures in the crystal structure through subcritical crack propagation as has been observed in rocks and other materials. Subcritical growth can occur when the stress intensity factor is less than the fracture toughness and proceeds at slow speeds until the stress intensity factor exceeds the fracture toughness and further growth is described by LEFM. There are no field or laboratory data on ice that can be used to test this model. Alternatively, centimeter-scale defects in firn may result from burial of sastrugi and sun crusts, or from folding of internal layers with different densities.

If the crevasse is water-filled, the water pressure compensates part or all of the lithostatic stress in the ice, thereby allowing the crevasse to penetrate deeper. Because the density of water is greater than that of ice, if the water level remains close to the glacier surface, water pressure increases more rapidly with depth than does the lithostatic stress associated with the weight of the ice, allowing the crevasse to penetrate the full ice thickness. The observation that most ice-shelf break-up events in the Antarctic Peninsula have occurred during longer melt season during which melt ponds formed on the surface, led to the suggestion that crevasse propagation driven by meltwater ponding is the main mechanism by which ice shelves weaken and rapidly disintegrate into a myriad of icebergs. Similarly, calving rates on tidewater glaciers and Greenland outlet glaciers increase in the spring with the onset of surface melting, lending support to the hypothesis that full-thickness fracturing of water-filled crevasses is an important control on iceberg calving.

Orientation

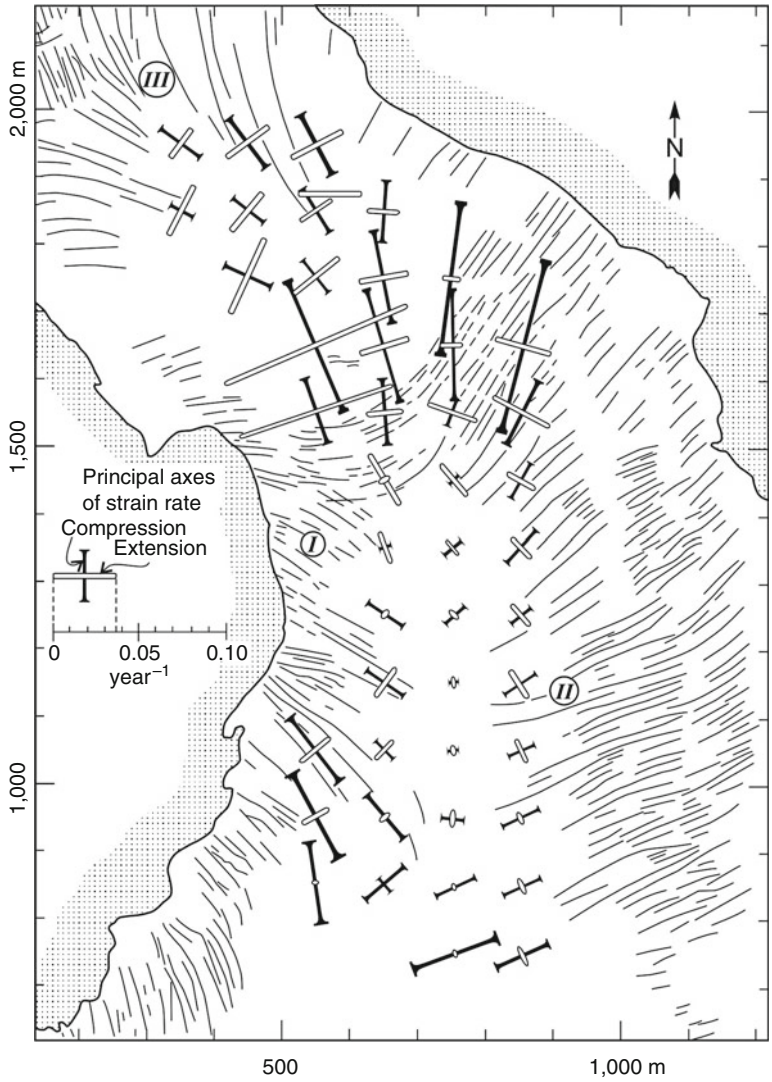
The assumption that crevasses form perpendicular to the direction of the principal tensile force was first applied by Hopkins (1862) to explain the orientation of crevasses as frequently observed on valley glaciers in the European Alps. If A represents the normal force in the direction of flow (generally along the axis of the glacier), B the normal force in the direction perpendicular to ice flow, and F the tangential or shearing force, the direction of the principal tensile stress, P, is given by

$$\tan 2\alpha = \frac{2F}{A-B}$$

where α represents the angle between the direction of P and the ice flow. Consider the principal surface strain rates and crevasse orientation measured on Blue Glacier in the Olympic Mountains, shown in Figure 1. Towards the margins, the ice velocity decreases and the dominant force is the tangential force, F, representing lateral drag originating at the valley walls. Setting $A = B = 0$ in the above equation gives an angle of 45° with the axis of the glacier as the direction of principal tension. Thus, near the glacier margin, crevasses will strike at an angle of 45° as in region I in Figure 1. Near the centerline of the glacier, drag from the margins is small ($F = 0$) and the force responsible for crevasse opening is the normal tension, A, acting in the flow direction so that crevasses open perpendicular to this axis (region II in Figure 1). Where the valley walls diverge, longitudinal or splaying crevasses may form. As the ice spreads laterally, the speed decreases and A becomes compressive (negative) while the other normal force, B, is tensile (positive). Where the tensile force in the cross-flow direction becomes sufficiently large, fracturing in the direction of glacier flow can occur. The diverging flow causes these crevasses to splay radially, resulting in the pattern in region III.

While in many cases crevasse patterns predicted by the Hopkins model agree with observations, there are exceptions, in particular where crevasses meet glacier margins. On many glaciers, including Blue Glacier shown in Figure 1, crevasses are oriented perpendicular to the margins. Further, a number of observations indicate strike-slip or shear displacement of crevasse walls, suggesting that mixed-mode fracturing may better describe crevasse growth. Thus, for modeling crevasse propagation along the glacier surface, it may be more appropriate to consider a combination of fracturing modes. Traditionally, crevasses are associated with Mode I fracturing ("opening mode") with displacements of the fracture surfaces in the direction of the tensile stress. Allowing also for Mode II fracturing ("sliding mode"), in which the fracture surfaces slide parallel to the plane of fracturing, shows that the predicted crevasse orientation can deviate from the direction perpendicular to the principal tensile stress. While this model can explain at least in a qualitative sense some of the observations, a rigorous test based on measurements and theory is still lacking.

Crevasses often persist over periods of several years and can be used to estimate surface velocity if individual and distinct crevasses can be identified on successive images. As crevasses are advected by ice flow, their orientation may change, especially where the velocity field is characterized by strong shear. However, several studies that compare calculated rotation with observed crevasse orientation along glaciers do not show good agreement. For example, on Whillans Ice Stream, west Antarctica, progressive rotation is not evident on a map of crevasse trains despite the presence of strong velocity shear. This may indicate that crevasses are more transient features with old and inactive ones disappearing once they are no



Crevasses, Figure 1 Principal surface strain rates and crevasse orientation on Blue Glacier, Olympic Mountains, Washington, USA. Ice flow is towards the top of the figure. From Meier et al. (1974).

longer oriented perpendicular to the principal tensile stress. The process whereby new crevasses are constantly formed while older ones are closed may explain why crevasses in fields often intersect at shallow angles. If crevasses formed as a result of surface tension, one would expect a crevasse, once formed, to relieve this tension, thus disfavoring formation of new crevasses. It has been suggested that crevasses reflect processes acting at some depth below the surface. In low-density firn, the tensile stress may increase with depth below the surface as density increases and the firn becomes stronger and able to support larger stresses. This raises the possibility that crevasse initiation occurs at some depth below the surface, rather than at the surface as commonly assumed. Ground-penetrating radar measurements on Rutford Ice Stream, west Antarctica, show subsurface crevasses occurring at depths ranging from 3 to 20 m in areas where surface crevasses are absent. Application of LEFM models shows that subsurface crevasse initiation is (theoretically) possible.

Bottom crevasses

Bottom crevasses extend from the base upward into the ice and can exist on floating ice shelves and on grounded glaciers where abundant basal water at sufficiently high pressure is available for the crevasse to remain water-filled. The water pressure, together with a tensile longitudinal stress, must be large enough to overcome the weight-induced lithostatic stress, which reaches its maximum at the glacier base. In practice, this means that the ice must be at or very near to flotation. Observational evidence supports this conclusion. Bottom crevasses have been observed using radar sounding on ice shelves, floating ice tongues, and in the vicinity of grounding lines.

Extensive radar sounding over Greenland and Antarctica, indicates that bottom crevasses are very rare in the more interior regions.

Summary

Crevasses remain among the least studied and understood features on glaciers and are usually not included in models of glacier flow. From an ice-dynamics perspective, there may not be any compelling reason for incorporating crevasses in glacier models. However, better understanding of crevasse initiation and propagation is needed for modeling transfer of surface meltwater to the glacier base, and for developing more realistic models for iceberg calving. This requires more systematic observations of crevasse properties (depth and spacing) and concurrent measurements of surface strain rates.

CRITICAL TEMPERATURE

Pratima Pandey
Centre of Studies in Resources Engineering, Indian Institute of Technology, Bombay, Maharashtra, India

Definition

The *critical temperature* of a substance is the temperature at and above which vapor of the substance cannot be liquefied, regardless of the pressure applied on the substance. Gases become more difficult to liquefy as the temperature increases because the kinetic energies of the particles that make up the gas also increase. Every substance has a critical temperature. For example, for water critical temperature is 374°C.

CRUSH

Pratima Pandey
Centre of Studies in Resources Engineering, Indian Institute of Technology, Bombay, Mumbai, Maharashtra, India

Definition

Crushing is the process which results from pressure exerted by the debris and ice carried by the glacier during erosion. A glacier can erode rock by a mixture of abrasion, crushing and fracturing, and plucking. Crushing causes mineral boundaries to disintegrate into separate minerals. Glaciers crush, grind, and move large rocks and scour bedrock to form the floor and wall of mountain valleys.

CRUST

Pratima Pandey
Centre of Studies in Resources Engineering, Indian Institute of Technology Bombay, Mumbai, Maharashtra, India

Definition

An upper hard layer of snow or a film of ice or compacted snow lying upon a softer layer where liquid water has refrozen into grain fabric is known as crust. It represents a crisp, firm, outer surface upon snow. Freezing rain, direct sunlight, wind, or the melting and refreezing of snow helps in forming the snow crust.

CRYOCONITE

Nozomu Takeuchi
Department of Earth Sciences, Graduate School of Science, Chiba University, Inage-ku, Chiba-city, Chiba, Japan

Definition

Cryoconite: Dark-colored sediment deposited on snow or ice surfaces of glaciers.
Cryoconite hole: A water-filled cylindrical hole on glacial ice surface, in which cryoconite is deposited.
Cryoconite granule: A spherical aggregate of mineral particles, organic matter, and microbes in cryoconite.

Introduction

Cryoconite was first noted by an Arctic explorer, A. E. Nordenskjöld, on his trip over the Greenland ice sheet (Nordenskjöld, 1875). He observed numerous water-filled cylindrical pits sunk into ice. The bottom of these pits was covered with fine dust. He named the dust cryoconite after the Greek *kruos* (ice) and *konis* (dust), and called the pits

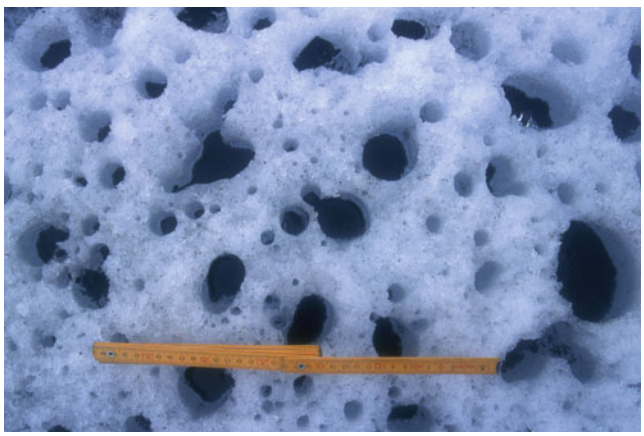
cryoconite holes. As the cryoconite absorbs solar radiation and promotes melting of the ice beneath it, the cylindrical holes are formed. Constituents of cryoconite have been studied mineralogically and biologically. Cryoconite contains mineral particles supplied from surrounding ground by wind and, on some glaciers, micrometeorite collected by glacial flow. It also contains abundant microbes and organic matter. The microbes are cold-tolerant species living on the glacial surface. Cryoconite holes seem to play a role of favorable habitats on glaciers for such organisms. Recently, cryoconite and cryoconite holes have been studied biogeochemically to understand their ecological roles on biological communities on glaciers. Dynamics of cryoconite holes have also been investigated in terms of the heat balance of glacier surface. The formation process of cryoconite holes is strongly associated with physical conditions on glacier surface and also can affect total ablation of glaciers (Figure 1).

Components of cryoconite

Terrestrial mineral particles are major components of cryoconite. They usually include quartz, feldspar, mica, calcite, and clay minerals. Fine mineral particles (0.1–10 μm in diameter) are supplied from surrounding grounds by wind. They are also carried from a far away desert in arid regions. Coarser mineral particles (>10 μm in diameter) are derived from rock wall, nunataks, and moraines of glaciers.

Other major components of cryoconite are microbes and organic matter. A large amount of photosynthetic microbes, such as snow algae and cyanobacteria, are commonly observed in cryoconite. They photosynthetically produce organic matter in the holes and sustain other heterotrophic microbes, such as rotifers, tardigrada, fungi, and bacteria. These organisms are specialized taxa that have adapted to cold environments.

Dark-colored organic matter, which is often contained in cryoconite, is humic substances (Takeuchi et al., 2001). Humic substances are thought to be highly polymerized compounds of residues that remain after bacterial decomposition of organic matter. The dark-colored humic substances effectively absorb solar radiation and result in the formation of cryoconite holes.



Cryoconite, Figure 1 Cryoconite holes on a Himalayan glacier.

These constituents, such as mineral particles, microbes, and other organic matter, usually conglomerate into small spherical granules, called cryoconite granules (Takeuchi et al., 2001). The granules are dark colored and 0.5–2.0 μm in diameter. The surface of the granule is usually covered with filamentous cyanobacteria. The spherical shape of the granules is maintained by the entanglement of filamentous cyanobacteria and adhesive substances around the mineral or organic particles.

Micrometeorites have been reported in cryoconite on the Greenland ice sheet (e.g., Maurette et al., 1987). The meteorites that fall on the ice sheet can be concentrated in cryoconite holes by ice flow and ablation. The cryoconite in Greenland is well known as the richest and best-preserved mines of cosmic dust grains found on the Earth. Their size is usually less than 1 mm in diameter. Micrometeorites can be identified by morphology and element analyses. They usually have evidence of surface heating such as glassy coatings or thin rims of Fe-rich material. And, they contain terrestrially less abundant elements such as Ir, Ni, Co and Cr.

The ecological aspects of cryoconite holes

Cryoconite holes play important roles in glacial ecosystems. As mentioned above, holes are inhabited by various kinds of organisms. For example, on Himalayan glaciers, there are rotifers, tardigrada, copepods, and larvae of midges sustained by snow algae and cyanobacteria. On North American glaciers, ice worms and collembolas are commonly observed in cryoconite holes. Organisms found in cryoconite holes on worldwide glaciers have been listed in Mueller et al. (2001). Although there are still a few measurements on photosynthetic rate of snow algae and cyanobacteria in cryoconite holes, the rate is comparable to other aquatic ecosystems in polar regions (Hodson et al., 2008). Wharton et al. (1985) suggested that cryoconite holes are individual ecosystems with distinct boundaries, energy flow, and nutrient cycling. The holes trap nutrient-rich particles, prevent nutrient washout by meltwater, and provide a semi-stagnant aquatic habitat for various algae and animals. Furthermore, cryoconite holes have recently gained attention because they may furnish refugia of organisms during glacial periods (Warton et al., 1985). They may play in the survival of microorganisms during ice ages and the colonizing of newly exposed areas after a glacier retreats. Also, cryoconite holes are possible analogues for similar structures on icy planets, such as Mars and Europa, or on the Earth during its hypothesized global glaciations (Snowball Earth) 600–800 million years ago (Fountain et al., 2008).

Dynamics of cryoconite holes

Formation and evolution of cryoconite holes are associated with physical conditions of glaciers. The size of cryoconite holes usually ranges from 1 to 50 cm in

diameter and from 3 to 50 cm in depth, and varies among places, times, and geographical locations of glaciers. Generally, holes are deeper on polar glaciers (20–50 cm), compared with those on middle- and low-latitude mountain glaciers (3–20 cm). On the other hand, the diameter of holes is not related to latitude, but probably to the age of holes.

The depth of the holes is determined by the balance of melting rate between the hole bottom and the surrounding ice surface (McIntyre, 1984). Depths should reach an equilibrium when the hole-deepening rate matches the ablation rate of the glacier surface. The heat sources of glacier surface are solar and long-wave radiations, and sensible and latent heats from air. On the other hand, those of the hole bottom are the circulation of warm water within the holes, solar radiation transmitted obliquely through the ice, diffuse and direct radiation entering the hole from the top, and heat generated metabolically by the microbes in cryoconite. The equilibrium depth of holes is determined by relative importance of these different energy sources. Average hole depth on a glacier temporally changes due to weather conditions. It also changes decadally or in longer timescales with climate (e.g., Gajda, 1958; Fountain et al., 2008; Takeuchi et al., 2000).

The horizontal growth of cryoconite holes occurs through coalescence of holes located close to each other or by trapping of more material into the holes. Since shrinkage in size or division of holes are rarely observed, the diameter of cryoconite holes generally reflect age of the holes.

The life span of cryoconite holes ranges from weeks to months on mountain glaciers, to more than years on polar glaciers. The holes on glaciers where melt rates are high are easy to collapse due to daily variation of the hole depth or to meltwater flows on the glacier surface. The cryoconite may be washed into streams and may accumulate in new deposits that often result in the formation of new holes. In contrast, on less melt rate glaciers in polar regions, a life span of 100–200 years was suggested to be possible. Analyses of the water chemistry of cryoconite holes on Antarctic glaciers showed life spans of 10 years or more (Fountain et al., 2008). On the Antarctic glaciers, ice-riddled cryoconite holes have been observed. The cryoconite in such holes is isolated from the atmosphere for 10 years or more.

Effect of cryoconite on glacier melting

In Antarctica, although cryoconite holes cover only a small portion of the entire glacial surface, they create a significant amount of meltwater runoff at near-surface hydrologic system. The contribution of meltwater produced by cryoconite to the total runoff on a glacier in the Mcmurdo Dry Valleys has been estimated approximately 15% (Fountain et al., 2008).

On some glaciers, the cryoconite lies not only in cryoconite holes, but also on whole glacier surfaces in the ablation area. It substantially reduces albedo and thus accelerates melting of the glacier surface (e.g., Takeuchi et al., 2008; Kohshima et al., 1993). The effect was first suggested on Greenland ice sheet (Gaja, 1958). A surface coating of cryoconite was observed close to the ice margins as well as farther back from it, and had a significant effect on melting of the ice. Kohshima et al. (1993) observed that the albedo of the intact surfaces bearing the cryoconite was substantially lower than that of the surface from which the cryoconite was artificially removed (5% versus 37%) on a Himalayan glacier. The melting rates of the intact surfaces were reported to be three times larger than that of the surfaces without the cryoconite. Thus, cryoconite on the glacier surface has a major influence on the glacial mass balance on such glaciers. On Asian glaciers, the effect is particularly significant compared to those in other regions (Takeuchi et al., 2008). Comparison of the amount of cryoconite on the glacier surface shows that the Asian glaciers, including the Himalayan, Tibetan, and Tienshan mountains, were more than 200 g m^{-2} in dry weight of cryoconite, whereas glaciers in the Arctic, Alaska, and Patagonia were less than 100 g m^{-2}. The large amounts of cryoconite on Asian glaciers are probably due to a large supply of windblown desert sand and a high biological production. In particular, the organic fraction in cryoconite is optically effective on the surface albedos as organic particles in cryoconite are usually dark colored and large in volume. Therefore, biological productivity on the glacier surface plays a significant role in glacial ablation.

Summary

Cryoconite is dark-colored sediment on glacier surface, and usually deposited at the bottom of water-filled cylindrical pits, called cryoconite holes. Cryoconite and cryoconite holes can be commonly observed from polar ice sheets to low-latitude mountain glaciers in the world. Cryoconite consists of mineral particles supplied from surrounding ground by wind, biogenic organic matter produced by microbes living on the glacial surface, and also micrometeorites in some glaciers. These constituents are usually conglomerated into small granules, called cryoconite granules. Abundant microbes in cryoconite indicate that glaciers are biologically active environments. Thus, it is important to study cryoconite to understand the ecology of organisms in such cold environments. Furthermore, dynamics of cryoconite holes are strongly related with physical conditions on glacier surface and can affect total ablation of glaciers. Thus, physical process of cryoconite holes is important to evaluate mass balance of glaciers. The information on cryoconite and holes, however, is still limited on particular glaciers, further studies, therefore, are necessary to understand them both biologically and physically on worldwide glaciers.

Glacial Ecosystems

CRYODESSICATION

P. Pradeep Kumar
Department of Atmospheric and Space Sciences, Pune University, Pune, India

Definition

Freeze drying (cryodessication) combines the virtues of dehydration and chilling for preserving. Freeze drying works by freezing the material and then reducing the surrounding pressure and adding enough heat to sublime the ice.

The mars analogue carbonate deposits in subglacial volcanic complex on Svalbard (Norway) is believed to have been formed through a process of cryodessication and/or thermal evaporation.

CRYOGENESIS

P. Pradeep Kumar
Department of Atmospheric and Space Sciences,
Pune University, Pune, India

Definition

Cryogenesis is the combination of thermophysical, physicochemical, and physicomechanical processes occurring in freezing and thawing earth materials.

Soil cryogenesis is defined as a process dictating many important properties and regimes of cold and permafrost-affected soils. Soil cryogenesis is influenced by climatic parameters, the earth–atmosphere interactions, the properties of soils, and the conditions of the permafrost.

CRYOGENIC AQUICLUDE

P. Pradeep Kumar
Department of Atmospheric and Space Sciences,
Pune University, Pune, India

Definition

Aquiclude can be defined as layer of rock that has almost no porosity and does not allow the flow of water. Cryogenic aquiclude can be considered as layer of ground which, because of its frozen state, has a low enough permeability to act as a confining bed for an aquifer.

In cryogenic mountainous stony organic soils, the peat usually covers 25 or 30 cm or more and the permafrost

table lies at 100 cm as aquiclude. The cryogenic acquiclude slows down the migration of organic matter through iron elements through soil profile.

CRYOGENIC FABRIC

P. Pradeep Kumar
Department of Atmospheric and Space Sciences,
Pune University, Pune, India

The distinct soil micromorphology is produced due to the effects of freezing and thawing processes and is termed as cryogenic fabric. Layers, lenses, and streaks of segregation ice are typical elements of the cryogenic fabric of ice-saturated frozen soil of loamy and clay texture. The formation of cryogenic fabric can be influenced by the mineralogical composition in the soil.

CRYOPEG

P. Pradeep Kumar
Department of Atmospheric and Space Sciences,
Pune University, Pune, India

Cryopeg is a layer of unfrozen ground that is perennially cryotic (forming part of the permafrost) in which freezing is prevented by freezing-point depression due to the dissolved-solids content of the pore water. Cryopegs remain liquid at the in situ temperature of −9°C to −11°C and make up the only habitat on the Earth that is characterized by permanent subzero temperatures, high salinity, and the absence of external influence during geological time. Cryopegs are mineralized headwater lenses below the Arctic massive ground ice bodies.

CRYOSTATIC PRESSURE

Pratima Pandey
Centre of Studies in Resources Engineering,
Indian Institute of Technology Bombay, Mumbai, India

Definition

Cryostatic pressure is the pressure exerted on the rock/soil by existing ice body such as glaciers, ice sheets, etc. It is represented by the product of the weight and the thickness of ice. Such pressure is responsible for cracks in rocks resulting in higher rate of erosion from the underneath rocks and soil.

CRYOSTRUCTURE

Pratima Pandey
Centre of Studies in Resources Engineering,
Indian Institute of Technology Bombay, Mumbai, India

Definition

Cryostructure is the structural characteristics of frozen earth materials. The time dependent mechanical properties of ice-rich frozen soils such as creep and long-term strength are studied in relation to their cryostructure. Through cryostructure, the permafrost geology is related to the time dependent mechanical properties of frozen soils.

CRYOTURBATION

P. Pradeep Kumar
Department of Atmospheric and Space Sciences,
Pune University, Pune, India

Cryoturbation (mixing of soil layers due to repeated freeze-thaw processes) is a major soil-forming process in Arctic regions or periglacial regions. It represents the churning up of rocks and soil. Cryoturbation may contribute to long-term storage of carbon in soils of northern latitudes. Cryoturbation, therefore, may lead to additional long-term storage of carbon in the system by (1) retarding decomposition processes of buried organic material and (2) enabling the soil to restart carbon accumulation in topsoil layers.

DATING GLACIAL LANDFORMS

Jason P. Briner
Department of Geological Sciences, University at Buffalo, Buffalo, NY, USA

Definition

Dating glacial landforms. Applying geochronological tools (e.g., relative- and absolute-dating methods, etc.) to glacial landforms (e.g., moraines) to yield the timing of past glaciation (Moraine and Glacial Geomorphology and Landforms Evolution).

Introduction

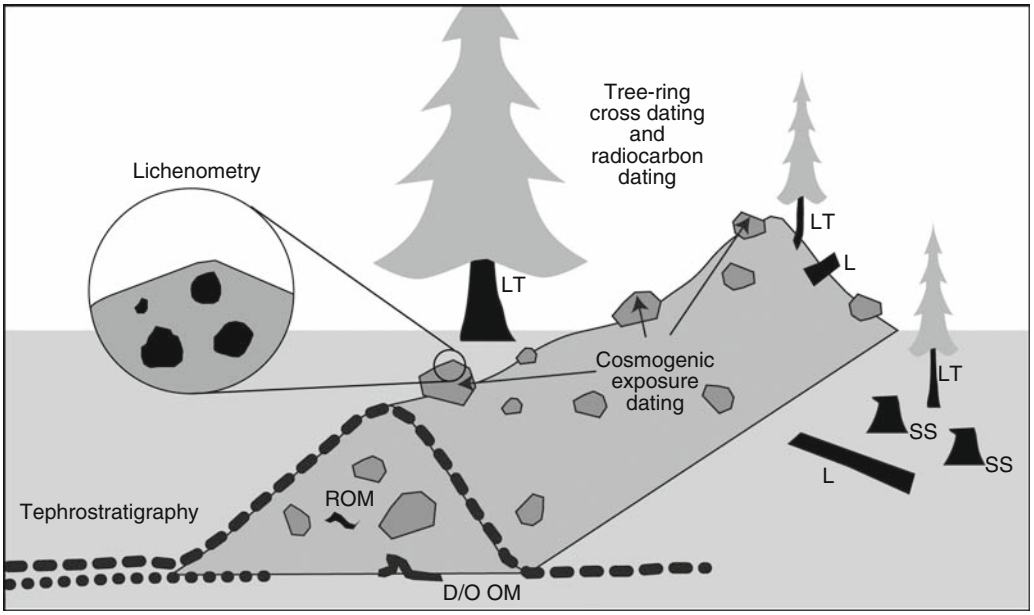
Ever since scientists first recognized that glaciers and ice sheets were once larger in the past, they have desired to know the precise timing of past glaciation. Today, there is a more urgent need to tightly constrain patterns of past glaciation through time and space as projections of future global change rely upon knowledge from the past. Crude approaches have given way to complex techniques with increasing precision and decreasing uncertainty. Certainly, however, we are only a short way down a long path that carries us closer to a complete understanding and ability to date glacial landforms.

The techniques employed to date glacial landforms have been cleverly devised. For example, determining the growth rate of lichens and then measuring lichen diameters on moraine boulders to elucidate their exposure age (hence the timing of moraine deposition), using the patterns of tree-ring thickness to "cross-date" exhumed stumps that were eroded by a former glacier advance, and measuring the accumulation of isotopes in rocky surfaces that result from the bombardment of cosmic radiation to calculate the time elapsed since glaciers retreated. Our current understanding of when former glaciations occurred is better than ever, but is far from complete. Even with the dating techniques currently available, we could vastly improve our current understanding with more resources and time.

Here, I focus on dating glacial landforms, such as moraines and outwash terraces (depositional landforms), and glacially-eroded bedrock features and U-shaped troughs (erosional landforms). Thus, not included are the wide variety of techniques used to date stratigraphic sequences of glacial sediments. In some cases, the boundaries of dating glacial landforms and dating glacial sediments are blurred. For example, moraines comprise glacial sediments, and dating sediments associated with a landform can constrain landform age. However, focus on dating landforms inherently results in omitting certain landforms from this entry whose age in absolute time can only be constrained by dating glacial stratigraphy, such as subglacial depositional landforms (e.g., eskers) or depositional/erosional landforms (e.g., drumlins). Of course, dating both landforms and glacial sediments, combined with additional information, such as records of global ice volume from $\delta^{18}O$ measurements from benthic marine organisms, has led to the present understanding of the timing of Earth's glaciations.

The focus on dating glacial landforms inherently results in discussion of recent (middle and late Quaternary) landforms. In some cases, landforms survive from pre-late Pleistocene glaciations, which can be a result of slow rates of landform degradation and the survival from erosion from successive glaciations. However, in most cases where old landforms remain intact on the landscape (e.g., pre-late Pleistocene), the ability to date them is hampered by the limits of the method or by the increasing uncertainty of dating techniques back in time. Finally, this entry focuses on the dating tools that are widely used today. Although some commonly used relative- and

Vijay P. Singh, Pratap Singh & Umesh K. Haritashya (eds.), *Encyclopedia of Snow, Ice and Glaciers*, DOI 10.1007/978-90-481-2642-2,



Dating Glacial Landforms, Figure 1 Common methods used to date moraines. Targets for radiocarbon and tree-ring cross dating are labeled: *LT* living tree, *L* log, *SS* sheared stump, *ROM* reworked organic material, *D/O OM* deformed/overridden organic material. *Dashed* and *dotted lines* represent tephra layers.

calibrated-dating techniques are discussed, more emphasis is placed on the absolute-dating techniques that are most commonly applied to glacial landforms (Figure 1).

Relative-dating techniques

The initial and most fundamental approach to dating glacial landforms is ordering landscape features in a relative sense. In terms of moraines, those closer to the ice source are younger because in almost all cases subsequent glaciations obliterate prior surface features beneath their footprint. When dealing with moraines deposited by alpine glaciers (i.e., moraines in mountain valleys), assigning relative ages to moraines is fairly straightforward. Much like assigning relative ages to rock layers (stratigraphy), there is a relative age assignment to surface features (morphostratigraphy). In some cases, moraines can be cross-cutting, where younger moraines are deposited on top of, and truncate, older moraines. A classic example is Bloody Canyon, eastern Sierra Nevada, USA (see Phillips et al., 1990), but there are a surprising number of other examples.

In rare cases, for example where polar ice sheets are cold-based, the obliterative nature of glacier flow is replaced by non-erosive characteristics. In these settings, it is possible to preserve glacial landforms that were formed during previous glacial cycles, and the relative ordering of landforms is more complicated. On the other hand, this rarely happens in alpine landscapes. In other cases, subglacial bedforms (e.g., drumlins, megaflutes, etc.) in areas that were occupied by Pleistocene ice sheets reveal shifting flow directions. The preservation of these stacked sequences of bedform orientations reveals that, at least in some locations, bedforms can be preserved from not just the most recent flow direction.

Slightly more sophisticated approaches to the relative dating of glacial landforms rely on the physical and chemical weathering that takes place on and within glacial deposits. The application of soil chronosequences to moraine and outwash surfaces has been used to assess the relative age of these features, and in some cases to correlate glacial landforms from valley to valley in a given mountain range. In particular, soil thickness, B-horizon thickness, B-horizon development, and weathering-rind thickness measured in clasts in soil profiles have been used as indicators of relative age (Porter, 1975; Burke and Birkeland, 1979; Colman and Pierce, 1986; Birkeland et al., 1991). The weathering of surface rocks has also been employed as a relative-age indicator, specifically, characteristics such as the abundance and depth of pitting, grussification, and hardness have been used to make relative subdivisions of moraines (e.g., Birkeland et al., 1979). The degree of degradation of depositional landforms (landform morphology) has also been used as a relative-dating parameter. Because moraines are originally deposited with relatively steep slopes that degrade with time, the steepness of moraine slopes, or degree of surface roughness within hummocky moraine belts that we see on the landscape today is partly of function of moraine age. Slope angle, crest width, and the degree of gullying are parameters that have been measured and linked with relative age (e.g., Kaufman and Calkin, 1988).

Despite the factors that complicate the accuracy of relative-dating techniques, they nonetheless remain useful. Relative-dating techniques are useful for correlating moraines from valley to valley, provide the only chronology in many cases where materials for absolute dating are absent, and act as an aid even when absolute dating is available. Furthermore, it is generally less time-consuming and less expensive to employ relative-dating techniques versus absolute-dating methods, and thus characteristics of many more moraines can be included in a dataset. Finally, because of the high cost of many absolute-dating techniques, using relative-dating methods to correlate a low number of landforms with absolute-age control to many more landforms of the same properties across a region is a powerful approach.

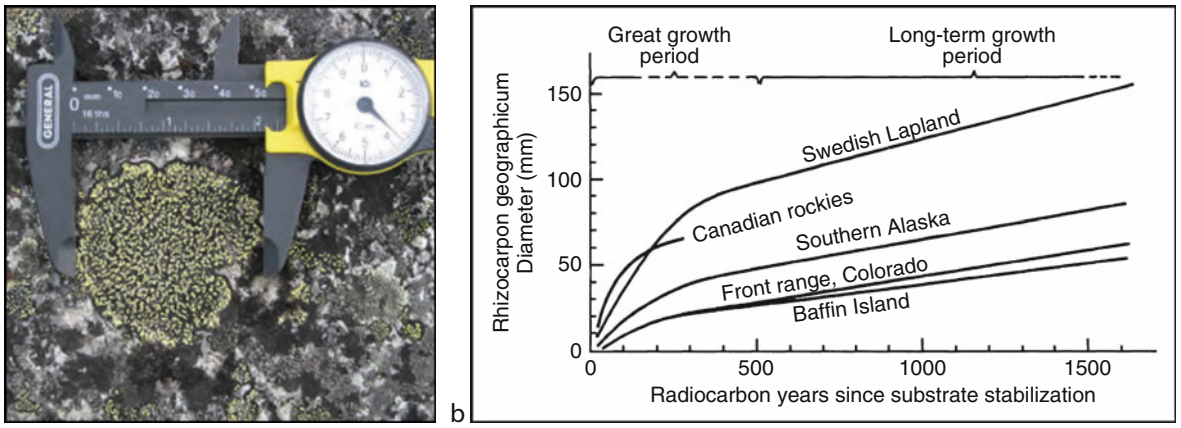
Lichenometry

Lichenometry is a surface-exposure dating method that uses lichen-growth rates to infer the age of young (few thousand years old or younger) glacial landforms, typically bouldery deposits such as moraines. The technique combines measurements of the size of lichens growing on rocky glacial deposits with independently derived lichen growth rates to derive lichen age, and thus moraine age. Lichen types that grow radially and regularly are used, most commonly the crustose lichen genus *Rhizocarpon*, where *R. geographicum* is specifically targeted in most cases, but field identification to the species level is difficult (Figure 2). The method has been widely applied since its development in the mid-twentieth century (Beschel, 1950).

Several approaches have been employed to measure lichens, and a distinct advantage of lichenometry over other techniques is its simplicity (Bradwell, 2009). One approach is to measure the diameter of dozens to hundreds of semi-circular lichens on boulders scattered about on a moraine surface. The largest diameter measured, or the average of the five largest diameters measured, can be used with the growth curve to obtain a surface age. Additional approaches include determining the size frequency of all lichens in a representative area, or measuring the total lichen cover on a substrate. Ongoing research includes more advanced statistical approaches to extract the most meaningful age from field measurements (cf. Bradwell, 2009) and placing more emphasis on the controls on the pattern of lichen growth (Loso and Doak, 2006).

Used in the right circumstances, lichenometry can be a successful numerical-dating method. This success relies on several factors. First, because lichen-growth rates are a function of a variety of conditions (e.g., regional climate, substrate, microenvironment, species competition), the growth rate needs to be well constrained in the area of application (Figure 2). Independently dated surfaces upon which lichens grow that are commonly used for calibration include tombstones, mining waste, and archaeological sites. Furthermore, because growth rate is not linear, but rather has an initial period of fast growth, followed by a slower, linear growth rate, multiple calibration points are required to quantify the growth rate through time (Figure 2). With a well-constrained growth rate that spans the same time period of study and that was measured on similar substrates, the lichenometry method can be reasonably accurate. Because of increasing uncertainty back in time, changing climatic conditions through time, and the intersection of individual lichens as surfaces become heavily colonized, the lichenometry method becomes less reliable beyond a few thousand years. The highest accuracy with lichenometry is its application to glacial landforms deposited within the last millennium.

There are many uncertainties with lichenometry. Many involve how applicable the growth curve is to any single area of study. As with any surface-exposure dating technique, lichenometry best dates the timing of landform stabilization, as in the case of moraines (Putkonen et al., 2008). Furthermore, there is an unknown amount of time it takes for lichens to colonize a surface, but this is thought



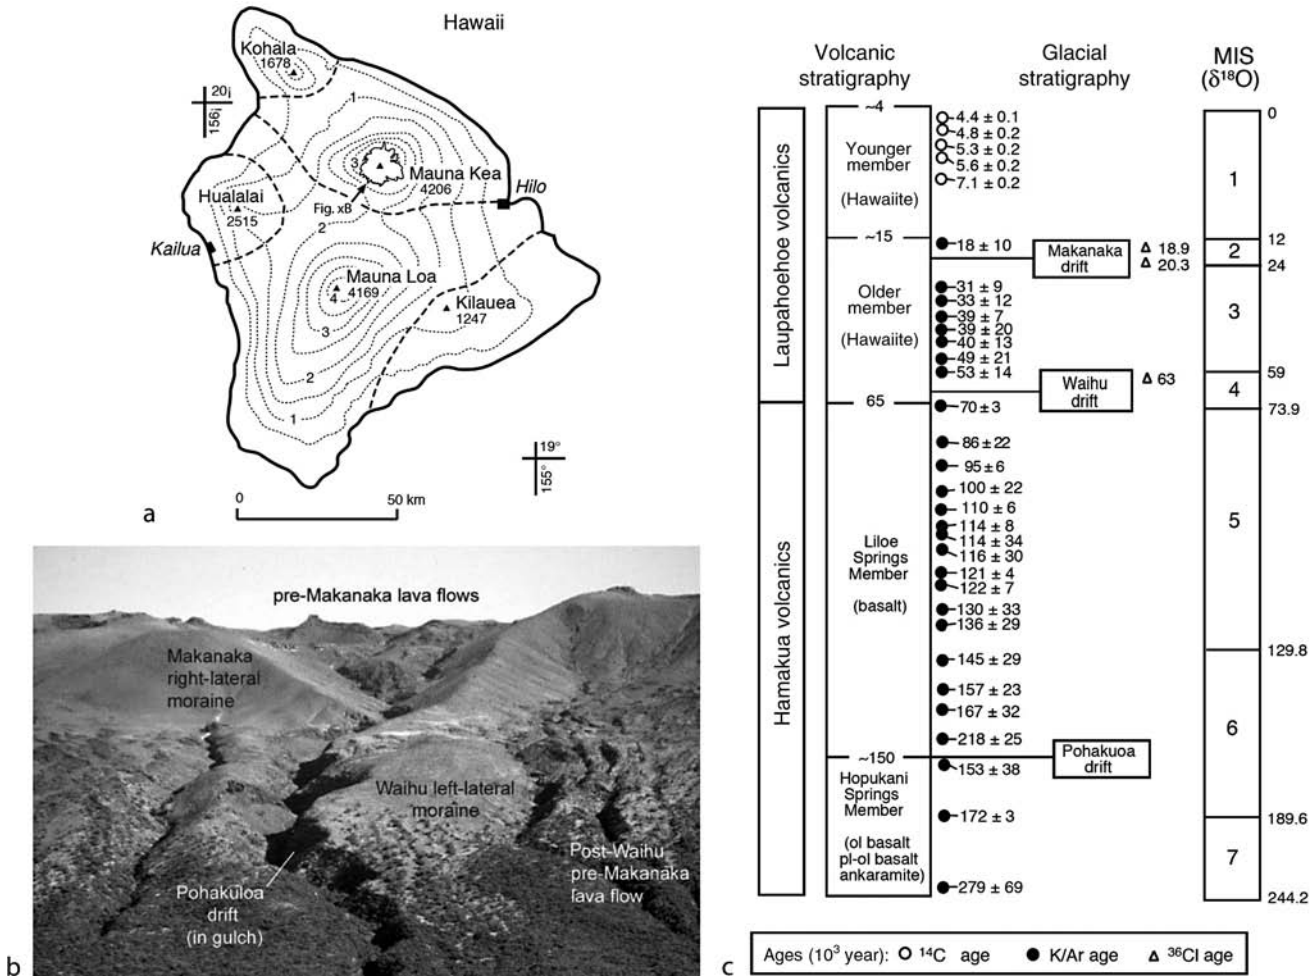
Dating Glacial Landforms, Figure 2 (**a**) Photograph of *R. geographicum* thallus measured on a moraine boulder (from Young et al., 2009). (**b**) Selected *R. geographicum* growth curves (from Calkin and Ellis, 1980).

to be years to decades, not centuries. Finally, it should be mentioned that even where well-constrained lichen growth curves are absent, lichenometry can still serve as a valuable relative-dating technique. For example, determining the largest lichen diameters on individual moraines among a sequence can be useful where correlating moraines between valleys across a mountain range. Additionally, the full range of lichen diameters present on a large group of moraines might indicate whether all the moraines are of similar age, or whether moraine ages span millennia (Solomina and Calkin, 2003; Barclay et al., 2009a).

Association with volcanic deposits

In regions where glaciers exist in proximity to volcanoes, glacial landforms can be dated by their association with volcanic flows that are radiometrically dated. In addition, where glaciation takes place near volcanic arcs or other areas with explosive volcanism, the age of glacial landforms can be constrained by tephrostratigraphy. These techniques are useful throughout the Quaternary, spanning the time period represented by the record of glacial landforms.

One example of dating glacial landforms by their association with dated volcanic flows took place near the summit of Mauna Kea, Hawaii (Figure 3). Mauna Kea periodically supported an ice cap during the Pleistocene, from which outlet glaciers flowed radially part way down the volcano flanks. Potassium–argon dating of lava flows that overlie and underlie drift units associated with two of the most recent moraines deposited on Mauna Kea provided bracketing ages on moraine age (Porter, 2005). A second example regards dating moraines in Patagonia



Dating Glacial Landforms, Figure 3 Example of dating volcanic deposits to constrain moraine age from Hawaii modified from Porter (2005). (**a**) Hawaii showing location of Mauna Kea. (**b**) Oblique photograph showing late Pleistocene moraines deposited on flank of Mauna Kea. (**c**) Summary diagram showing K/Ar ages on lava flows interbedded with glacial drift units; in particular the K/Ar ages constrain the deposition of the Waihu and Makanaka moraines. Note how K/Ar ages compare to ^{36}Cl exposure ages from boulders on the moraine surface.

bounded by basalt lava flows. Argon–argon and potassium–argon dating was used to constrain the age of several moraines deposited during the middle and late Pleistocene (Singer et al., 2004). In some locations (e.g., Iceland), volcano-glacier landforms occur, such as table mountains (or tuyas), which are volcanoes that erupt subglacially and eventually emerge through the ice, ending in a subaerial eruption phase. These features can be dated radiometrically using volcanic materials (Kaufman et al., 2001), or by cosmogenic-exposure dating (see below) on the subaerial surface lava flows (Licciardi et al., 2007).

Volcanic ash, or tephra deposits, that lie beneath or overlie moraines can be used to constrain moraine age. Tephrostratigraphy is the field of matching unknown tephras at a study site with a database based on prior work of tephras of known ages and chemistries. By analyzing tephra chemistry at a study site and comparing it to a database, tephras and their ages can be identified. Because tephras are airfall deposits, they form stratigraphic layers on the Earth's surface. Thus, they can underlie or overlie glacial landforms like moraines, and provide maximum and minimum ages, respectively (Figure 1). In some cases, tephra can be reworked into glacial depositional landforms, which can also provide a maximum age of moraine deposition. In this way, moraines can be dated by their association with tephras. Some examples are dating moraines in Alaska (e.g., Begét, 1994), and in the Cascade Range, western U.S. (e.g., Porter, 1976; Heine, 1998).

Radiocarbon dating

Radiocarbon dating is probably the single most important dating method in Quaternary science. With a usable age range between ~300 and ~40,000 years in most applications, and sample types that include most organic-material, radiocarbon dating is widely used to date sediments and landforms. Typical analytical uncertainties are ~2–5%, although uncertainty typically becomes larger when ages are calibrated into calendar years. In terms of dating glacial landforms, radiocarbon dating has been most useful for dating moraines, although ultimately the dating of the moraine itself arises by dating the sediments that comprise the moraine, or sediments associated with moraines (Figure 1). Studies have applied radiocarbon dating to sediments below, within, and above moraines to provide maximum (below and within) and minimum (above) age constraints.

Dating moraines with radiocarbon works best in environments where glaciers flow across forested landscapes. Radiocarbon dating of wood is used to constrain moraine age in several ways. When a glacier advances into a forest, its proglacial sediments sometimes partly bury tree trunks. By the time the glacier snout reaches these partly buried trees, it shears them off part way up the tree trunk. Following moraine deposition and glacier retreat, the in-situ sheared tree trunks become exhumed and available for sampling. Radiocarbon dating of their outer rings provides a maximum age on moraine formation. In other cases, sheared trees become incorporated in moraine sediments, become deposited on the landscape as erratic logs, or are deposited in till blanketing the landscape, and eventually exposed or washed out. In these cases, radiocarbon dating outer rings of glacially transported logs also provides maximum ages on moraine formation. There are many good examples of using radiocarbon dating to date Holocene moraine formation from southern Alaska (e.g., Barclay et al., 2009a), western Canada (Menounos et al., 2009), and in the Alps (Joerin et al., 2006). In rare cases, glacier snouts tilt trees as they deposit moraines; in this case, radiocarbon dating the damaged tree can provide a close-limiting age on moraine formation. Where logs are involved, radiocarbon dating is commonly used in conjunction with tree-ring cross dating, which is a more precise method to constrain moraine age (see below) (Figure 4).

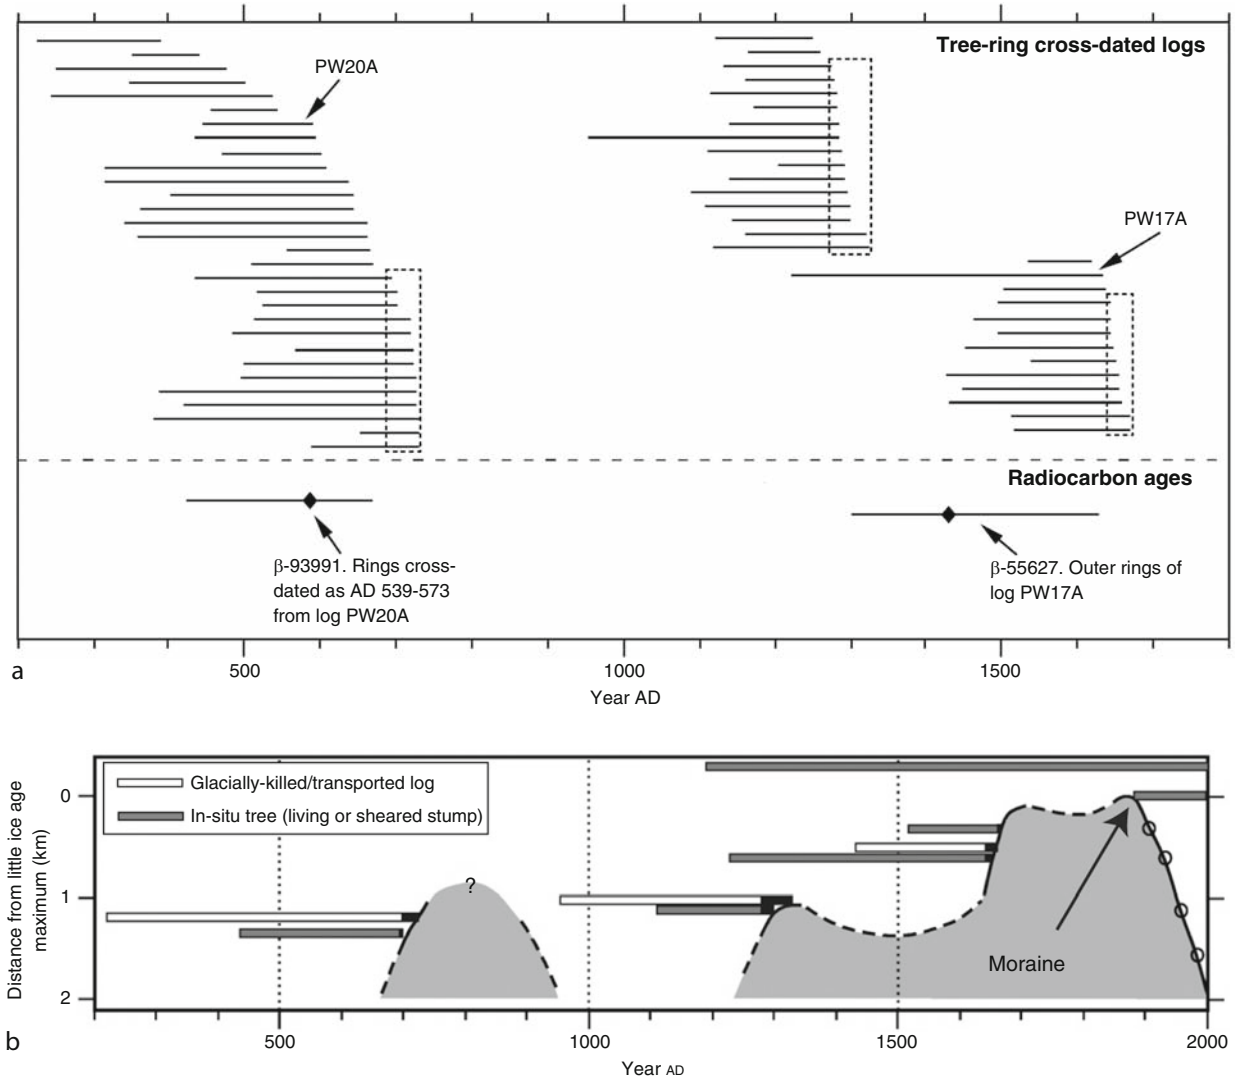
There are many cases, of course, where entire logs are not preserved, but rather pieces of wood or cones and other organic material are reworked and incorporated into moraine sediments. In places where glaciers advance through marine embayments and fjords, they can rework fossiliferous marine sediments into their moraines. In Greenland, for example, radiocarbon dating of reworked fossil material, including marine bivalves, whale bones, and even a walrus tusk provided maximum constraints on the age of late Holocene moraine formation (Weidick et al., 2004). In some cases, glaciers overrun lakes or bogs and deform peat; in these cases radiocarbon dating of the uppermost layers of disturbed peat provide close maximum age constraints on moraine formation (Mercer and Palacios, 1977; Buffen et al., 2009).

In most cases, finding organic materials below or within moraines is rare. More widely used are organic deposits that accumulate behind or on top of moraines. Obtaining so-called basal radiocarbon ages from lakes and bogs is a powerful approach to providing minimum constraints on moraine age in both alpine and continental ice sheet settings (e.g., Thackray et al., 2004; Lowell et al., 2005).

Radiocarbon dating of glacial landforms includes features in addition to moraines. Organic deposits on top of, beneath, and incorporated into outwash deposits allow radiocarbon dating to constrain the age of outwash terraces (e.g., Porter et al., 1983; Hamilton, 1986). Radiocarbon dating has also been used extensively to date raised glaciomarine landforms, such as ice-contact deltas, that are deposited during ice retreat in isostatically recovering (emerging) landscapes (Dyke, 1999). In these cases, radiocarbon ages of in-situ bivalves from the delta sediments provide a direct age on ice-contact delta formation.

Tree-ring cross dating

Tree-ring cross dating is a precise means to date logs, and where logs are associated with moraines (see above), tree-ring cross dating can provide more precise age control than radiocarbon dating alone (Wiles et al., 1996).



Dating Glacial Landforms, Figure 4 Example of using radiocarbon and tree-ring cross dating. (**a**) *Horizontal black lines* in upper portion of figure represent the lifespan of each cross-dated log found in front of a retreating glacier in south Alaska; *dashed line boxes* represent timing of glacier advance when the majority of the trees were killed, indicating glacier advance. The lower portion shows the 2-σ age range (*black bar*) and median (*diamond*) of radiocarbon ages of the outer rings of select logs. Modified from Barclay et al. (2009a). (**b**). Time-distance diagram of the Tebenkof Glacier, south Alaska, constrained by tree-ring cross dating of glacially transported trees and in-situ sheared stumps that were killed upon glacier advance and living trees growing on and outboard of the Little Ice Age moraine. Modified from Barclay et al. (2009b).

The principles rely on wiggle-matching patterns of tree-ring widths between a "master" tree-ring width series and tree rings in a specimen of which the age is unknown. In this manner, logs can be placed in absolute time, and their age of death in some cases can be constrained to a single year. Thus, over time periods spanned by a master ring-width series, using tree-ring cross dating to determine the age of trees can be much more precise than radiocarbon dating.

Because of regional variations in climate and other factors that influence tree growth, tree-ring master series are constructed and applied within specific regions. Because living tree-ring width time series only go back a few centuries in time, subfossil trees are used to extend the time series farther back in time. Once master chronologies exist, placing glacially transported logs and sheared stumps into an absolute age provides tight age control on moraine formation. For example, when glacially-transported logs in glacier forefields are dated by cross dating, they reveal when a stand of trees were glacially overrun, and hence provide a maximum age for moraine formation (Barclay et al., 2009b). Similarly, in-situ stumps that have been sheared from advancing glaciers also provide maximum ages of moraine formation, and also

pinpoint the exact location of glacial overriding (Barclay et al., 2009b; Menounos et al., 2009) (Figure 4). Tree-ring counting from living trees that grow on moraines can provide a close minimum age of moraine formation, but the method can be complicated somewhat by the ecesis time (the time it takes for a tree to germinate on fresh glacial deposits). In some cases, glaciers that advance into forests can damage or tilt trees in the processes of moraine deposition. In these cases, cross-dated damaged trees can provide a precise time of moraine formation (Wiles et al., 1996; Barclay et al., 2003).

Cosmogenic-exposure dating

Cosmogenic-exposure dating (also referred to as surface-exposure dating and terrestrial cosmogenic-nuclide dating) has emerged over the last two decades as the premier chronological tool to date glacial landforms such as moraines, erratic boulders, and glacially eroded bedrock. As with the other dating methods above, the details of the method are not discussed herein, but rather focus is placed on its application to dating glacial landforms. See Gosse and Phillips (2001) for a thorough treatment of background and fundamental principles.

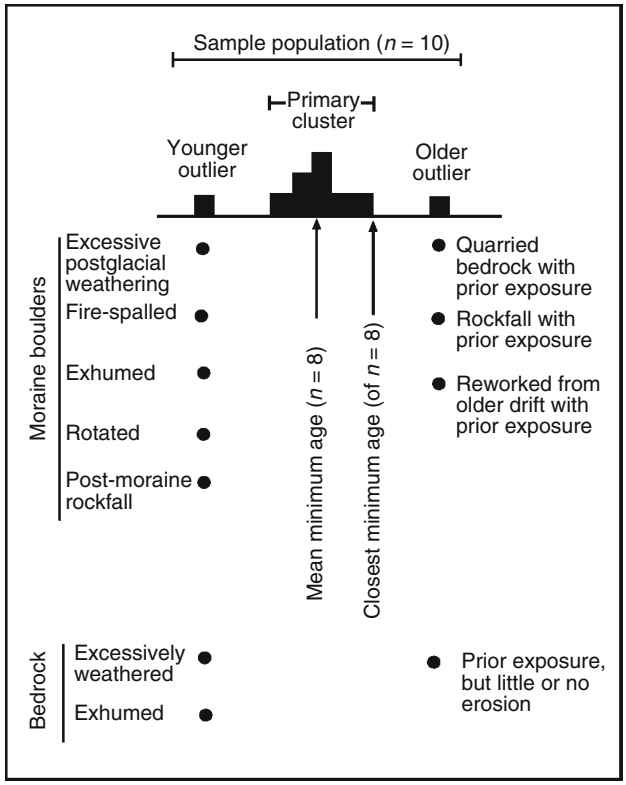
Briefly, a family of isotopes is produced in Earth's rocky surface (mostly in the upper few meters) as a result of cosmic-ray bombardment. Many of the resulting "cosmogenic" isotopes are radioactive (e.g., ^{14}C, ^{10}Be, ^{26}Al, ^{36}Cl), whereas others are stable (e.g., ^{3}He, ^{21}Ne). Some of the isotopes are produced solely from cosmic ray bombardment (e.g., ^{10}Be), whereas others can be formed by additional means (e.g., ^{36}Cl). The different isotopes have differing target, or parent, minerals. For example, applications of ^{10}Be mainly use quartz-bearing rocks, whereas applications of ^{3}He commonly rely on olivine phenocrysts in igneous rocks. And, some methods use a "whole-rock" approach because there are several parent elements that produce the cosmogenic isotope (e.g., ^{36}Cl). Furthermore, the radioactive cosmogenic isotopes (radionuclides) are used for different applications depending on their varying half lives.

Because organic matter and glacial deposits are rarely associated, radiocarbon dating cannot be applied in many areas. On the other hand, cosmogenic-exposure dating can be used in more widespread locations because the target materials are rocky deposits typical of glacial landscapes. Moraines, more specifically boulders on moraine surfaces (Figure 1), have been the primary target of cosmogenic-exposure dating, although there have been many other applications. Ultimately, because the target samples (e.g., boulders and bedrock) for cosmogenic-exposure dating are different, and perhaps more common, from organic material required for radiocarbon dating, and are more common than materials targeted for other dating techniques mentioned above, cosmogenic-exposure dating has revolutionized the ability to date glacial landforms. Furthermore, although radiocarbon dating is usable only to about 40,000 years ago, the analytical limit of cosmogenic-exposure dating extends back hundreds of thousands to millions of years.

Early studies that applied cosmogenic-exposure dating to moraines and glacial boulders took place primarily in the western U.S. and Antarctica (e.g., Phillips et al., 1990; Brook et al., 1993). Since then, there have been dozens of studies that have generated moraine chronologies from around the globe. These studies range from moraines deposited by mountain glaciers in tropical latitudes (e.g., Smith et al., 2005a), middle latitudes (e.g., Phillips et al., 1997), and high latitudes (e.g., Briner et al., 2005a). Moraines deposited by ice sheets have also been targeted (e.g., Balco et al., 2002). Until recently, most research has focused on late Pleistocene deposits (~120,000–11,700 years ago), and most specifically, on deposits created during the peak of the last glaciation (~25,000 to ~11,700 years ago). This time period has the advantage of being geologically young enough such that moraines are not too intensely weathered and degraded, yet old enough that concentrations of cosmogenic nuclides are high enough to be analytically measurable. In some locations with apparently slow rates of erosion and moraine degradation, exposure dating works reasonably well farther back in time (Smith et al., 2005b; Licciardi and Pierce, 2008; Porter and Swanson, 2008), but in general, moraine chronologies become increasingly scattered beyond 50,000–100,000 years ago. Recently, as analytical techniques and chemical procedures in preparation laboratories have improved, dating moraines deposited during the Holocene (last 11,700 years), and even during the last millennium, has become more common (Schaefer et al., 2009; Licciardi et al., 2009).

Producing reliable moraine chronologies with low uncertainty relies on several important criteria (Figure 5). To ensure that boulders receive constant exposure to cosmic-ray bombardment since their deposition, the upper, skyward-facing surfaces of large boulders (usually >1 m high, but even larger boulders typically are more stable on moraines) are sampled. Because there are a number of geologic and analytical uncertainties that can affect any given boulder age, researchers typically average cosmogenic-exposure ages from five to ten boulders per moraine crest. Although analytical uncertainties can be significant (particularly for young surfaces), geologic uncertainties, and uncertainties in isotope production rates and spatial scaling rules are typically more significant. Because this entry emphasizes the application, the discussion herein is limited to the most important geologic uncertainties.

Because moraines are depositional features, gravity efficiently decreases moraine slope angles and thus moraines degrade through time (Bursik, 1991). The tilting and rolling of surface boulders, and the exhumation of subsurface boulders to the surface, yield cosmogenic exposure ages that are younger than the true timing of moraine deposition (Figure 6). Thus, moraine degradation severely hampers tightly-clustered moraine chronologies, and skews average ages toward a younger age. In addition

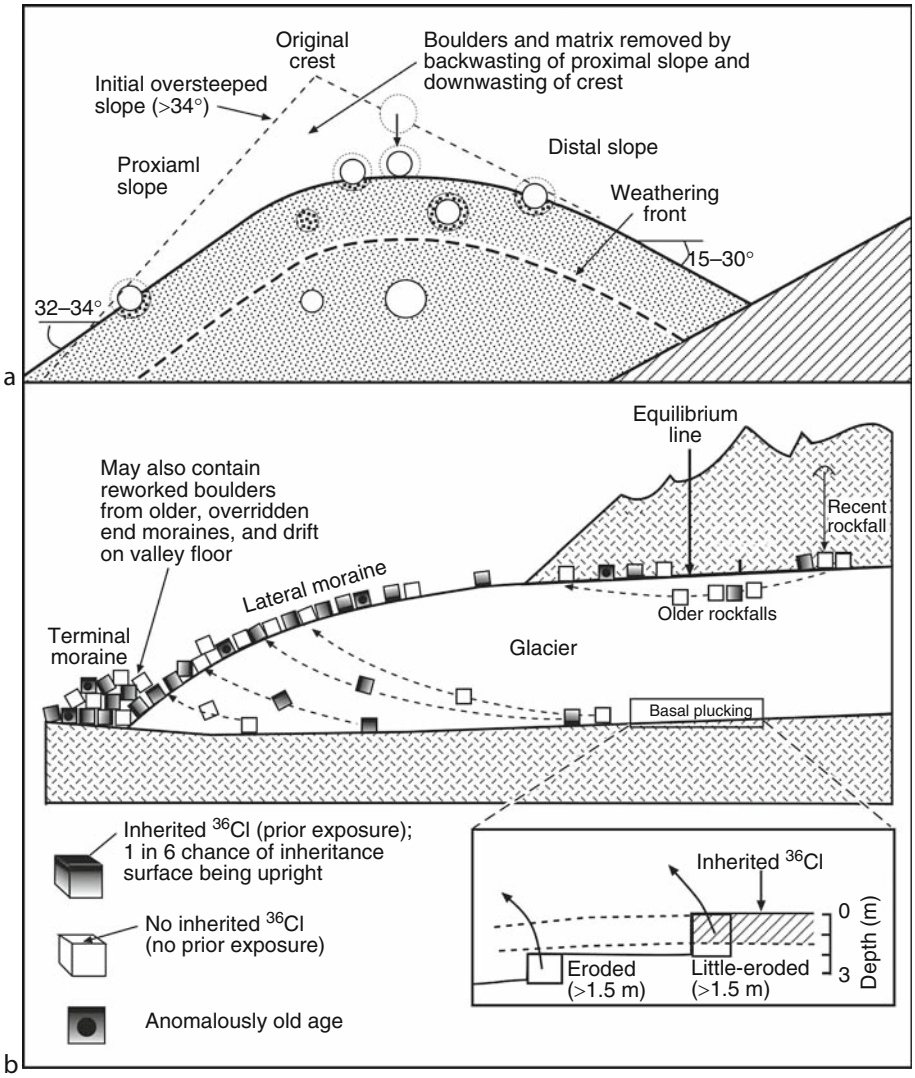


Dating Glacial Landforms, Figure 5 Complicating factors that potentially influence the distribution of cosmogenic exposure ages of moraine boulders (*top*) and glacially-eroded bedrock (*bottom*). In addition, the diagram provides guidelines for interpreting a population of cosmogenic exposure ages of moraine boulders, such as identifying outliers and interpreting an age cluster as the mean minimum age versus closest minimum age. From Porter and Swanson (2008).

to moraine degradation, rock-surface erosion acts upon boulder surfaces and is a process that decreases the cosmogenic-isotope inventory, and thus decreases cosmogenic-exposure age. Despite rock-surface erosion being most important for poorly indurated lithologies and/or for pre-latest Pleistocene moraines, it is commonly difficult to determine how much rock-surface erosion has taken place, and thus remains a potential complication (Figure 6). Sampling boulder surfaces that retain glacial striations or polish avoids this issue, but these features are rarely preserved. Multiple cosmogenic isotopes with different depth-production profiles have also been used to solve for surface erosion (Phillips et al., 1997). Finally, partial burial of moraine boulders by loess or seasonal snowfall also yields cosmogenic exposure ages that are younger than the timing of moraine deposition. Correcting for snow and loess cover is challenging because it is difficult to reconstruct the magnitude of shielding for the duration of a sample's surface history. Most researchers collect samples from tall boulders on high parts of the landscape to increase the likelihood that boulder surfaces are windswept. In some cases, collecting samples during the snow season to evaluate modern snow cover is helpful. In any case, these three complications (moraine degradation, boulder-surface erosion, snow/loess shielding) lead to ages younger than the true timing of moraine formation, which further complicates determining their relative importance. In all cases, careful field sampling can significantly reduce these complications.

Another type of geologic uncertainty arises from isotopic inheritance (Figure 6). Isotopic inheritance refers to cases where moraine boulders are deposited on a moraine surface already containing some inventory of cosmogenic isotopes. These isotopes are "inherited" from a period of prior exposure, a situation that results from inefficient glacial erosion, rockfall onto a glacial surface, or reworking of older materials. In cases where eroded and transported blocks are deposited with their previously exposed surface facing skyward, a chance exists that inherited isotopes combine with isotopes that accumulate during the targeted period of exposure. Thus, these boulders yield cosmogenic exposure ages that pre-date the actual time of moraine deposition. In many cases, inheritance is a much less likely complication than moraine degradation. However, certain contexts exist in which the likelihood of inheritance occurring significantly increases. Primarily, inheritance occurs where glaciers are cold-based or polythermal, and thus do not deeply erode landscapes. There are several examples at high latitude study areas of the prevalence of inheritance and the complication that it imposes in producing moraine chronologies (e.g., Briner et al., 2005b). Indeed, in many settings the presence/absence of isotope inheritance has been used to elucidate patterns of glacial erosion (Sugden et al., 2005; Briner et al., 2006). Another likely context in which inheritance can be common is in short glaciers (e.g., cirque glaciers) where the proportion of head- and valley-wall-sourced boulders is relatively high compared to subglacially sourced boulders. Finally, in some cases, very near the terminus of glaciers and ice sheets, erosion becomes less efficient, and reworked boulders have a better chance of appearing in younger deposits (e.g., Balco et al., 2002).

Assessing the various geologic means by which scatter in a population of cosmogenic-exposure ages arises is critical to ultimately assigning moraine age (Figure 5). To date, there have been several investigations regarding the relative importance of these major complicating factors (Hallet and Putkonen, 1994; Putkonen and Swanson, 2003). In most cases, these studies document the stronger and more typical influence of moraine degradation on a suite of cosmogenic-exposure ages. For this reason, many researchers interpret cosmogenic-exposure ages as providing the timing of moraine abandonment and hence the onset of deglaciation following a glacier advance. That is, boulders that are sampled at the moraine surface were the last deposited on the moraine crest just prior to retreat of the ice margin. In addition, due to the prevalence of moraine degradation, many researchers interpret cosmogenic exposure ages as minimum ages for the onset



Dating Glacial Landforms, Figure 6 (**a**) Diagram illustrating complication of applying cosmogenic exposure dating to degrading moraines, in particular, the issue of boulders exhumed to the moraine surface as the crest lowers through time. The additional complication of boulder erosion is also illustrated; "zoned" boulders indicate weathering rinds and grussification. (**b**) Sketch showing different processes that lead to inherited cosmogenic isotopes (e.g., ^{36}Cl) in moraine boulders. Modified from Porter and Swanson (2008).

of deglaciation. In some rare cases where moraine crests are stacked together, the outermost moraine crest may not date the onset of deglaciation (Gosse et al., 1995). A misconception that still arises in the literature is that cosmogenic-exposure ages yield the timing of glacier advances, or the timing of glacier maxima. This can result in incorrectly assigning leads/lags between one study area compared with glacier and climate-change records from elsewhere. Thus, it is critical to have a firm understanding of complications in producing cosmogenic-exposure dating chronologies, and to acknowledge what part of the glacial cycle the ages constrain.

In addition to moraines, cosmogenic-exposure dating has been applied to other glacial landforms with great success. Common glacial landforms targeted with cosmogenic-exposure dating are outwash and marine terraces (e.g., Anderson et al., 1996). Because fine-grained sediments (as opposed to large boulders on moraine surfaces) can become mixed after their deposition by soil and bioturbation processes, merely dating a collection of surface pebbles potentially would yield an age younger than the true timing of sediment deposition. An additional complication is that a small proportion of inherited isotopes can be present in sediments. Both of these complications can be elucidated by collecting samples of sediment along a depth profile, measuring cosmogenic isotope concentrations in each, and matching the resulting profile of concentration versus depth to the expected theoretical

profile. In this manner, inheritance can be detected (if, with depth, concentrations decrease to a value above zero, which represents the inherited component). Furthermore, the depth profile can be extrapolated to the surface to estimate the surface exposure age. Although useful, this approach does require multiple measurements for a single surface age.

Dating glacial erosional landforms

Glacial-erosional landforms, such as the variety of bedrock landforms common in glaciated landscapes (e.g., roche moutonnées, whalebacks, etc.), are commonly polygenetic features (depending on their size). In many cases, these bedrock features have been reshaped during the most recent period of glaciation. Cosmogenic-exposure dating has been employed with success to assign ages to glacially eroded bedrock surfaces. Dating the landform, in most cases, is accomplished to place timing on the most recent period of ice recession. Many studies have successfully placed constraints on ice sheet thinning (e.g., Stone et al., 2003) and recession (e.g., Briner et al., 2009) using transects of samples from glacially eroded bedrock landforms.

In some ways, cosmogenic-exposure dating can also constrain the actual age of erosional landforms. For example, where cosmogenic-isotope inheritance exists, the magnitude of glacial reshaping of the landform during the last glacial cycle can be determined to be minimal. In fjord landscapes, the spatial distribution of isotope inheritance can constrain how much these large-scale glacial landforms evolved during the most recent glaciation (e.g., Sugden et al., 2005; Briner et al., 2006). In some cases, researchers have used two isotopes with different half lives (e.g., ^{10}Be and ^{26}Al) to assess glacial erosion not only for the most recent period of glaciation, but the general magnitude of erosion and landscape modification during prior glaciations (e.g., Bierman et al., 1999). An additional tool applied to determine the timing of formation of large-scale glacial erosional features, such as fjords, is thermochronology. In particular, low temperature thermochronology techniques (e.g., (U-Th)/He and ^{4}He/^{3}He; Reiners and Brandon, 2006) have recently placed constraints on the evolution of glacial landscapes and the timing of major fjord incision (Shuster et al., 2005).

Summary

Reliably, dating glacial landforms are fundamental to the field of paleoclimatology. All dating methods have uncertainties and room for improvement. Just as multiple proxies are needed to reconstruct past climate change, or multiple climate models should be used to predict future climate change, more than one geochronological tool should be employed wherever possible to date glacial landforms. Newer and more powerful techniques (e.g., cosmogenic-exposure dating) need to be used in concert with relative-dating techniques, beginning with a foundation of geomorphic mapping and morphostratigraphic relationships. The geochronologic toolbox employed to date glacial landforms is expanding, and it is exciting to think about what additional techniques will be available in the future. At the same time, however, the tools already in hand are sufficient to read landscapes upon which there are widespread traces of former glacier change.

DEAD ICE

D. P. Dobhal
Wadia Institute of Himalayan Geology, Dehradun, Uttarakhand, India

Definition

The dead ice is defined as the ice which does not move, that is, it becomes stagnant. Generally, dead ice is formed due to detachment of/from the active glacier and topographic conditions do not allow for its movement, and it is covered with thick piles of moraine/debris, which act as insulator and protect from quick melting. It is also known as stagnant ice.

DEBRIS

Department of Geography, University of Zürich, Zürich, Switzerland

Synonyms

Boulder; Detritus; Scree material

Definition

Unconsolidated sediment, larger than 1 mm, of angular or rounded angular fragments of boulders (clasts), predominantly originating from physical weathering.

Introduction

Debris occurs in a wide range of environments, but most significantly in those where physical weathering rates dominate, such as periglacial environments. Hence debris is common in glacierized areas, affecting glaciers and ice in the ground, as well as their appearance and characteristics, in a great variety of ways. Debris e.g. significantly influences the glacier melt and the glacier movement. Debris can be found on the surface of glacier ice (supraglacial), within glacier ice (englacial), as well as below (subglacial) and beside glacier ice. Coarse debris in periglacial scree slopes plays an important role in the development of so-called rock glaciers (Barsch, 1996, Haeberli et al., 2006). The focus here is on debris related to glacial environments.

Debris sources

The principal sources of debris are mass movements such as rockfalls, rock avalanches, debris flows, debris-laden ice, and snow avalanches from surrounding mountain slopes (Hambrey et al., 2008; Kirkbride, 1993). These sudden and sometimes vast events of debris relocation are common phenomena in alpine regions. The amount of debris that reaches a given glacier depends on the characteristics and extent of the catchment area, especially its weathering and erosion rates (Haeberli, 1986). These again are influenced by the lithology of the source material. Scree slopes (debris deposits) situated in a periglacial environment favor the development of firn patches and rock glaciers due to the different thermal regime of blocky material (Haeberli et al., 2006). An additional source of debris is recycled material from lateral moraines. These moraines become unstable as the glacier lowers and permafrost thaws, enabling moraine material to fall onto the glaciers (Nakawo et al., 1986). Debris eroded from the glacier bed may also become entrained into the ice. The extent of subglacial entrainment depends mainly on thermal regime and substrate erodibility.

Distribution of debris

The spatial distribution of debris in and on the glacier is the result of three main processes (supraglacial, englacial, and subglacial; Hambrey et al., 2008, Nakawo et al., 1986), and depends primarily on the location of the entrainment zone and the transport of the sediment away from it. Debris supplied in the accumulation zone is buried by snow and becomes entrained into the ice, while debris supplied in the ablation zone usually remains on the surface due to emergent glacier flow. Debris supplied from below generally remains in the ice. However, some basal or even subglacial debris can also reach the glacier surface along shear horizons and become supraglacial debris (Hambrey et al., 2008). On the other hand, debris can become entrained in crevasses and then into the ice by falling from the surface (Gulley and Benn, 2007). The distribution of debris is usually inhomogeneous. Debris from point sources usually accumulates in planar shapes (debris septa) or as discrete bodies of variable geometry. Supraglacial debris can cover whole or substantial parts of the glacier tongue (debris-covered glacier), given low surface slope values (Paul et al., 2004). Supraglacial debris cover can also form at the margin of glaciers

(side moraines), or over the glacier surface in longitudinal strips (medial moraines). The latter can develop only where debris is supplied almost continuously. This is typically the case when two or more glaciers join and the side moraines converge into medial moraines (Anderson, 2000). Debris from supraglacial sources is generally dominated by angular clasts (Benn and Owen, 2002). Fluvially rounded gravel or sand can be found on debris-covered glaciers, indicating the existence of debris redistribution due to meltwater (Hambrey et al., 2008). Englacial debris is found mainly in lenticular bands, but discordances and folded forms exist as well due to the action of compressive flow (Gulley and Benn, 2007). Boulders commonly retain their size, although they might become slightly rounded during the englacial transport due to clast collisions. The shapes are altered efficiently in the englacial fluvial environment. They rapidly become rounded and break down into platy clasts.

Glaciological effects of debris

Debris influences the glacier system in fundamental ways. Most important are the effects on ablation and mass balance, glacier rheology and glacier dynamics. Depending on its thickness, thermal conductivity, and thermal gradient, debris can cause ablation to increase or decrease. In general, thin (~15–80 mm) and dispersed debris cover enhances ice melt, while the insulating effect increases as the debris cover becomes thicker (Nakawo and Young, 1981; Tangborn and Rana, 2000). However, significant melt rates do occur on a glacier with a thick debris cover if it has steep ice slopes and glacier ponds (Sakai et al., 2000). Large individual boulders reduce ablation and glacier (or "boulder") tables develop, while cryocronites are a sign of enhanced melt due to small debris. Englacial debris influences the rheology (deformational behavior) of the ice. The existence of undeformable material in the glacier reduces the creep rate of ice (Nickling and Bennet, 1984). Debris has an indirect effect on ice crystal growth. A thick supraglacial layer on the ablation zone of the glacier alters glacier dynamics and its sensitivity to climate. Reduced ablation causes glacier tongues to be more stable and to react with greater delay to climate fluctuations than clean ice glaciers. In addition, some debris-covered glacier tongues contain stagnant ice parts at their fronts (Bolch et al., 2008a; Quincey and Glasser, 2009). Debris cover can also hamper the identification of the actual terminus, and the reaction of the glacier to climate influences can be recognized mainly by the downwasting that occurs (Bolch et al., 2008b). Conversely, large rockfalls onto glaciers can trigger glacier advances (Porter and Orombelli, 1981).

Conclusions

Debris is widespread in glacier environments and affects glaciers in a variety of ways. Although knowledge about the influence of debris on glaciers has increased significantly in the last decades, especially through remote sensing, modeling, and field investigations, much still remains to be discovered in this regard.

DEBRIS THERMAL PROPERTIES AND IMPACT ON ICE ABLATION

Ryohei Suzuki
Hydrospheric Atmospheric Research Center, Graduate School of Environmental Studies, Nagoya University, Nagoya, Japan

Definition

Debris thermal properties. The thermal conductivity of the debris, which varies with mineralogy, porosity, and moisture content. In this chapter, the thickness of the debris layer is also discussed as a factor of thermal properties.

Introduction

Debris layers often cover the surface of ablation zones in *valley glaciers* surrounded by steep, bare rock walls (Debris-Mantled Glacier Snouts). Because supraglacial debris affects the transfer of heat between the atmosphere and ice surface, the ice *melt rates* under these layers depend on the thermal properties (e.g., debris thickness, thermal conductivity, and heat capacity) of the debris as well as the *meteorological conditions* on the glacier. This means that the methodologies for observing and estimating *mass balances* of debris-free glaciers cannot be applied to debris-covered glaciers without taking into account the influence of debris on ice melt.

The spatial distribution of debris thermal properties is heterogeneous even in an ablation area. Furthermore, each glacier has its own characteristics of thermal properties and their spatial distribution. Such characteristics are determined by the different supply mechanisms of the debris, which depend on the type of rock and the topographic and climatic conditions (Debris).

Due to the factors described above, there exists a necessity to clarify the state of debris thermal properties on glaciers in order to understand the physical processes involved and evaluate the glacier melt under debris layers. This chapter illustrates the relationship between debris thermal properties and impact on ice ablation along with the development of studies in this field.

Debris thickness and ice melt rate under debris layers

The relationship between debris thickness and ice melt rate under debris layers has been studied since the late 1950s. Early experimental research focused on debris layers with a thickness of several centimeters. The results of these studies were often expressed in graph form, with the horizontal axis indicating debris thickness and the vertical axis indicating ice melt rate under the debris layer (e.g., Mattson et al., 1993).

The absorbed amount of solar radiation on a glacier surface increases where the debris layer has a thickness of several centimeters because such a debris layer causes a decrease in *albedo*. Although the range may not be uniform, the ice melt rate is sometimes several times faster than that of a bare ice surface. On the other hand, a thicker debris layer leads to an increase in heat release from the surface. This means that a thick debris layer acts as a heat insulator that reduces the transfer of heat to the ice surface. At the critical thickness of debris, the ice melt rate under the layer equals that on the bare ice surface. Where the debris layer is thick in comparison with the critical thickness, the ice melt rate is smaller than that of bare ice. In other words, the ice melt rate is suppressed by the debris layer.

Although the above studies showed some common characteristics, the ice melt rate differed quantitatively from case to case. For instance, some experiment results showed the maximum values were twice that of bare ice, whereas other studies showed only a 20% increase. It is also important to note that the value of critical thickness differed from study to study, and some values were more than twice others. Additionally, some studies showed ice melt rates that were two or three times slower than others where the ice melt rate was suppressed by debris layer thickness (e.g., Mattson et al., 1993).

The causes of the above differences can be understood as follows: the ice melt rate is accelerated only if the albedo of the debris surface is lower than that of the glacier ice. This means that the ice melt rates of each study depend on the albedo of the debris used in each experiment. Because the values of albedo on bare ice are not uniform, we cannot regard the ice melt rate on bare ice as a basis for evaluating the influence of debris by comparing the ice melt rates under the debris layers. Additionally, because the impact of differences in albedo depends on the intensity of solar radiation, meteorological conditions must also be considered as controlling factors in ice melt rates.

The studies mentioned above discussed ice melt rates as a function of debris thickness only, but the use of thermal properties to evaluate ice melt rate should not be neglected if a thick debris layer covers the ice. The fact that the thermal conductivity of debris layers is different from

case to case is one possible reason why differing ice melt rates were found.

As mentioned above, applying the physical parameters concerning energy balance calculations at one point on a glacier to other areas causes considerable discrepancies in ice melt rate estimation. Furthermore, most debris-covered glaciers are located in remote high mountain areas and the topographic conditions of their ablation areas are so arduous that in-situ observations are hardly feasible. These factors show the limitations of using a methodology based on the debris thickness function to evaluate the ice melt rates of a whole ablation area on a single glacier or multiple glaciers.

Thermal resistance as an index of debris thermal properties

Taking into account the above issues, Nakawo and Young (1981, 1982) proposed a physical parameterization of thermal resistance that is defined as a value of thickness divided by thermal conductivity of a debris layer to estimate ice melt rates. This methodology is based on Fourier's law of heat conduction; the heat used for ice melt under a debris layer can be estimated using the relations among the heat provided from the surface, temperature profile, and heat conductivity of the debris layer. The *energy balance* method, for which the input parameters are the surface temperature of the debris layer and the meteorological conditions, specifies the heat amount conducted from the surface to the bottom of the debris layer. This method assumes that all the heat derived from the energy balance calculation is transferred to the debris layer. The temperature at the bottom of the debris layer can be assumed to be the ice melt point during glacier melt season for *temperature glaciers*. Therefore, we only have to measure the surface temperature to obtain the temperature difference between the top and bottom of the debris layer. If a linear temperature profile in a debris layer is assumed, the temperature gradient can be calculated by the temperature difference divided by the thickness of the debris layer. Here, we cannot solve the equation because it contains two parameters that are usually unknown: the thickness and heat conductivity of the debris layer. However, by replacing these two parameters with the value for the thermal resistance and treating them as a single parameter, thermal resistance can be solved for the equation of Fourier's law.

Thermal resistance increases with an increase in debris thickness and a decrease in heat conductivity; the ice melt rate under the debris layer decreases with an increase in thermal resistance. Because variations of debris thickness and heat conductivity over a period of several years should be negligible on average, thermal resistance is often assumed to be a constant value. This means that the ice melt rate under a debris layer can be derived if the thermal resistance is known and meteorological data for an adequate and appropriate period of time can be obtained. By combining two equations regarding energy balance and heat conduction, we can solve the equation numerically for the heat used for ice melt without having to remeasure the surface temperature.

As mentioned above, one of the advantages of using thermal resistance is that two unknown parameters can be combined into a single parameter. Although investigating the states of these parameters on a debris-covered glacier also has been essayed (e.g., Conway and Rasmussen, 2000), no study has found a method that is sufficiently versatile to be applied extensively on glaciers due to the difficulties in making the requisite observations. Similarly, there is currently no known feasible method for collecting surface temperatures over a period of time on debris-covered glaciers. These reasons indicate that the method for estimating ice melt rate under debris layers by using thermal resistance which is derived from combining surface temperature data at a point in time and data about meteorological conditions over a period of time is another advantage for overcoming the difficulties in observations.

Nakawo and Young (1981, 1982) showed that the ice melt rates that were estimated from the above method are compatible with measured ice melt rates using sample debris layers of which thermal resistances were previously known. Rana et al. (1997) and Nicholson and Benn (2006) also support the validity of this methodology when using daily meteorological data for the input.

Satellite utilization

Since the methodology using thermal resistance was proposed, it has been applied to optical satellite remote sensing data (Satellite Applications on Snow, Ice, Glacier Studies), for example, obtained from LANDSAT TM and ASTER, which observe the reflected solar radiation between visible to near infrared wavelengths and the emission of infrared light on ground surfaces (e.g., Rana et al., 1997; Nakawo et al., 1999; Suzuki et al., 2007). These multi-spectral sensors provide spatial distributions of surface temperature and albedo of ground surfaces as digital images in the range of about 60–180 km square. The idea of applying satellite data was originally proposed by Nakawo et al. (1993). After that, Rana et al. (1997) compared the estimated runoff from the Langtang glacier in the Himalayas to the measured runoff to show the validity of estimation. Combining the other data, for example, the ice flow vectors derived from SPOT-HRV, has been shown to discuss the variations in the Khumbu glacier of in the Himalayas (Nakawo et al., 1993).

The advantage of utilizing satellite data is not only that spatial distributions of physical parameters can be collected, but also that the complex debris-covered areas can be averaged into the pixel sizes of each satellite sensor. There are ponds and ice cliffs on the ablation areas of debris-covered glaciers and their absorbed heat is roughly ten times larger than that under a debris layer (Sakai et al., 2000). Because such areas can be averaged spatially by using satellite data, thermal resistance calculated from these data represent averaged thermal properties on target

areas (Nakawo et al., 1993). On the other hand, the limitations on taking optical satellite data (mainly due to cloud cover) make the study of thermal properties of debris more difficult.

Summary

The study of the relationship between debris thermal properties and ice ablation has developed from experimental research into debris thickness and ice melt rates to observational research using satellite remote sensing. With the escalated concern over global warming of recent years, the importance of clearly understanding the facts about glacier mass balances in debris-covered glaciers is also increasing. One example of an important issue on which attention has been focused is the impact of variations in glacier mass balances on local water environments, such as the *Glacier Lake Outburst Floods (GLOFs)* that are often caused by *moraine-dammed lakes*. Since ice ablation has direct impact on development of glacier lakes, the studies to specify the thermal properties of debris and ice melt rates under the debris layer play important roles in such field, too.

Debris-mantled glaciers; Glaciers noirs

Definition

A glacier where part of the ablation zone has a continuous cover of supraglacial debris across its full width. Some authors apply a more rigorous definition of debris cover over at least 50% of the ablation zone.

Debris covered-glaciers probably exist in all the major mountain regions of the world, and are the dominant valley glacier type in high-relief orogenic belts, where high denudation rates of mountain faces supply copious quantities of rock debris by rockfall, rock avalanching, and mixed snow/ice/rock avalanching. They are especially well-developed in the Himalaya (Racoviteanu et al., 2008a), Karakoram (Owen and Derbyshire, 1993; Shroder et al., 2000), Caucasus (Stokes et al., 2007), Alaska, New Zealand (Kirkbride, 1993) and parts of the Andes (Racoviteanu et al., 2008b). Small covered glaciers are also widespread in some regions of cirque glaciation such as northern Iceland and the Sierra Nevada, California (Clark et al., 1994). Supraglacial debris covers form where debris supply is high and ice flow is slow relative to bare-ice ablation, so that a glacier is unable to evacuate rock debris efficiently. Debris covers therefore develop mostly on the lower parts of ablation zones.

Though varied in extent and form, supraglacial debris covers tend to thicken downstream to between 0.5 and 2.0 m maximum thickness, and to comprise sandy boulder-gravels (Hambrey et al., 2008). A distinct vertical sorting often exists in which a surficial openwork clast layer overlies more matrix-rich gravels of lower void ratio. Eluviation of fines through the layer may coat the ice surface with sandy silt. While angular rockfall material dominates, debris covers may also contain comminuted basal debris, fluvially rounded clasts and sand, and aeolian and anthropogenic material. The composition of any debris

cover depends on the local availability of debris from different sources and on the large-scale structure and thermal regime of the glacier.

Debris covers are functional components of glacier systems because of their influence on sub-debris ice melt and mass balance. Debris cover extent varies inversely with mass balance as glaciological conditions alternate between transport-dominant (higher velocities, lower ablation) and ablation-dominant (lower velocities, high ablation) conditions (Kirkbride, 2000). The insulating effect of supraglacial debris was quantified in a classic study by Østrem (1959). Dispersed debris and thin covers enhance melting above "clean" (uncovered) ice rates because low-albedo rock surfaces absorb much of the incoming short-wave radiation. However, under a continuous clast-thick cover, heat transfer to the debris-ice interface is reduced due to the low thermal conductivity of the void-rich debris layer (typically 0.8–1.5 W m^{-2}). Melt rate declines asymptotically with increasing debris thickness: a 10 cm layer may reduce ablation by 60% and a 50 cm layer by 90%. Many experimental studies using fine debris (sand, volcanic ash, coal dust) show these relationships well (e.g., Nakawo and Rana, 1999; Adhikary et al., 2000), but the threshold debris loads associated with optimum enhancement of ablation and with the onset of reduced ablation are not well established for coarse debris on real glaciers. Energy balance modeling of the thermal behavior of debris covers is complex, as models have to integrate energy transfers across the atmosphere–debris and debris–ice interfaces, as well as time-dependent variations in heat storage and transfer within the debris layer itself (Bozhinskiy et al., 1986; Mattson and Gardner, 1989; Nicholson and Benn, 2006; Brock et al., 2010). The complexity derives from the fact that all three are to varying degrees related by feedback mechanisms and lags in heat flow.

At the glacier scale, the insulation of ice beneath debris covers means that a greater ablation area is required to maintain equilibrium mass balance (Benn et al., 2003). Accumulation-area ratios (AARs) of Himalayan debris-covered glaciers are typically 0.25–0.50 instead of the 0.60 typical of uncovered valley glaciers. Ablation zones tend to be long, narrow, and gentle and ice velocities at the terminus are very low. Climatic fluctuations of the glacier tend to be expressed as thinning and thickening of the ablation zone rather than as advance and retreat of the terminus, and the maximum amplitude of change is located near the upstream margin of the continuous cover. The common maxim that debris-covered glaciers are "unresponsive" to climate variation refers only to the subdued fluctuations of glacier termini: glacier volume adjusts sensitively to climate but volume losses are redistributed by the insulating debris cover.

Geomorphologically, such glaciers are inefficient at evacuating their debris loads into the proglacial system, and may build lateral moraines tens to hundreds of meters high. Different forms of terminus may develop from the sluggish flow of debris-covered ice. These may include moraine-dammed raised-bed glaciers such as Hatunraju, Peru (Lliboutry, 1977), outwash-head termini such as Tasman Glacier, New Zealand (Kirkbride, 1993), and rock-glacier-type lobes such as Sachen Glacier, Pakistan (Shroder et al., 2000). Where bounding moraines are breached by overspilling ice lobes, multi-lobed termini will develop, for example, Miage Glacier, Italy (Deline and Orombelli, 2005). Which form develops depends on the discharge and stability of the outwash stream, the slope of the proglacial area, and the debris load of the glacier itself, but their interrelationships are not well understood. Over millennial timescales and multiple mass-balance cycles, geomorphic and chronological evidence suggests that some heavily debris-covered and moraine-bounded glaciers have progressively expanded while nearby uncovered glaciers have retreated. This suggests a long-term net accumulation of supraglacial debris on lengthening glacier tongues, in which glaciological feedbacks promote further supraglacial debris accumulation, reduced mean specific net balance, and therefore a long-term dynamic in which the ablation zone must expand to maintain equilibrium mass balance of ice (Kirkbride, 2000). At shorter timescales, recent climatic amelioration in alpine ranges is associated with increasing supraglacial debris loads due to higher rates of rockfall supply, such as at Miage Glacier (Figure 1), where a continuous debris cover has developed since the maximum of the Little Ice Age (Deline, 2005).

Much of the research interest in these glaciers is because their retreat dynamics endanger downstream populations (Quincey et al., 2005). Recent retreats of debris-covered valley glaciers have resulted in the formation of calving ice cliffs in moraine-dammed lakes. Catastrophic floods may result from calving waves overtopping the moraine dams, and/or sudden lake drainage due to dam failure. Fatal incidents of glacial lake outburst floods (GLOFs) have occurred in recent decades,

Debris-Covered Glaciers, Figure 1 Debris-covered Miage Glacier (Mont Blanc massif, Italy). Photograph by Ben Brock.

leading to early-warning systems and engineering operations being introduced at some glaciers to manage the risk.

Conclusions

Debris-covered glaciers have recently become the focus for much research, notably using remote-sensing techniques (Quincey et al., 2005; Racoviteanu, 2008a, b) to monitor changing debris-cover areas, and geohazard monitoring in relation to lake outburst floods. Much remains to be discovered about the topographical, geological, and glaciological controls on debris cover evolution, and on how such covers modify the responses of such glaciers to climate change.

DEGLACIATION

Vinvent Rinterknecht
School of Geography and Geosciences, University of St Andrews, St Andrews, Scotland, UK

Definition

Deglaciation refers to the uncovering of land and water that was previously covered by ice. The process corresponds to the retreat of the glacier terminus or the ice sheet

margin toward its source area (cirque, ice sheet center). This occurs when the ice mass transfer from the accumulation zone to the ablation zone (see *Glacier Mass Balance* for details) is not sufficient to replace the ice lost by melting or calving. As glaciers and ice sheets are highly sensitive to climate variations, their mass balance budget will primarily reflect prevailing climate conditions: cooling (ice advance), warming (ice decay), and stable (ice stagnation). In the case of the deglaciation, more ice will melt in the ablation area than could be replaced by precipitation (mostly as snow) in the accumulation area, resulting in a net glacier/ice sheet margin retreat.

Mechanisms of deglaciation

Warming temperature

The main mechanism involved in deglaciation is the melting of ice due to air temperature warming. While the accumulation usually happens during winter time, the ablation season or melting season usually occurs during the summer months. The direct consequence of warmer summer temperatures is an increase in the rate of glacial meltwater. The increased melting rate results in a negative mass balance and ultimately in the retreat of the glacier to higher altitudes.

Glaciologists use the equilibrium line altitude (ELA) to define the boundary between the accumulation zone and the ablation zone. The elevation of this line defines where a glacier is in balance, i.e., where the volume of ice accumulated equals the volume ablated. As the mass balance becomes increasingly negative (more ablation than accumulation), the ELA will shift progressively to higher elevations, corresponding to glacier recession. Ultimately, if the ELA is higher than the highest topography for a sustained period of time, glaciers will retreat continuously until deglaciation is complete.

For glaciers and ice sheets terminating in water, the water temperature also plays a role in deglaciation. Recently, Holland et al. (2008) demonstrated that increased ocean water temperature had a direct effect on the retreat rate of the Jakobshavn Isbræ because of rapid basal thinning of the floating ice tongue.

Decreasing precipitation

The process of ice flow from the accumulation zone to the ablation zone dictates the ice mass transfer (Paterson, 1994). This means that a decrease in precipitation will affect negatively the mass balance by decreasing the accumulation, resulting in net retreat. Such a scenario could occur when the climate becomes drier or when the source of precipitation does not reach the interior of an ice sheet, literally starving the ice sheet.

Successive negative mass balance for years due to reduction or absence of precipitation could lead to the surface of the glacier becoming entirely prone to ablation (ELA above the elevation of the glacier surface). In turn, this could result in catastrophic downwasting by areal stagnation.

Calving

A particular case of a deglaciation mechanism can be observed for glaciers and ice sheets terminating in lakes or oceans (tidewater glaciers). Calving allows much faster ablation as compared to melting, by removing large blocks of ice from the ice margin (Figure 1). Glaciers terminating in water are subject to increased calving when water levels are increasing. This can happen in lakes when the water level is raised by damming (by ice, landslide, or lava flow), forcing the glacier to a new grounding line. For example, in Argentina, the Moreno glacier periodically dams an arm of Lake Argentino, increasing the lake water level upstream from the ice dam. Once the water level builds up sufficient pressure, the ice margin bursts and retreats to its original grounding line near the lake shore.

In the case of tidewater glaciers or ice shelves, water level fluctuation in conjunction with increasing air temperature could lead to catastrophic events, such as the ongoing breakup of the Wilkins shelf in Antarctica.

Long-term monitoring of calving glaciers shows that lake-terminating glaciers calve much slower than ocean-terminating glaciers, which are subject to the constant action of waves and tides (van der Veen, 2002).

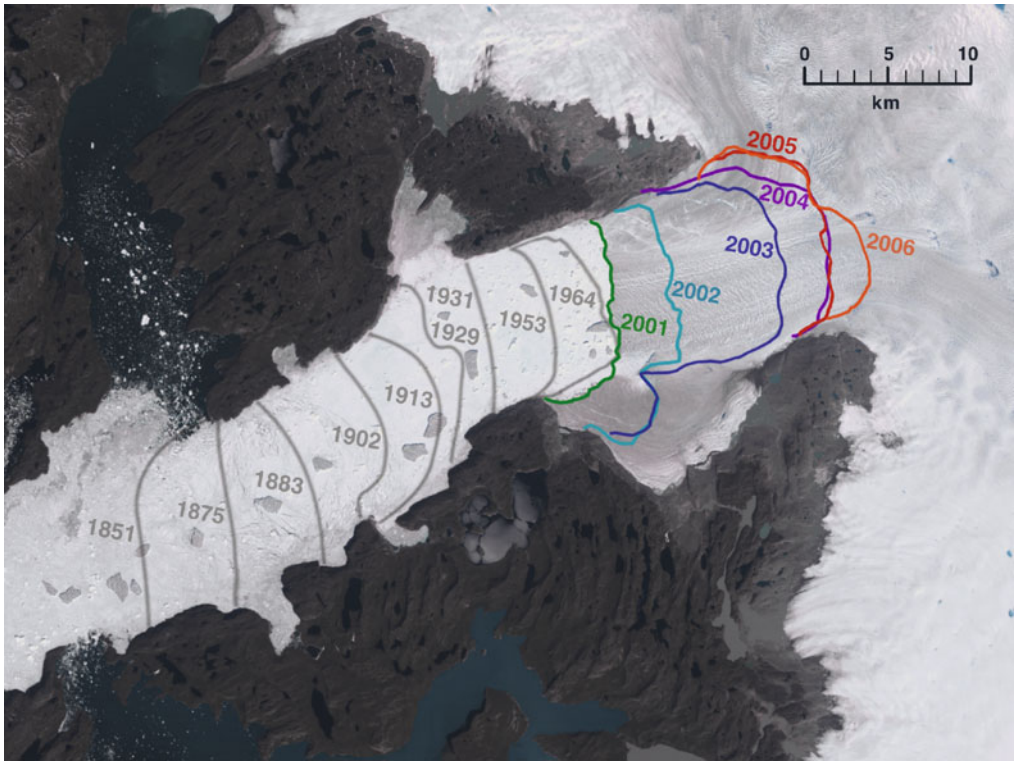
Consequences of deglaciation

New landscape

Deglaciation produces new landforms and sediments that provide an endless source of information to understand glacial processes (Benn and Evans, 2010). Modern glacial retreat produces landforms such as sandar (singular: sandur), push moraines, kettle holes, or leaves on the newly-exposed landscape typical features such as eskers, roches moutonnées, and perched erratic boulders. These glacial features provide the foundations for our understanding of glacial processes, as the bases of active glaciers and ice sheets are mostly inaccessible and, thus, very rarely studied.

Sea level rise

During deglaciation, more water is lost by glaciers and ice sheets via melting and calving than is stored via precipitation. The net addition of water from land-based glaciers and ice sheets to the ocean results in an increase of sea level. This has been recorded for the last deglaciation. At the time of the last glacial maximum ~21,000 years ago, when glaciers and ice sheets reached their maximum volumes, the relative sea level was lowered by ~120 m compared to today's sea level. Most of the sea level rise occurred in the following 14,000 years. In today's context of global warming, ice sheets and glaciers are monitored by remote sensing and ground surveys. These studies tell us that the melting of ice is contributing to the global sea level rise, although detailed figures are still elusive (Meier et al., 2007; Pfeffer et al., 2008; Siddall et al., 2009).



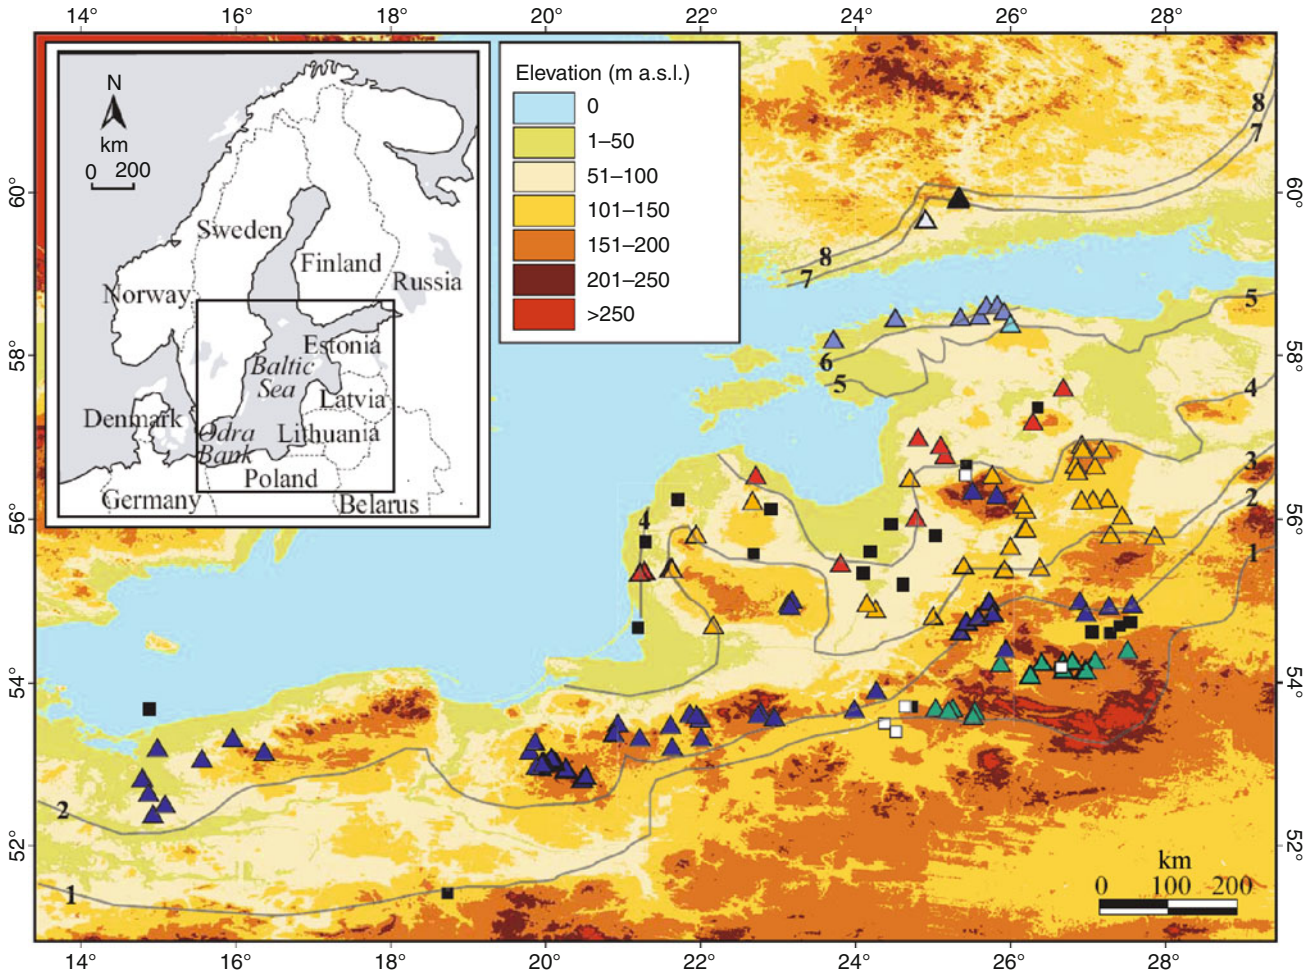
Deglaciation, Figure 1 The Jakobshavn glacier, Western Greenland, shows the changes in the glacier's calving front between 1851 and 2006 (note the scale in kilometers). Historic calving front locations, 1851 through 1964, were compiled by Anker Weidick and Ole Bennike, and are shown here in gray. Recent calving front locations, 2001 through 2006, derived from satellite imagery are shown in colors (source: NASA/Goddard Space Flight Center Scientific Visualization Studio, accessed 07/08/09).

Glacial isostatic adjustment

Landmasses respond to the unloading of ice by rising with respect to the relative sea level. The process can be illustrated primarily as a postglacial rebound of the landmass, but is in fact accompanied by a range of adjustments, such as downward land movements, changes in the Earth's gravity field, changes in the Earth's rotational motion, and can possibly trigger earthquakes. An example of glacial isostatic adjustment can be found in the United Kingdom where the Scottish coast is slowly rising in response to the unload of the last Scottish ice cap (11,000 years ago), and where the southern English coast is virtually sinking due to faster sea level rise compared to land uplift rates.

Deglaciation information

The deglaciation process is rarely uniform, and the ice margin could display a retreat punctuated by a succession of stillstands, leaving behind a characteristic landscape, such as moraine sequences. Geomorphology and dating techniques such as surface exposure dating using cosmogenic nuclides (^{10}Be, ^{26}Al, ^{36}Cl) provide information that helps us to understand deglaciation in the past (Rinterknecht et al., 2009; Briner et al., 2009). From these studies, it is possible to estimate the rate of glacial retreat and infer possible patterns and mechanisms of deglaciation. Rinterknecht et al. (2006) used a multi-proxy approach using cosmogenic ^{10}Be dates and ^{14}C ages to provide a new and comprehensive chronology that constrains the timing of fluctuations of the southern margin of the Scandinavian Ice Sheet in central and Eastern Europe (Figure 2). These results allowed the assessment of the contribution of the ice sheet to the large and often abrupt sea level and climate changes since the last glacial maximum 21,000 years ago. The results also provide the first direct evidence that the ice sheet contributed to the abrupt rise in sea level 19,000 years ago, but not to the similar abrupt sea level event 14,600 years ago. Not surprisingly, the authors found that the ice sheet responded to the abrupt climate changes originating in the North Atlantic Ocean. However, what is surprising is that they were able to demonstrate that those responses varied as a function of the mean climate state; warming during a cold climate caused ice sheet advance, whereas warming during a warm climate caused ice sheet retreat. These responses are exactly of the kind that are expected for the Antarctic (cold climate) and Greenland (warm climate) ice sheets as the Earth's surface temperature warms in the coming century, and thus provides a striking validation of such behavior.



Deglaciation, Figure 2 Digital elevation model of Northern Europe (Adapted from http://lpdaac.usgs.gov, accessed 24-06-2005), with main palaeo ice-marginal positions outlined in gray: 1, LGM Moraine; 2, Pomeranian Moraine; 3, Middle Lithuanian Moraine; 4, North Lithuanian Moraine; 5, Pandivere Moraine; 6, Palivere Moraine; 7, Salpausselkä I Moraine; 8, Salpausselkä II Moraine. ^{10}Be sites: LGM Moraine (*green-blue triangles*), Pomeranian Moraine (*dark blue triangles*), Middle Lithuanian Moraine (*orange triangles*), North Lithuanian Moraine (*red triangles*), Pandivere Moraine (*light blue triangle*), Palivere Moraine (*purple triangles*), Salpausselkä I Moraine (*gray triangle* represents nine samples), Salpausselkä I Moraine (*black triangle* represents four samples). ^{14}C sites: *white squares* and *black squares* represent various studies. (Figure from Rinterknecht et al., 2006.)

Link with the atmosphere and ocean

Ice masses have a direct influence on the air masses that are in direct contact. As deglaciation occurs and glaciers disappear, specific winds like katabatic winds will no longer be generated. As such, deglaciation has a direct influence on the local state of the atmosphere. At the hemispheric scale, the maximum extents of ice sheets in the past are known to have influenced the position of the jet stream, pushing it southward compared to its present position, and thus creating a different overall atmospheric circulation. With the decay of the northern hemisphere ice sheets at the end of the last glaciation, the jet stream migrated northward to its present position, resulting in the global atmospheric circulation with which we are familiar. If tomorrow the last two remaining ice sheets were to disappear, a new pattern of atmospheric circulation would emerge.

Melting ice masses also influence the ocean circulation. Currently, the shallow Gulf Stream brings warmth from the southern latitudes to Western Europe. This oceanic current then sinks in the North Atlantic, where deep water is formed, and flows southward as part of the great oceanic conveyor (Broecker, 1991). Deep sea core sediment data document that the thermohaline circulation (driven by sea temperature and salinity differences) has undergone major shifts in the past. Major inputs of freshwater by: (1) quick release of meltwater stored in proglacial lakes, or (2) rapid surging of ice sheets, are among the current theories to explain the Younger Dryas cold interval (11,000 years ago), and possibly the 8.2 kyr cold event

(8,200 years ago). By adding freshwater to the North Atlantic, the supply of warmth from the southern latitudes would have been decreased or suppressed during these cold events. While these events involved far more extensive decaying of ice sheets than currently observable in both poles, these kinds of cooling episodes are not expected to happen in the future.

DEGREE-DAYS

Roger J. Braithwaite
Geography Programme, School of Environment and Development, University of Manchester, Manchester, UK

Synonyms

Degree-day factor; Degree-day methods; Degree-day total or positive degree-day sum

Definition

Degree-day methods. The melting of snow and ice is assumed to be related to air temperature as long as air temperature is above a critical threshold, usually close to the melting point of ice. In particular, the amount of snow or ice melted at a certain place, during a certain period, is assumed proportional to the sum of positive temperatures (on the Celsius scale) at the same place and in the same period. The amount of melt is linked to this *positive degree-day sum* by the *degree-day factor*. In the present entry, *air temperature* refers to conventional measurements made c. 2 m above the snow or ice surface, or extrapolated from a similar station in the same region.

The melting of snow and ice and air temperature

By the end of the nineteenth century, the general importance of air temperature for the melting of snow and ice was widely recognized (Hann, 1903) although few data were then available. Finsterwalder and Schunk (p. 82, 1887) assume "in the absence of direct observations" that ice ablation on a glacier depends on the length of the snow-free period and on the average temperature above the freezing point during that period. The product of these two factors is clearly related to our degree-day sum. Finsterwalder and Schunk (1887) made no connection but temperature sums above some critical threshold were already widely used in discussion of temperature control of vegetation (Hann, 1903).

The full history of degree-day methods in hydrology remains to be written but the relation between snowmelt runoff and degree-day sums was already well known to Wilson (1941) who tried to explain it in thermodynamic terms. Early workers appear to have compared snowmelt runoff from a whole basin with the degree-day sum at a particular site so the numerical value of any factor linking the two variables has no general significance and is not usually published. The degree-day approach is still widely used for estimating runoff from melting snow although, significantly, De Walle and Rango (2008) do not include values of the degree-day factor in their detailed table of Snow Runoff Model (SRM) applications and results for 112 case studies. The TS-variable developed by Hoinkes and Steinacker (1975) is also based on the degree-day concept and gives a reasonably high correlation with annual mass balance series but, again, the numerical value of the factor linking the TS-variable to the annual balance is not given.

Zingg (1951), de Quervain (1979), and Kuusisto (1984) estimate degree-day factors for seasonal snow by comparing data from snow stakes with air temperature data at the same site, and their degree-day factors can therefore be compared, see Hock (2003).

The key role of air temperature in variations of glacier mass balance may seem obvious to us today but Hoinkes (1955) explicitly downplayed the role of air temperature in controlling glacier melt. Slater (1927) may have been the first worker to measure ablation and air

temperature at the same location. Leaving aside the crudity of his instruments, his result is equivalent to a degree-day factor for melting ice of 9.1 mm d^{-1} K^{-1}. From various glaciers in the former Soviet Union, Krenke and Khodakov (1966) suggest degree-day factors of 4.5 and 7 mm d^{-1} K^{-1} for snow and ice respectively. Orheim (1970) also calculated degree-day factors for melting ice over 2 years on a Norwegian glacier and found values of 6.1 and 6.5 mm d^{-1} K^{-1}, which are not included in Hock (2003).

The measurement of daily melt on glaciers by Müller and Keeler (1969) in parallel with meteorological measurements was a significant development and allowed Braithwaite (1981) to model daily ablation in terms of air temperature and energy balance. He obtained an average degree-day factor of 6.3 ± 1.1 mm d^{-1} K^{-1} for the four series studied, equivalent to a total of 123 days of record. Daily measurements of ice melt were made over a number of summer seasons (1979–1986) at two sites on the Greenland ice-sheet margin at Nordbogletscher (415 days) and Qamanârssûp sermia (512 days) (Braithwaite, 1995).

Variations in degree-day factors

There are substantial variations between degree-day factors at various sites on glaciers. For example, see extensive tables and discussion in Braithwaite (1995), Braithwaite and Zhang (2000), Hock (2003, 2005), and especially some previously unpublished values from the high mountains of China in Zhang et al. (2006). These results are mainly based on melt data from stakes on glaciers but Braithwaite (2008) has also used a simple model to assess degree-day factor at the equilibrium line altitude (ELA) of 66 glaciers.

Degree-day factors are generally lower for snow and higher for ice (Table 1). Monthly estimates of degree-day factors for melting ice at Nordbogletscher and Qamanârssûp sermia (Braithwaite, 1995) describe time variations in degree-day factor. Similarly, time variations are illustrated by a 28-year series of snow melt data from Weissfluhjoch, Switzerland (de Quervain, 1979). Degree-day factors listed by Hock (2003) for both ice (32 sites) and snow (18 sites) illustrate variations between different locations and periods. Results from Braithwaite (2008) reflect different locations (66 glaciers) but also different methods based on either winter balance or "winter balance plus summer precipitation" from Ohmura et al. (1992).

From Table 1, it is clear that degree-day factors for ice and snow are not precise single values, even at the same place. Variations in degree-day factor in Table 1 are denoted by standard deviations but field data (Krenke and Khodakov, 1966) and analysis of the energy balance (Braithwaite, 1995) both suggest that very high degree-day factors for ice should only occur at low temperatures and not at random. The generally lower degree-day factor for melting snow compared with ice is mainly due to higher albedo which reduces the energy available for melting (Braithwaite, 1995), while time variations at the same locations presumably reflect differing weather conditions as expressed by variations in the surface energy balance.

Insofar as we can expect the different terms in the energy balance to vary geographically and temporally (Braithwaite, 1995; Guðmundsson et al., 2009), we may expect some systematic variations in degree-day factor and there is some evidence for this. Zhang et al. (2006) claims a clear geographic variation in degree-day factor for ice from low values (2–3 mm d^{-1} K^{-1}) in the relatively continental Tien Shan in Northwest China to high values (15 mm d^{-1} K^{-1}) in the relatively maritime mountains of South China. Fausto et al. (2009) have suggested different degree-day factors for ice over colder and warmer parts of the Greenland ice sheet, i.e., 15 and 7 mm d^{-1} K^{-1}, respectively. Huss and Bauder (2009) claim to detect multiyear variations in glacier-averaged degree-day factor for Swiss glaciers (roughly equal to the degree-day factor for snow?) which they explain in terms of secular variations in global radiation.

Estimation of degree-day sums

The calculation of degree-day totals from raw temperature data is a trivial one of summing all the positive temperatures in a time series, and a computer can do this easily. However, it would be very laborious to find and store long series of daily, or better sub-daily, temperature data if all

Degree-Days, Table 1 Mean and standard deviation of degree-day factors for melting ice or snow (from Braithwaite, 2008)

		Degree-day factor mm d^{-1} K^{-1}		
Location	Type	Mean	St. devn.	Sample
Nordbogletscher Braithwaite (1995)	Glacier ice	6.9	±1.1	Nearly daily data for 14 months
Qamanârssûp sermia Braithwaite (1995)	Glacier ice	7.8	±1.0	Nearly daily data for 21 months
Hock (2003)	Glacier ice	8.9	±3.7	32 sites
Weissfluhjoch, Switzerland De Quervain (1979)	Seasonal snow on land	4.2	±1.0	28 melt seasons
Hock (2003)	Snow on glaciers	5.1	±2.2	18 sites
Braithwaite (2008) using data from Ohmura et al. (1992)				
(1) Winter balance	Snow at ELA	3.5	±1.4	66 glaciers
(2) Winter balance plus summer precipitation	Snow at ELA	4.6	±1.4	66 glaciers
(1) and (2) Combined	Snow at ELA	4.1	±1.5	2 × 66 glaciers

we want to do is to calculate monthly or annual sums. Braithwaite (1985) therefore suggested that monthly degree-day totals can be calculated from monthly mean temperature by assuming that temperature is normally distributed within the month with standard deviations of about ±2 to ±4 K. The advantage of this approach is that monthly mean temperatures are now more widely available in digital form for individual climate stations, or for cells in a gridded climatology like that of New et al. (1999).

Reeh (1991) extended the approach of Braithwaite (1985) by noting that monthly mean temperatures can be approximated by a sine curve around the annual mean temperature if the annual temperature range is prescribed. Temperatures at any particular time are then assumed to be normally distributed around the sine curve. Carlov and Greve (2005) revisit the calculations of Braithwaite (1985) and Reeh (1991) and propose a much more efficient algorithm suitable for the many repeated calculations needed for long-term simulations of the Greenland ice sheet.

Degree-day models

A degree-day model is one where snow and ice melt are calculated according to the degree-day method, for example, as opposed to the energy-balance model, although extra procedures are needed to account for snow accumulation and refreezing of melt water. According to Hock (2003), degree-day models are widely used for four reasons: (1) wide availability of air temperature data, (2) relatively easy interpolation and forecasting possibilities for air temperature, (3) generally good model performance despite their simplicity, and (4) computational simplicity.

The reported success of the degree-day approach to ice and snow melt at two sites in Greenland (Braithwaite and Olesen, 1989) inspired Reeh (1991) to further develop the model and test it with the limited amount of data from other sites in Greenland. Huybrechts et al. (1991) then used the degree-day model to calculate mass balance forcing for their model of ice dynamics for the whole Greenland ice sheet, assuming degree-day factors of 3 and 8 mm d^{-1} K^{-1} for snow and ice, respectively. Many of the current models of Greenland mass balance follow Huybrechts et al. (1991).

Laumann and Reeh (1993), Jóhannesson et al. (1995), Jóhannesson (1997), Marshall and Clarke (1999), Braithwaite and Zhang (2000), Braithwaite et al. (2002), De Woul and Hock (2005), Raper and Braithwaite (2006), Anderson et al. (2006), Braithwaite and Raper (2007), Liu et al. (2009), Shea et al. (2009), Hughes and Braithwaite (2008), and Rasmussen and Wenger (2009) use different variants of the degree-day model to calculate mass-balances of glaciers outside Greenland. The relevant degree-day factors are either found by tuning models onto field data or are prescribed. In general, modelled accumulation depends upon the degree-day factor for snow, and mass–balance sensitivity depends upon the degree-day factor for ice (Braithwaite and Raper, 2007). Balance gradients near the ELA depend on both degree-day factors with higher gradient in the upper ablation area and lower gradient in the lower accumulation area (Braithwaite and Raper, 2007). This predicted nonlinearity of the balance gradient is in reasonable agreement with observations (Furbish and Andrews, 1984; Rea, 2009).

Many workers use a simpler approach than the degree-day model whereby glacier melt is assumed to be a function of summer mean temperature. With appropriate choice of averaging period, e.g., June–August, May–September, or May–October, the summer mean temperature mainly represents the effects of temperatures above freezing point. For example, Krenke and Khodakov (1966) assume a power-law relation between melt and summer mean temperature and their equation was used in constructing the *World Atlas of Snow and Ice Resources* (Kotlyakov et al., 1997). Other workers follow Ahlmann (1924) in using an exponential relation to link melt to summer mean temperature (Nesje and Dahl, 2000). As the degree-day model predicts a family of curves linking melt to summer mean temperature (Reeh, 1991: Braithwaite, 2008) these different approaches are not in serious conflict as long as it is accepted that there can be no single curve linking melt to summer mean temperature.

Summary and outlook

There is generally a relation between the melting of snow and ice and air temperature which can be modelled using degree-day methods. No doubt the relative merits of degree-day and energy-balance methods will continue to be discussed but more climate data from glaciers in different climatic regions should be collected using modern data loggers that can be left unattended for long periods. At the same time, running degree-day and energy models in parallel may also be a fruitful line for future work in trying to understand the possible variations in degree-day factor. In particular, the role of sublimation in the energy balance of very high mountains in the Andes and High Asia deserves further study as does the effect of debris cover.

DEPLETION OF SNOW COVER

Sanjay K. Jain
National Institute of Hydrology, Roorkee, Uttarakhand, India

A snow cover is formed by deposition of snow on the ground surface and has different characteristics as compared with fresh snow. The term areal extent of snow cover may be defined as the extent of ground area covered by snow irrespective of its depth and water equivalent, while a snow pack refers to the total volume of snow on the catchment. In warm conditions, the snow may melt away just after its fall or stay for a short period. Snow cover that stays only for a few days and then depletes away due to climate conditions is known as temporary snow cover. The snow cover accumulated during accumulation period called as seasonal snow cover area, melts away during the next summer season. Depletion curves of snow-covered areas continuously indicate the gradual areal diminishment of the seasonal snow cover during the snowmelt season. The snow cover depletion curves normally relate the areal extent of the snow cover to elapsed time. Or in simple words, snow-cover variations during the snowmelt season are displayed as depletion curves. Snow-covered area of a zone or basin is usually obtained from a depletion curve. A variety of sources of snow-cover area may be used to compile the depletion curves including ground observation, aircraft photography, and satellite imagery. If data are available, it is recommended that satellite imagery be used since it is the easiest to analyze and also quite accurate, depending on the basin size.

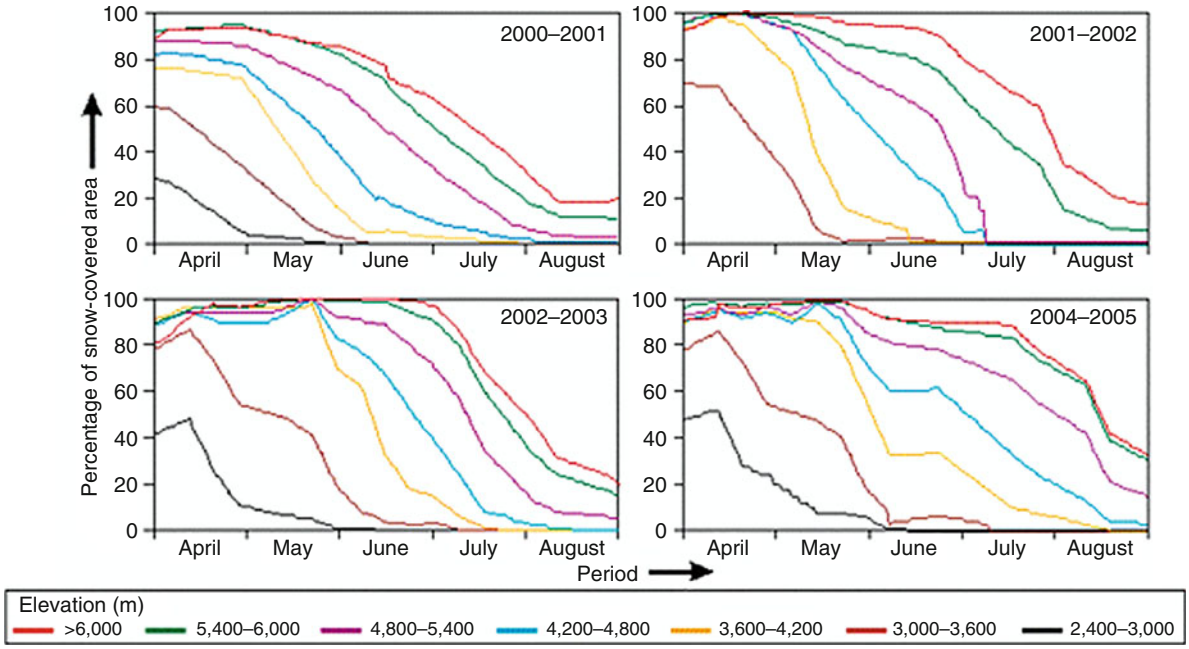
Satellite products have the potential for obtaining snow-cover area data in near-real time. Snow-cover area is an important natural element that is mapped successfully by satellite remote sensing owing to its high albedo. Since the first mapping of the snow cover from satellites, the spectral and spatial resolution of the available sensors has been much improved. The high spatial resolution satellites (Earth Resources observation satellites) such as Land sat, SPOT, Indian Remote Sensing Satellite (IRS) and Japan's Earth Resources Satellite (JERS), and the medium resolution satellites such as NOAA and MODIS are widely used for mapping snow cover. The Landsat Multispectral Scanning System (MSS) and IRS Linear Imaging Self Scanner-1 (LISS-I) have a spatial resolution of about 79 and 72 m, respectively, and are suitable for snow mapping in basins larger than 10 km^2. Improved spatial resolution has been available from Landsat Thematic Mapper TM (30 m), IRS LISS-II (36 m), JERS Optical Sensor System (OPS) (20 m) and High Resolution Visible instrument (HRV) from the French SPOT satellite (20 m in multi spectral mode and 10 m in panchromatic mode), and IRS Resourcesat/Cartosat ISS IV (5.6 m). However, the repetition cycles of Landsat 1, 2, 3, (18 days) Landsat 4, 5 (16 days), SPOT 1, 2, 3 (26 days), IRS 1A, 1B (22 days), IRS-P2 (24 days), and JERS-1 (44 days) have serious limitations for frequent periodical snow-cover mapping in connection with snowmelt runoff forecast, because all the acquired images cannot be used owing to extensive cloud cover or their acquisition after new snowfall. In the case of the above satellites, the period between two usable satellite images is often more than one month. This may not be sufficient during periods of maximum change of snow cover for an adequate determination of the snow-cover depletion. The sampling period may be improved for snow-cover depletion studies by taking multisensor data from various high spatial resolution satellites into consideration.

Now there are many sensors providing images with great spectral, spatial, and temporal resolution, which can be used, based on the need of the study. With the availability of a large number of satellite data, it is now left up to the choice and requirement of the user community to use particular data. A long interval between the measurements increases the uncertainty and risk of errors in drawing these curves. For a precise derivation of the depletion curves, weekly satellite images are necessary, therefore satellite with larger revisit time such as NOAA and MODIS are better than satellite with low frequency.

The depletion curves are prepared periodically monitoring for snow-covered area and for snowmelt runoff simulations. The snow-cover depletion curves for different bands in Satluj basin located in Western Himalayan regions are shown in Figure 1. These depletion curves are, as explained, influenced by different factors and are not predictable. Due to the temperature lapse rate, maximum accumulation of snow is not synchronous at different altitudes, while the snowmelt season starts in the lower parts, the accumulation of snow continues at the higher altitudes. A fast decrease of the snow-covered area can mean a shallow snow pack or high melt rates. On the other hand, a slow decrease is the result of either a high snow accumulation or of low melt rates. The snow cover must be monitored again in each new year because the depletion curves always take a different course depending on the initial snow reserves, meteorological conditions, and intermittent precipitation during the snowmelt season.

In order to simulate the runoff in a new climate, it is necessary to determine a new set of snow-cover depletion curves that would result from higher temperatures and changes in precipitation. For a more confidential interpretation of the climatic differences between the basins, "modified depletion curves" have to be introduced. The new depletion curve (for use in the climate change study) can thus be plotted by using the modified curve. There will be a shift of the conventional depletion curve for a new warmed climate, because in a warmer climate a greater part of the winter precipitation will be rain instead of snow. This will cause the snow accumulation at the start of the snowmelt season to decrease so that the decline of the snow-covered area will be accelerated.

In many situations, however, the climate change will result in an increase in winter precipitation, which will probably offset the decline of the amount of solid



Depletion of Snow Cover, Figure 1 Snow cover depletion curves for different bands in Satluj basin.

precipitation. The shape of a depletion curve in a given basin is determined by the initial accumulation of snow and by the changing melt rates, which depend mainly on the air temperature. Conventional depletion curves, which relate the percentage of a basin or zone covered by snow to the elapsed time during the snowmelt season, do not enable these effects to be identified. Therefore, modified curves have been introduced (Martinec, 2000) in which the time scale is replaced by accumulated degree days. Since the effect of temperature fluctuations in the different weeks or months is eliminated, the decline of these curves is steep in a year with a shallow snow cover and slows in a year with a deep snow cover. Rango and Martinec (1994) outlined a procedure for generating snow depletion curves for changed climatic scenarios and applied the procedure to a number of basins. For warmer temperature scenarios, a modified depletion curve for a zone is obtained by relating snow-cover area to the cumulative snowmelt corresponding to the temperature scenarios.

DEPOSITION FROM DEBRIS-RICH ICE

Gulab Singh, Farjana S. Birajdar
Centre of Studies in Resources Engineering, Indian Institute of Technology Bombay, Powai, Mumbai, India

Definition and origin

Deposition within the glacier system can occur in numerous ways. Rock fall can deposit boulders or sediment on top of the glacier, which then are transported and redeposited in a different glacial environment. Deposition can also occur in a proglacial environment through the process of glaciofluvial actions, or even marine environments. Glacial deposits are composed of different amounts and shapes of till (Trenhaile, 2007). Till is a general term used to describe all the unsorted rock debris deposited by glaciers. Till is composed of rock fragments ranging from clay to boulder size. Till is generally identified by being unsorted (all the rock is jumbled together) and unlayered. The glacier will often carry large boulders, sometimes as large as cars or small homes, as they advance. When the glacier retreats, these large boulders are left behind, often dropped among much smaller glacial till. These large boulders are called erratics (Dreimanis, 1988).

The main glacial deposits are as follows.

Moraines

Moraines (ablation, lateral, medial, and terminal moraine): The term "moraine" covers a wide range of depositional features associated with glaciers and normally consists of unstratified material. Moraines may be categorized on the basis of their position (lateral, medial, or end moraines), their state of activity (active – in contact with ice, or inactive – not in contact with ice), and their method of formation(ablation or ground moraine) (Embleton and King, 1975). Ablation moraine is a conspicuous layer of active moraine on the surface of glacier.

Esker

An esker is a long-winding ridge of stratified sand and gravel, examples of which occur in glaciated and formerly

glaciated regions of Europe and North America. Eskers are frequently several miles long and, because of their peculiar uniform shape, are somewhat like railroad embankments.

Most eskers are believed to form in ice-walled tunnels by streams which flowed within (englacial) and under (subglacial) glaciers. After the retaining ice walls melt away, stream deposits remain as long-winding ridges.

The concentration of rock debris in the ice and the rate at which sediment is delivered to the tunnel by melting and from upstream transport determines the amount of sediment in an esker. The sediment generally consists of coarse-grained, water-laid sand and gravel, although gravelly loam may be found where the rock debris is rich in clay. This sediment is stratified and sorted, and usually consists of pebble/cobble-sized material with occasional boulders. Bedding may be irregular but is almost always present, and cross-bedding is common (Easterbrook, 1999).

DIGITAL ELEVATION MODEL GENERATION OVER GLACIERIZED REGION

Thierry Toutin
Canada Centre for Remote Sensing, Natural Resources Canada, Ottawa, ON, Canada

Introduction

Digital elevation models (DEM) represent one of the most important data source for investigating the geophysical science of glaciated regions, not only the Earth's Polar Regions, but also the inland ice caps and the high-mountain ice fields. To name a few applications: (1) Multi-date multisource DEMs enable derivation of 3D glaciers parameters, such as elevation and volume changes, surface displacements, surface mass balance (since Krabill et al., 1995 to Bamber and Rivera, 2007). (2) Regions of basin can be determined with highly accurate DEM (Hardy et al., 2000). (3) Hazards assessments due to rapid changes of high mountains environment can be performed with continuous monitoring based on regular remote sensing observations (Kääb et al., 2005). Stereo-photogrammetry applied to air photos acquired at different dates can be used to simultaneously computed DEM and velocity fields (Kääb et al., 2005). Because most of these applications are addressed in this Encyclopedia, this entry only gives an in-look for the generation of DEMs using Earth observation (EO) data from multi-platform and multi-sensor.

Some data and methods for DEM generation could have some limits (orbit inclination, elevation accuracy and grid spacing, strong terrain slopes) in their usefulness for some applications in glaciated regions. The synergy of terrestrial, airborne, spaceborne data from various sensors in the visible and microwave spectrum using different methods and algorithms (clinometry, stereoscopy, interferometry, and altimetry) could thus overwhelm these limitations.

Relevant sensor technologies

The relevant sensors are easier to distinguish as a function of the energy wavelength: the optical sensors in the visible and infrared (VIR) spectrum and the radar in the microwave spectrum. The following gives the basic description for each sensor useful for the comprehension of DEM generation over glaciated regions.

Optical sensors

The main optical sensors used for elevation extraction and/or DEM generation are: (1) the digital scanners and (2) the laser altimeter or the Light detection and ranging (Lidar).

Digital scanners (ASTER, SPOT)

The two main satellites with stereo capability (Toutin, 2001) of specific interest for DEM generation over large glaciated regions are:

1. The Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER), a Japanese instrument launched on December 19, 1999, on the Terra platform as part of National Aeronautics and Space Administration's (NASA) Earth Observing System (EOS).
2. The SPOT-1 to -5 series (*Satellite Pour l'Observation de la Terre*) with the high-resolution, optical imaging sensors, as part of Earth observation strategy of the Centre National d'Etudes Spatiales (CNES), the French Space Agency.

As a matter of fact, ASTER is the prime instrument that is used to produce an inventory of glaciers around the world as part of the Global Land Ice Measurements from Space (GLIMS) project due to the high resolution (15 m) of the visible and near infrared (VNIR) subsystem and its along-track stereo capability. ASTER has been developed and launched in order to provide a new source of topographic data for the land surface of the Earth (Welch et al., 1998). In summary, the most important specifications of the ASTER stereo subsystem that govern the DEM generation capabilities include: along-track

same-date stereo geometry; one nadir-viewing and one 27.7° aft-viewing telescope; base-to-height (B/H) of 0.6; ground resolution of 15 m; 9 s required to acquire a 60 × 60 km scene; 64 s required to acquire a stereo pair; bandpass of 0.76–0.86 μm (near infrared) in channel 3N (nadir) and 3B (aft). In October 2009, the distribution of an ASTER global DEM (GDEM) for all the land regions between ±83° latitude (http://www.ersdac.or.jp/GDEM/E/2.html) generated using all available stereo-pairs started: the size of each tile is 1° by 1° with 30-m posting interval and an estimated elevation accuracy (standard deviation) of 10 m.

Since February 22, 1986, the SPOT series include five satellites with two fully-operational: SPOT 4, launched on March 24, 1998, and SPOT 5, launched on May 3, 2002. They maintain the main features of its predecessors but with enhanced resolutions, and SPOT 5 has also new along-track stereo sensors, High Resolution in Stereoscopy (HRS), with 10-m resolution to measure relief elevation (Figure 1).

The most important specifications of the SPOT series that govern the DEM generation capabilities include:

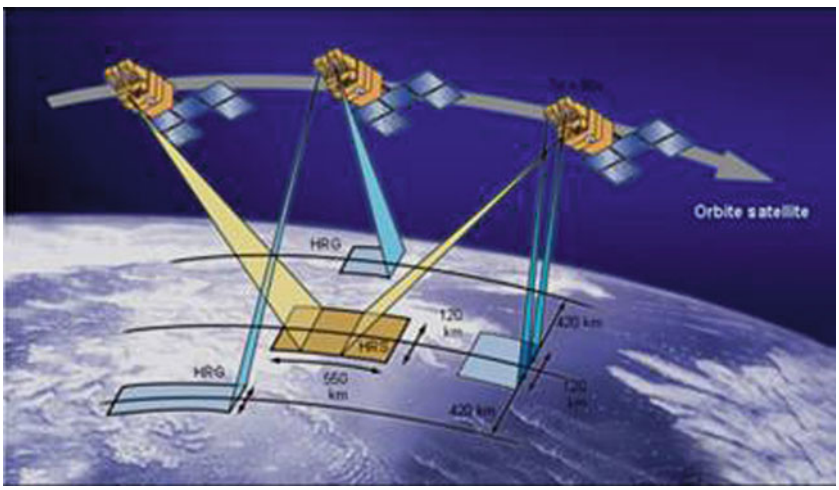
- For SPOT 1-4 HRV, 10 m panchromatic images and across-track stereo capability with variable B/H up to 1.1; 60 × 60 km scene; bandpass of 0.50–0.73 μm but 0.61–0.68 μm for SPOT 4
- For SPOT 5 HRG, 2.5–5-m panchromatic images and across-track stereo capability with variable B/H up to 1.1; 60 × 60 km scene; bandpass of 0.48–0.71 μm
- For SPOT 5 HRS, 10 by 5-m panchromatic images and along-track same-date stereo capability; B/H of 0.8; 120 × up to 600 km long scene; bandpass of 0.48–0.70 μm

Laser altimeter (Lidar, laser scanning, ICESat)

The laser altimeter, or Lidar or airborne laser swath mapping (ALSM), is an optical remote sensing technology (micropulse lidar system and short wavelengths) that measures properties of scattered light to find range and/or other information of a distant target. The range to an object is determined by measuring the time delay between transmission of a pulse and detection of the reflected signal. In addition to the 3D surface mapping capability of the Lidar, a laser scanning sensor can also record the intensity of the backscattered pulse energy returned from the surface. The intensity return is a function of the pulse range, the pulse footprint, the angle of incidence, and the spectral characteristics of the optical sensor in combination with the surface and object imaged on the ground.

There are several major components to a lidar system: (1) the *Laser* (generally 1,047, 1,064, 1,550 nm, beam divergences of 0.3–0.5 mrad); (2) the *Scanner and optics* (displacement of the platform provides the along-track distribution of pulses while the scanner redistributes pulses in the across-track direction ±40° being the more common); (3) the *Receiver and receiver electronics*; and (4) the *Position and navigation systems* (GPS receiver, IMU or star-tracker system). Better target resolution is achieved with shorter pulses, and the pulse footprint is a function of beam divergence, range, and angle of incidence.

January 13, 2003, a spaceborne laser altimeter (ICESat) was launched with the objectives of monitoring ice-surface elevation in a short-term period over Artic and Antarctic ice sheets (http://icesat.gsfc.nasa.gov/). One lidar of the Geoscience Laser Altimeter System (GLAS) transmits short pulses (4 ns) at 1,064-nm wavelength for deriving topography using also a GPS receiver and a star-tracker attitude determination system. The specific near-circular near-polar orbit of ICESat results in across-track spacing at the equator of about 84 km, reduced to around 54 km at latitude of 50°, and provides coverage to ±86° latitude (full Greenland and Artic ices masses and much of Antarctic) with orbital crossovers to estimate elevation changes in Antarctica (Zwally et al., 2002).



Digital Elevation Model Generation Over Glacierized Region, Figure 1 Stereo geometry of SPOT-5 and its sensors HRG and HRS.

The footprint is 76 m in diameter with 175-m along-track spacing. The planimetric location of footprints is better than 6 m, and the satellite-surface distance has accuracy better than 10 cm under clear-sky conditions, diminishing to about 1 m at the Pole. However, the computed elevation accuracy varies from 30 cm over low slopes ice-sheet regions to 80 cm when slopes are 1–2°, while elevation changes can be estimated within 60 cm. The forward scattering in thin clouds and the errors in laser pointing are, however, the main limiting factors (Thomas et al., 2004). Because the return pulse width increases with surface roughness and/or slopes, its characteristics are used for determining these parameters (Brenner et al., 1983), but some imprecision can occur because the surface height represents a mean value over the footprint. Due to technical issues, the different GLAS lasers operated since February 20, 2003, in burst of 4–5 week long-periods three times a year during 16 operational campaigns (http://glo.gsfc.nasa.gov/).

GLAS data can be obtained from the National Snow and Ice Data Center (NSIDC) DAAC, which archived 15 Level-1 and Level-2 data products via FTP Pull or FTP Push (http://nsidc.org/data/icesat/index.html). Data also include the laser footprint gelocation and reflectance, as well as geodetic, instrument, and atmospheric corrections for range measurements. One Level-2 altimetry product is of special interests for surface elevations over ice sheets is GLA12 (GLAS/ICESat L2 Antarctic and Greenland Ice Sheet Altimetry Data). The GLA12 data from the first seven operational periods (from February 2003 through June 2005) were used to provide new surface elevation grids of the ice sheets and coastal regions, with greater latitudinal extent and fewer slope-related effects than radar altimetry. The DEMs of Antarctica and Greenland are reported on polar stereographic 500-m and 1-km grids, respectively, as centimeters above the datum relative to WGS84 ellipsoid and EGM96 geoid.

Microwave sensors

Only the active form of microwave sensing providing their own source of microwave radiation (approximately 1 cm to 1 m in wavelength) to illuminate the target can be used for elevation extraction or DEM generation on glaciated regions. Longer wavelength microwave radiation can penetrate through cloud cover, haze, dust, and all but the heaviest rainfall as the longer wavelengths are not susceptible to atmospheric scattering which affects shorter optical wavelengths. This property allows detection of microwave energy under almost all weather and environmental conditions so that data can be collected at any time. They are generally divided into two distinct categories: (1) *imaging*, the *Ra*dio *d*etection and *r*anging (radar) and the synthetic aperture radar (SAR) and (2) *non-imaging*, the radar and SAR altimeter.

Imaging: Radar and SAR

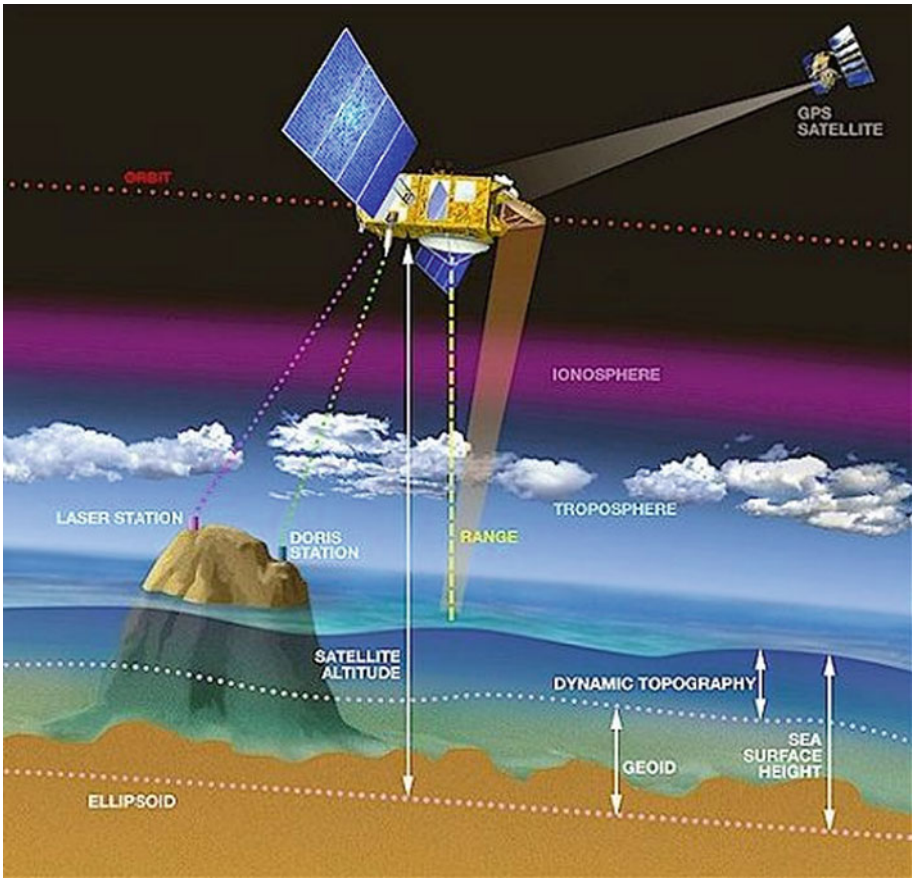
The sensor transmits a microwave (radio) signal toward the target and detects the backscattered portion of the signal. The strength of the backscattered signal is measured to discriminate between different targets and the time delay between the transmitted and reflected signals determines the distance (or *range*) to the target. Such radar systems will require long antenna to achieve fine resolution radar imagery, which is unacceptable for spaceborne radar. The solution is to combine information from the moving antenna to synthesize a long antenna: such radar systems are called synthetic aperture radar (SAR). Radar backscatter is sensitive to physical and structural properties of the target (dielectric properties, surface roughness, shape, etc) as a function of the wavelength, polarization, and incidence angle. More information on SAR and their applications can be obtained in the *Manual of Remote Sensing*, 3rd edition (1998) and the particular radar-target interactions with snow/firn medium in this Encyclopedia.

Since the 1980s, several research and commercial airborne radar systems around the world have been developed and are operational. Since the first ESA's ERS-1 (1991) to Radararsat-2 (2007), numerous spaceborne SAR data are available in different configurations. The most important characteristics for DEM generation can be summarized as follows:

- Single or multiple spatial resolutions between 1 m and 30 m
- Single or multiple radar frequencies: most popular wavelengths are X (2.4–3.75 cm), C (3.75–7.5 cm), and L (15–30 cm) bands
- Single/multiple polarization or full polarimetric modes
- Single or multiple incidence angles between 20° and 60°
- Swath coverage between 20 and 100 km (and 500 km for ScanSAR)
- Revisit time of few days (3–35)

Non-imaging: Altimeter (radar, SAR, CryoSat)

The primary method to provide the spatial coverage and density with sufficient elevation accuracy for mass balance and sea level assessments of large low-slope ice sheets is the radar altimeter (RA). Because they are nadir-viewing instruments, using the ranging capability, they provide a topographic profile of the Earth below the satellite track (Figure 2). Surface elevation is the difference between the satellite's position on orbit with respect to an arbitrary reference surface (the Earth's center or a rough approximation of the Earth's surface: the reference ellipsoid) and the satellite-to-surface range. In a first step, the time delay between the pulse emission and the returned echo from the surface is converted into an accurate measure of the satellite height with the knowledge of the propagation velocity. In a second step, the surface elevation is thus computed from the satellite ephemeris using several locating systems (Laser tracking, GPS system, DORIS instrument from Doppler location, Precise Range and Range-rate Equipment, PRARE, using range determination). This is a straightforward concept, but more difficult to understand in all details because the RAs emits pulses not in narrow beam, such as a laser but



Digital Elevation Model Generation Over Glacierized Region, Figure 2 The principle of altimetry. (Credits and reproduced with the permission of CNES and D. Ducros) (http://www.altimetry.info).

in a wider beam (more than 1°), which becomes wider the further it travels. Further details and discussions can be found in Rémy et al. (2001) and Rosmorduc et al. (2009).

The theoretical use of an active ranging system for mapping elevation of ice sheets was first proposed by Robin (1966). Its theoretical concept was thus scientifically demonstrated on inland ice sheets with Seasat (SEAfaring SATellite) in June 1978 and Geosat (GEOdetic SATellite) from April 1985 to January 1990 because of 72° latitudinal limit providing coverage of the southern half of Greenland and about one fifth of Antarctica. The ERS (European Remote Sensing) series starting 1991 resolved the problem of high-latitude coverage with 81.5° latitudinal limit, generating a continuous record from 1991 covering almost the whole Greenland and four fifths of Antarctica. Finally, Envisat (Environmental Satellite) carries ten complementary instruments, including dual-frequency RA-2 altimeter. Dual-frequency RA is useful (1) for ionospheric corrections over the oceans with the determination of atmospheric electron content, which affects the radar signal path delay, and (2) for measuring the amount of rain in the atmosphere (Rosmorduc et al., 2009), and (3) to be less sensitive to temporal snowpack artifacts.

A second generation of RA has been proposed that could resolve most of the problems encountered with the traditional pulse-limited footprint RAs, such as latitudinal limit, coverage, footprint size, surface gradient larger than the antenna beamwidth, poor accuracy in steep slopes (more than about 1°) and marginal outer regions, melting zones, etc. (Wingham, 1995). This novel-design RA is an altimeter/interferometer (Drinkwater et al., 2004): the SAR Interferometric Radar Altimeter (SIRAL) to be launched on ESA's CryoSat II in 2010, which can be operated in three modes (Rosmorduc et al., 2009):

1. A conventional low-resolution, nadir-pointing altimeter mode measuring the satellite-Earth's surface distance.
2. A conventional SAR mode: because SIRAL will send at 50-μs interval a burst of pulses, processed in one operation, it thus generates 250-m wide across-track strip using Doppler shifts in the forward- and aft-looking parts of the beam.

3. An interferometric SAR (InSar) mode, which uses a second receive antenna to measure the arrival angle. The radar echo is thus received by the two antennas with 1-m across-track interferometric baseline and will be processed with interferometric algorithms using the phase difference.

The last RA generation is the Glacier and Land Ice Surface Topography Interferometer (GLISTIN) using Ka-band radar wavelength, which was developed to support International Polar Year studies. During their first airborne mission on May 1, 2009, scientists from JPL and Dryden Flight Research Center, Calif. USA, applied for the first time, millimeter-wave interferometry with two receiving antennas, separated by about 0.25 m. They evaluated the ability to map ice surface topography of Greenland. About 250,000 km^2 were mapped during 110 h of data collection. The elevation should be accurate to within 0.1 m of elevation with a ground footprint equivalent to spaceborne lidar. Scientists expect GLISTIN to penetrate the snow and ice by just centimeters, rather than by meters, as current microwave radars do.

Various methods: description and results

Clinometry (shape from shading)

Using the principle that an image of a smooth object known to have a uniform surface will exhibit gradations of brightness, or shading, the shape can be determined to map the height of this surface. Because there are two degrees of freedom to surface orientation, the reflectivity does not uniquely determine the local normal but a set of possible normal directions. These directions describe a cone, whose axis is the illumination direction, and the half-angle the incidence angle. Consequently, local operation on the brightness alone cannot be used to determine the shape of the surface and its orientations. Additional constraint must therefore be added: generally the surface is assumed to be continuous and smooth, so that the surface orientations of neighboring surface elements are not independent. If the reflectivity function (a general Lambertian model) and the position of the illumination source are known, the shape can thus be obtained from the shading. In summary, the accuracy of this technique with remote sensing data is limited by intrinsic radiometric and geometric ambiguities (Toutin, 2001; Toutin and Gray, 2000):

1. The reflectivity is not only dependent on the local incidence angle, but also on the albedo related to land cover, rugosity, humidity, etc., as a function of the sensor (radiometric ambiguity).
2. The determined incidence angle yields to a set of potential orientations whose normal directions describe a cone (conic ambiguity). Some reference elevation information is thus needed to derive the absolute elevation, and the accuracy is limited by the height error propagation.

Consequently, clinometry remains a marginal technique, except on homogeneous low-slope terrain surfaces, such as ice sheets/caps: the radiometric/geometric ambiguities (albedo vs. reflectance; incidence angle with Lambertian surfaces) can these be resolved more easily.

Application with VIR (Landsat, SPOT, AVHRR, and MODIS)

Lodwick and Paine (1985) used two Landsat-1 and 2 MSS images (July and October) over an ice cap on Baffin Island, Canada, to obtain high and low sun angles and maximum difference in sun azimuth. Because they demonstrated that the reflectance conditions of an ice cap are non-Lambertian for a large range of incidence angles, they applied a simple linear model between typical maximum slopes in the "sun facing and away facing" directions and the reflectance values at the 1% level of the gray value histogram. Finally, a weighted third-order surface adjustment is carried out with nine control points to transform the 50-m posting slopes in the sun-azimuth direction into elevations. The results for the basic shape of the ice cap surface compared well with the base map. Some variations could be partly explained by the surges (melting and refreezing) of the ice-cap surface. No quantitative accuracy was performed due to the lack of accurate topographic information. Other experiments were thus developed either using Landsat or SPOT images (Dowdeswell and McIntyre, 1987; Bingham and Rees, 1999; Cooper, 1994). Different assumptions were made: (1) slopes are less than 2°; (2) surfaces have uniform reflecting properties; (3) the maximum slopes is smaller than the incidence angle; and (4) the sensor is not saturated. While quantitative accuracy evaluations were limited, it seems that the first solution (±2 m rms with Fourier domain, Cooper, 1994) achieved better results than the second one (±15–20 m rms with cosine of illumination angle, Bingham and Rees, 1999) for solving the Lambertian scattering properties.

On the other spatial range, Scambos and Fahnestock (1998) also applied the method with two low-resolution (1.1 km) cloud-free Advanced Very High-Resolution Radiometer (AVHRR) data and a coarse radar-altimetry-derived DEM (5-km grid spacing) previously generated over the northeast Greenland ice stream. The extracted slopes are transformed into elevation data adding topographic details to the coarse DEM with spatial scales of around 3–20 km. This was then confirmed by the comparison with airborne laser elevation profiles. Scambos and Haran (2002) applied the method with 44 AVHRR images using the full Greenland DEM (Bamber et al., 2001). The same experiments were performed in Antarctica with MODIS data taking profit of an improved spatial (250 m) and radiometric (12 bits) resolutions and input coarse DEMs derived from satellite laser and radar altimetry (Haran et al., 2008). However, the first conclusion of the first experiment that an ice cap is a non-Lambertian surface for a large range of incidence angles was never taken into

account in these experiments, which applied Lambertian reflectivity with large field-of-view images (Landsat, MODIS, and AVHRR).

Stereoscopy

To obtain good geometry for better DEM generation, the intersection angle (or B/H) should be large in order to increase the stereo exaggeration factor, or equivalently the observed parallax, which is used to determine the terrain elevation: B/H of 0.6 (ASTER) to 1.1 (SPOT) are a typical value to meet the requirements of topographic mapping (Toutin, 2001). Whatever the data sources, the different processing steps to produce DEMs using stereo images can be roughly described (Figure 3):

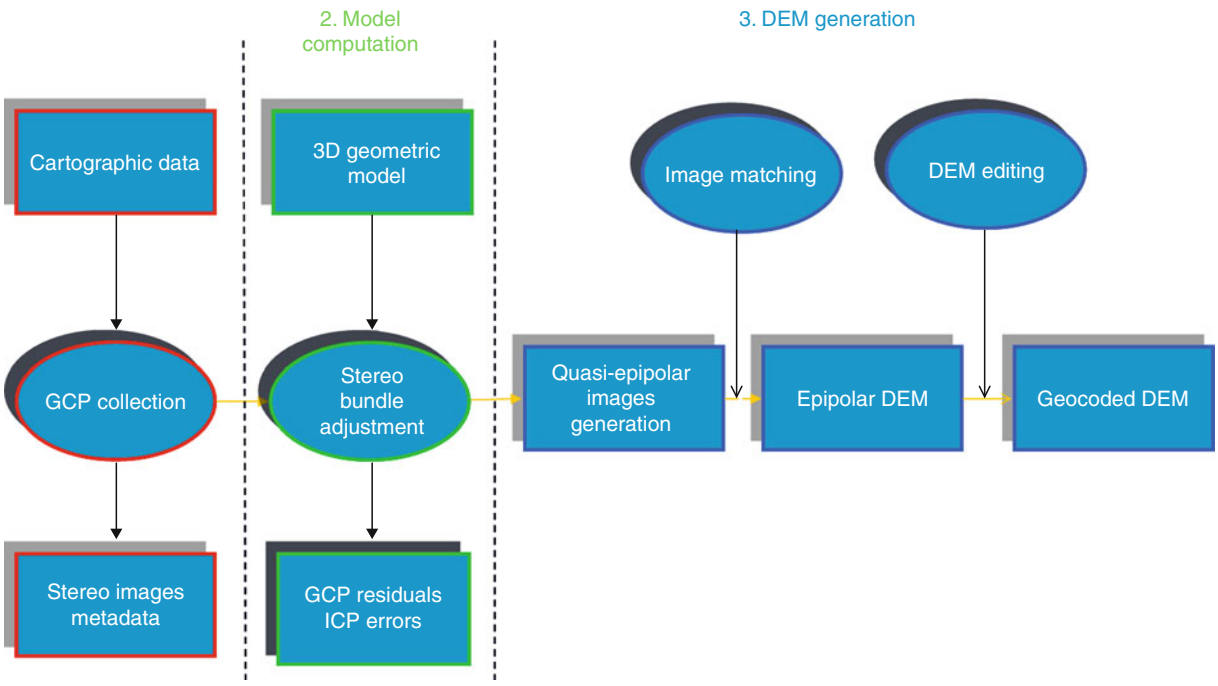
1. Data acquisition and pre-processing: the rawest available stereo images and their metadata and stereo GCPs
2. 3D geometric model computation: least-squares bundle adjustment using the stereo GCPs
3. DEM generation: image matching and editing in the quasi-epipolar geometry and cartographic reprojection with regular grid spacing

The image matching applied on the quasi-epipolar images can be based on single primitive approach (gray level, feature-based, etc.) or hybrid approach by combining multi-primitive geometrically constrained least-square matching, both using pyramid multi-scale algorithm. DEM editing includes blunder removal, mismatched filling by interpolation or with seed points, filtering and smoothing, as well as correction of land cover heights. The final step is to resample the epipolar DEM into the user map projection with regular grid spacing.

Analog (Finsterwalder, 1954), analytical (Reinhardt and Rentsch, 1986) and digital (Baltsavias et al., 2001) photogrammetry has demonstrated the relevance and benefit of air photos for topographic mapping of glaciers. The photo archives to compare multi-date photogrammetric DEMs of glaciated regions can also be exploited (Hopkinson, 1997; Bindschadler and Vornberger, 1998). Besides all these advantages (archives, stable geometry, resolution, level of details, customer control), airborne photogrammetry is mainly used for small-to-medium size mountains glaciers. However, the difficulty to collect GCPs and the image matching in snow fields are two key issues, which can lead to large DEM errors exceeding any measured changes in glacier volume. These DEMs are mainly limited to altitudes below the equilibrium line where crevasses and other features provide enough contrast (Howat et al., 2008).

For large remote regions with difficult ground accessibility satellite data are recommended. To obtain stereoscopy with images from VIR satellite scanners, two solutions are possible:

1. The along-track same-date stereoscopy from the same orbit (ASTER, SPOT5 HRS)
2. The across-track multi-date stereoscopy from two different orbits (SPOT HRV/HRG)



Digital Elevation Model Generation Over Glacierized Region, Figure 3 Processing flow for DEM generation by stereoscopy.

The almost-simultaneous along-track stereo-data acquisition gives a strong advantage in terms of radiometric variations versus the multi-date stereo-data acquisition with across-track stereo (Toutin, 2001): mainly in the image matching success due to less temporal radiometric difference. In addition, glacier flow (up to a few meters per day) during this few-day interval can bias the topographic measurement (Berthier and Toutin, 2008).

The advantages of using satellite data are:

- Images cover large regions: 60 by 60 km for SPOT HRV/HRG and ASTER, but 120 by 600 km for SPOT-5 HRS.
- Strips formed with consecutives images from the same-date orbital path and block of several strips can be simultaneously processed over large regions.
- Less processing is required with one satellite image than with a block of aerial photos.
- Less GCPs with a relaxed accuracy related to sensor resolution (10 m for ASTER and 2–5 m for SPOT) are required.

Some disadvantages specific to ice regions are related to the lower resolution of satellite sensors (Berthier and Toutin, 2008): sufficient variation of albedo over few pixels for a better image matching; frequent cloud cover over mountainous and polar regions; surface features greater than the sensor resolution; and elevation changes greater than the stereo capability. Numerous researches generating DEM over mountain glaciers have been reported within GLIMS projects (Kääb et al., 2005), and the fourth International Polar Year (IPY) projects (Berthier and Toutin, 2008; Korona et al., 2009) over the glaciers of the Antarctic and Greenland ice sheets (Howat et al., 2008). Elevation errors equivalent to the resolution, e.g., 15 m for ASTER and 5–10 m for SPOT (Kääb et al., 2005; Berthier et al., 2004) were generally reported when comparing with limited or not-always-accurate ground truth (old photogrammetric DEM, SRTM, bedrocks profiles, ICESat data, independent check points, etc.). An almost linear correlation between accuracy and terrain-slopes was also found (Berthier et al., 2004; Korona et al., 2009).

US Geological Surveys and the Earth Remote Sensing Data Acquisition Centre in Japan have agreed to produce high-quality global DEM (GDEM) from the ASTER data acquired within 83° latitudinal limit. It thus covers all the land on Earth and the majority of glaciated regions. These data are freely available to all users whatever the area size and location. Because the ASTER GDEM (30 m grid spacing; 7-m accuracy 1σ) is developed based on a grid of 1° × 1° in latitude and longitude, no scene selection or mosaicking is required (http://www.ersdac.or.jp/GDEM/E/1.html).

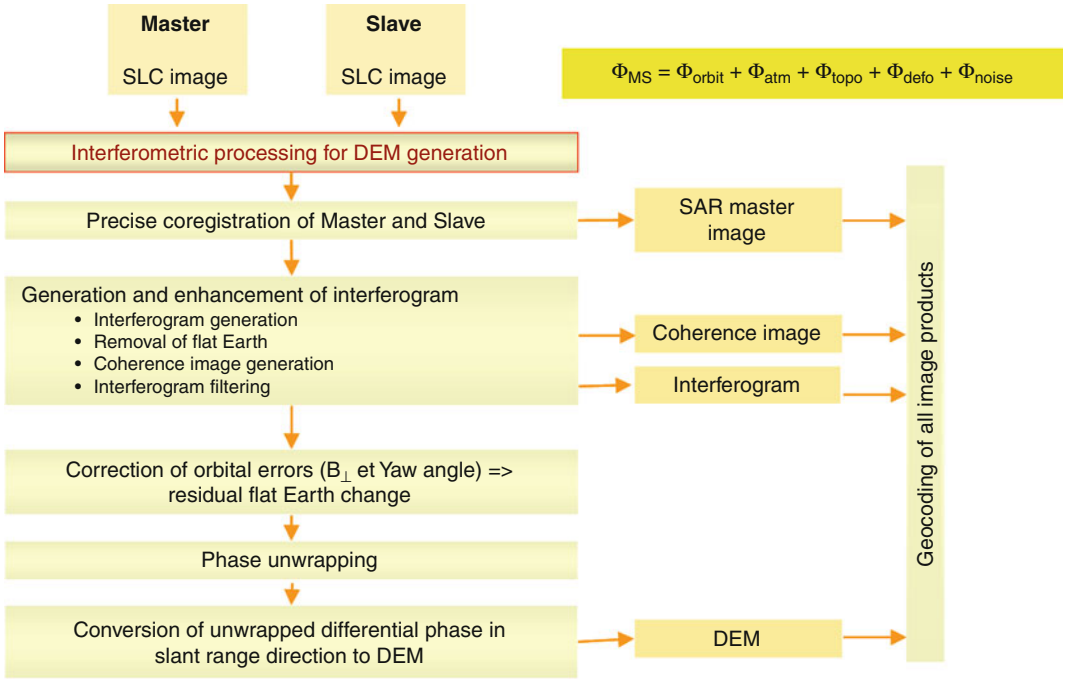
Interferometry

Radar interferometry, using the coherent property of modern SAR, is a better alternative to the conventional stereoscopic method. Imaging interferometric SAR (InSAR) combines complex images recorded either by two antennas at different locations (across-track) or with the same antenna at two different times (repeat-pass). Both systems can be applied with air- and spaceborne SAR. Analysis of the differential phase between the SAR images can lead to information on terrain elevation or, with observations with the same antenna at different times, to terrain displacements. The InSAR processing for DEM generation is summarized (Figure 4), but more information can be found in (Rosen et al., 2000).

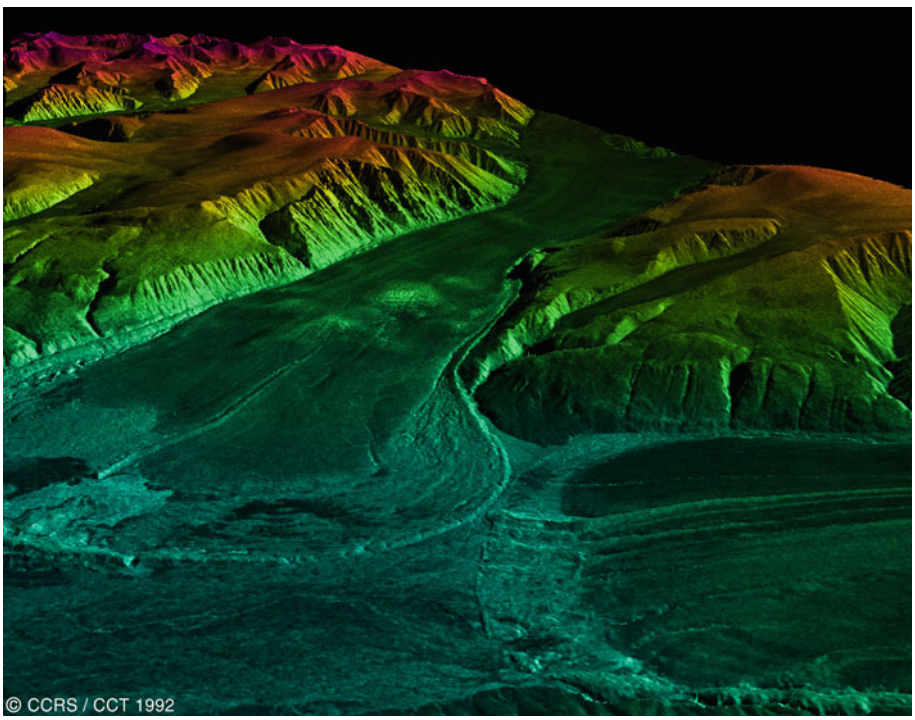
There are numerous public/private airborne InSAR systems around the world (Canada, USA, Denmark, France, Germany, China, etc.) using generally across-track and along-track interferometry from multiple SAR wavelength bands and polarizations. Depending of the wavelengths and the volumetric content of water in the snow, the SAR penetration can largely vary from the full depth of glaciers (P-band) to few centimeters (X-band over wet snow). Consequently, airborne SAR interferometry can provide either elevation of the bed rock or the top of glaciers (Figure 5). For most of the experiments, few-meter accuracy (1–3 m, 1σ) is achieved in horizontal and vertical directions, but can be dependent of the altitude and local incidence angle (Muskett et al., 2003) and of the SAR backscatter and penetration depth (Magnússon et al., 2005). It is also recommended to apply a multi-look process for reducing SAR noise (phase and speckle) and post-process the DEM for filtering/smoothing and removing noisy regions.

To date, only one across-track single-pass interferometric satellite mission, SRTM, derived DEMs, but only between 56° South and 60° North. It was thus used in mountain glaciers and ice caps (Kääb et al., 2005). The general vertical accuracy is around 16 m (better in some regions) with bias (10 m) at high altitudes, maybe due to SAR problems in mountains (Berthier et al., 2006). The fusion of SRTM DEM with air-photo DEMs could thus be a valid combination for mountain glaciers.

A recent interferometric satellite launched in 2010, TanDEM-X (TerraSAR-X add-on for Digital Elevation Measurement), is the name of TerraSAR-X's twin satellite, a German Earth observation satellite using X-band SAR. It is a second, almost identical spacecraft to TerraSAR-X launched in 2007. TanDEM-X is also the name of the satellite mission flying the two satellites in a closely controlled formation with typical distances between 250 and 500 m. The primary mission objective is to use almost-simultaneous across-track interferometry for the generation of a consistent global DEM with an unprecedented accuracy according to better than Digital Terrain Elevation Data (DTED) Level 2 specifications. The new DEM resolution will roughly correspond to DTED Level 3 (post spacing of better than 12 m) and a height accuracy of better than 2 m. However, the accuracy will degrade to tens of meters in mountainous regions. On July 2010, researchers at the German Aerospace Center facility in Oberpfaffenhofen published the first 3D images from the TanDEM-X satellite mission



Digital Elevation Model Generation Over Glacierized Region, Figure 4 Interferometric SAR processing for DEM generation.



Digital Elevation Model Generation Over Glacierized Region, Figure 5 This north-looking perspective of a section of the Bylot Island, Canada, using CCRS Convair580 InSAR DEM shows peaks and plateau ice caps of the Byam Martin Mountains. An unnamed glacier flows southward, and its terminal lobe almost meets the terminus of a westward flowing glacier, on their common outwash plain. Many geological features are clearly visible: crevasses (**a**), super glacial streams (**b**), lateral and terminal moraines. The raised medial moraines, and ablation moraines (**c**), and a dammed lake (**d**) are evidence of glacial retreat (Gray et al., 1995). http://www.ccrs.nrcan.gc.ca/radar/airborne/cxsar/sbinter_e.php.

(http://www.spacedaily.com/reports/TanDEM_X_Delivers_First_3D_Images_999.html). A group of icy Russian islands of the Severnaya Zemlya group in the Arctic Ocean was selected for the first test: the October Revolution island showed in 3D an ice cap with a diameter of 30–40 km and 700 m high, which is located on a landscape of snow and ice and where the drainage channels run from the ice cap. In 2014, this homogenous DEM will be available for the Earth's entire land surface, i.e., 150 Mio square kilometers. Without doubt, it will be of interest for all glaciological applications.

On the other hand, repeat-pass interferometry can be applied with ERS-1/-2, Radarsat-1/2 and TerraSAR-X at higher latitudinal coverage (80°) for covering ice sheets, but with limitations due to temporal decorrelation of the signal (mainly over moving glaciers) and the separation of topographic and displacement phases. However, the ERS tandem mission (1 day) gives a better temporal resolution than repeat-pass ERS-1 (3 days) and Radarsat (24 days). To name few examples: ERS-1 SAR data from one or more tracks were used over various outlet glaciers in Greenland to generate wide-area homogeneous DEM with 3–5 m accuracy (Joughin et al., 1996).

Altimetry

Lidar

The airborne lidar processing includes: (1) the determination of the absolute position of the laser scan system during the flight by analysis of the time-synchronized GPS and INS data, (2) the computation of the relative coordinates, (3) the system calibration with external data, (4) the calculation of the coordinates in a ground reference system, and (5) the post-processing of the DEM (Arnold et al., 2006). The uncertainties in the laser range (around 7 cm) and the GPS position (around 10 cm) are the main factors in the final elevation accuracy (Kennett and Eiken, 1997). In addition, the effect of calibration drift over time can generate 7-cm elevation drift for 1-h flight (Davenport et al., 2004). An airborne Lidar sensor with a good calibration can achieve 10–20 cm accuracy in the three axes (Davenport et al., 2004), but dependent of terrain slopes (Hodgson and Bresnahan, 2004). In addition to laser scanning, the Lidar DEM can be used to ortho-rectify the intensity image of the laser pulse return from the ground surface and to generate other 3D added-value products. The first experiments for 3D glaciological applications were performed with laser profiling (a single measurement line below the aircraft) in Iceland/ Greenland (Garvin and Williams, 1993) and Alaska (Echelmeyer et al., 1996) and then with laser scanning over Greenland (Krabill et al., 1995; Bindschadler et al., 1999), alpine glaciers (Kennett and Eiken, 1997), and small inland glaciers (Baltsavias et al., 2001; Arnold et al., 2006). They also have been used for calibration/validation over Greenland (Bindschadler et al., 1999; Bamber et al., 2001).

While the primary goal of ICESat is to measure elevation and its change of the vast polar ice sheets, it also collects data over large temperate glaciers (Patagonia, Alaska). Even if these glaciers display rougher surfaces and steeper zones, individual footprint rather than averaging over large regions or relying on crossovers can be used to estimate glacier elevation. A partial DEM over Antarctica (north of 86°S, 500-m spacing) was produced using only ICESat data (DiMarzio et al., 2008) or combined with slope-weighted data of scanning radar altimeter (SRA) for expanding Antarctica's DEM (Bamber et al., 2005). However, most of the experiments used ICESat data for calibration/validation of DEMs over Antarctica (Bamber and Gomez-Dans, 2005), ice sheets and caps (Korona et al., 2009) or glaciers (Berthier and Toutin, 2008).

SAR

To calculate precise ice surface elevations, the altimeter range measurements need to be referenced to a common datum and corrected for tracker misalignment of the waveform due to the undulating and nonuniform nature of ice surface. The corrected altimeter range measurement is then subtracted from a precision orbit to calculate a corrected surface height. The slope correction post-processing corrects for the largest errors (10–150 m). Then, the waveform retracking post-processing is required over ice sheets because the leading edge of the ice-sheet return waveform deviates from the onboard altimeter tracking gate, causing an error (±15 m) in the telemetry-range measurement. Finally, the atmospheric delay post-processing includes correction for dry and wet tropospheric refractions (1.5–2.5 m) and ionospheric refraction (0.02–0.10 m).

Before the 1990s, the topography of ice sheets was only known with few measurements and errors of hundreds of meters. Afterward, SRAs, in particular from ERS, have been one of the major sources for the generation of DEMs (5-km grid spacing) over Greenland (Bindschadler et al., 1989; Bamber et al., 2001) and Antarctica (Bamber et al., 2005). Elevation measurements can be adjusted at orbit crossover, mainly at the high latitudes. Over the latitudinal limit of the satellite (around 81.5°S), terrestrial measurements have been used to complete the Antarctic DEM (Bamber and Rivera, 2007) or to provide a better spatial sampling in low relief (Liu et al., 1999). More recently, the combination of slope-weighted ERS-SRA data with a good spatial coverage but a poor vertical accuracy, and the Lidar ICESat data with a poor spatial coverage but a good vertical accuracy maximized the grid spacing and the vertical accuracy of the final Antarctic DEM (http://nsidc.org/data/nsidc-0422.html). The spatial grid spacing of this ERS1-2 + ICESat DEM was then improved over West Antarctica using MODIS imagery with shapelets and krigging methods (Haran et al., 2008). The data and method cumulation was also applied to Greenland and Antarctica DEMs generated from ERS-SRA data with airborne laser, AVHRR or MODIS data using clinometry (Scambos and Haran, 2002).

Summary

Most geoscientific applications using georeferenced cartographic data need a good knowledge and visualization of the topography of the Earth's surface: three-dimensional (3D) information, such as digital elevation models (DEM), has to be generated or is to be added for a better interpretation of the two-dimensional (2D) data.

Since the early emergence of earth observation satellites, researchers have investigated different methods of extracting 3D information using satellite data. Apart from a few early stereo-images acquired with handheld cameras during the Gemini and Apollo missions, the first experiments to extract 3D data using stereo viewing from space began with the Earth Terrain Camera (ETC) flown onboard SkyLab in 1973–1974.

Since these early experiments, various analog or digital sensors in the visible or in the microwave spectrum have been flown to provide researchers and geoscientists with spatial data for extracting and interpreting 3D information of the earth's surface. Although the shape-from-shading technique can be applied to optical sensor images in ice sheets and caps with low slopes, stereo-viewing using airborne cameras or digital scanner images was, and still is the most common method used by the mapping, photogrammetry, and remote sensing communities. However, airborne and spaceborne altimeters, such as lidar become more and more popular.

On the part of the spectrum, radar data gives also the opportunity to extract 3D information using image-processing techniques appropriate to the nature of the data. With SAR data, three main methods have been developed: radargrammetry, interferometry, and altimetry. Radargrammetry is roughly similar to photogrammetry with stereo images acquisition from different viewpoints. Interferometry uses mainly the SAR signal data instead of the image, and altimetry becomes important sources of data in the 1990s with the scanning radar altimeter to generate small-scale DEMs.

The chapter reviews the different methods and sensors used to extract absolute or relative elevation and assess their performance applied to glaciated regions using the results from various research and university organizations. It also discusses the respective advantages, difficulties, and constraints of the sensors, the methods, and the technologies to take into account the strength of each when integrating them (input, algorithms, and outputs).

Concluding remarks

Elevation modelling from satellite data has been a vibrant R&D topic for the last 30 years since the launch of the first civilian remote sensing satellite. Different data (space photographs, VIR scanner, SAR, altimeter) in different formats (analog, digital) can be processed by different methods (clinometry, stereoscopy, interferometry, altimetry) taking advantage of the different sensor and image characteristics (geometric, radiometric, phase) using different types of technology (analog, analytical, digital) and processing (interactive, automatic).

Most of the techniques have been proposed and tested in the early years. Shape from shading provides cues all over the studied surface, but can be applied successfully only on homogeneous surfaces, and the method thus remains well adapted to glaciated regions, despite some of its disadvantages.

On the other hand, stereoscopy is generally the preferred method by the mapping, photogrammetry and remote sensing communities, most likely due to the heritage of the well-developed stereo photogrammetry. With the launch of Radarsat-1 in 1995, there is renewed interest in radargrammetry because researchers could take advantages of the R&D in image matching realized for SPOT at the end of the 1980s, and in the new computer technologies. Therefore, the DEM generation has become more automated, but not completely with occasional unmatched expectations, mainly in difficult terrain conditions, such as the glaciated regions, especially in mountain glaciers.

When ERS-1 was launched, scientists became enthusiastic over interferometric techniques using previously developed parametric modelling. Most research efforts have then focused in the first years on image processing (coherence image, phase unwrapping) and afterward on the newly identified physical artifacts (atmospheric conditions, sensor calibration, etc.). All these issues are of importance when generating DEMs in northern glaciated regions.

Finally, altimetry first remained more at the level of scientific interest in the physical parametric modelling and in data or image processing development in the academic and governmental institutions. They are now largely used over ice sheets or caps and alpine and small inland glaciers. They also are well used for calibration/validation of DEMs produced with other methods.

Since any sensor, system, or method has its own advantages and disadvantages, solutions already exploit the complementarity between the different sensors, methods, and processing. It has already been optimized in stereoscopy combining VIR and SAR data where the radiometric content of the VIR image is combined with the SAR's high sensitivity to the terrain relief and its "all-weather" capability. The complementarity of methods has already been applied with SAR combining altimetry and clinometry or to generate an approximate DEM to help the phase unwrapping in interferometry. In the same way, Lidar and SRA were combined to take advantages of their good vertical accuracy and good spatial coverage, respectively.

It seems obvious that the R&D for glaciated regions will then focus on the use of the new high-resolution satellites (VIR and SAR) and the development of their associated technologies. Already large data sets acquired from these types of new satellites (Ikonos, WorldView, KOMPSAT, etc.) have demonstrated their real potential for DEM generation and could potentially be used as primary DEM source or complementary sources for

improving the existing DEMs in glaciated regions, such as it has been shown with the first DEM over ice-cap islands generated from the high-resolution interferometric TanDEM-X mission in July 2010.

Definition

Digital image information extraction. A set of image-processing techniques applied to the satellite images in digital form for the enhancement and extraction of the required information.
Snow-cover mapping from remote sensing data. Mapping of the snow-covered areas in the satellite image by application of the specialized digital image information extraction techniques.

Introduction

Snow is one of the most sensitive and vital natural resources. Over the years, gradual technological progress in mapping of snow-covered areas using remote sensing data has been influenced by several interrelated factors. These include advancements in the satellite sensor and image-processing technologies, and increasing demand for accurate and frequent monitoring of snow-covered areas due to mounting pressures from rapid industrialization, urbanization, and changing climate. Thus, regular and precise mapping of snow-covered regions is important at various scales due to several reasons such as:

1. On global and continental scales, snow due to its highly reflective nature and large surface coverage (snow can cover up to 40% of the Earth's land surface during the Northern Hemisphere winter) has great impact on climate variations, surface radiation balance, and energy exchange (Wang and Li, 2003).
2. On a regional scale, snow cover estimates constitute the primary input parameter for hydrological modeling

(Rango and Martinec, 1981; Shiyin et al., 2003; Fukushima et al., 1991).
3. On a local scale, accurate estimates of snow cover areas form key inputs to the mass balance studies, volumetric estimates, meltwater runoff modeling and snow hazard prediction modeling (Haeberli et al., 1998 and 2001; Berthier et al., 2007; Oerlemans et al., 2007; Quincey et al., 2005; Khromova et al., 2006; IPCC, 2007; Kulkarni et al., 2007).

Remote sensing data acquired in relevant parts of the electromagnetic spectrum have been widely employed for mapping of snow-covered area throughout the world (Konig et al., 2001; Hall et al., 2005; Bamber, 2006). Present status of snow-cover mapping can broadly be described based on:

1. The scale of mapping (small, medium, or large) both at pixel and sub-pixel levels
2. The region of electromagnetic spectrum utilized, namely, ultraviolet, visible, infrared, or microwave (active or passive)
3. The type of sensor used (Landsat TM and ETM+, SPOT VGT, NOAA AVHRR, IRS LISS-III, IV, Terra MODIS and ASTER, etc.)
4. The image information extraction techniques employed on remote sensing data

The aim of this chapter is to review the status of snow-cover mapping based on image information techniques. First, the conventional techniques of snow-cover mapping have been reviewed and their limitations highlighted, which are followed by a discussion on the importance of remote sensing in mapping of snow cover. A number of digital image information techniques employed for mapping of snow-covered areas, till date, have been conversed.

Conventional approaches of snow-cover mapping

Traditionally, snow cover has been mapped using ground (Potts, 1944; Miller, 1953) and aerial photographic surveys. Ground surveys may not be as complete as aerial surveys because of the field of vision and other obstructions, such as hills. Aerial photographic surveys provide more comprehensive information of the snow cover as compared to the ground surveys. It, however, also has some limitations such as time required to process a large number of photographs covering a big basin, high costs of operation of the aircraft, and difficulty in interpretation of snow cover in the forested areas (Singh and Singh, 2001). Further, reliability of the snow cover estimates from extrapolation of the snow cover information from meteorological stations depends heavily on the density of the weather stations, which is often quite insufficient. The temperature lapse-rate method for snow cover area approximation ignores the snow cover area lying outside the glacier and assumes snow, glacial ice, and debris-covered glacial ice as one homogeneous body.

Remote sensing for snow-cover mapping

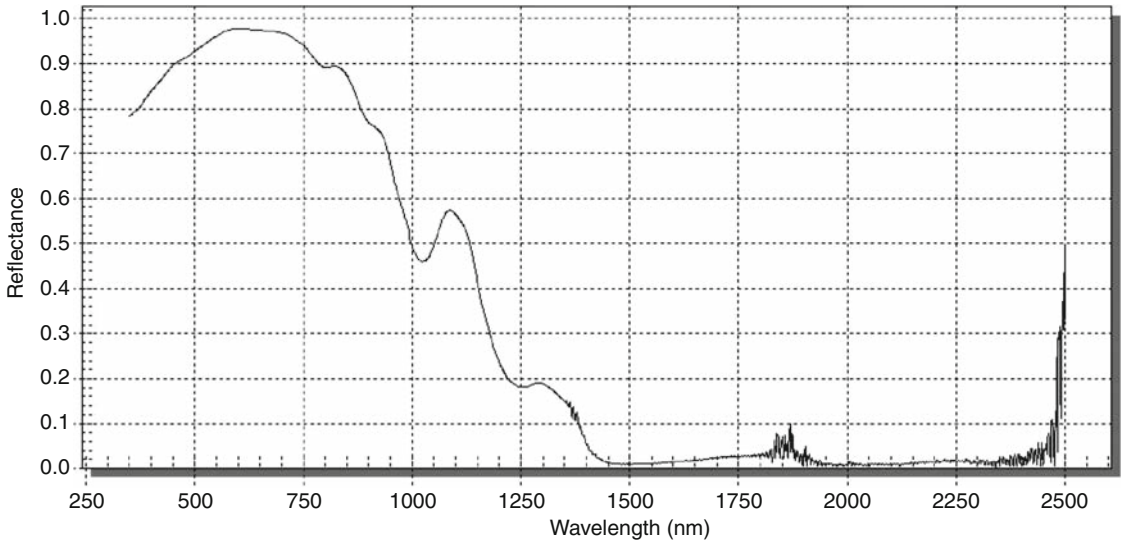
In view of the vastness, inaccessible nature and harsh climatic conditions of the snow-covered areas, remote sensing is perhaps the most effective tool for comprehensive and repetitive study of these areas in a cost-effective manner. The remote sensing data can be obtained at a range of spectral, spatial, and temporal resolutions, which make them suitable for snow-cover mapping and monitoring. In fact, the high albedo of snow presents a high contrast with most other land cover types (except clouds) and for this reason maps of snow-covered area were one of the first products of satellite remote sensing (Tarble, 1963).

Understanding of spectral characteristics of snow forms an important prerequisite in its mapping from the satellite remote sensing data. Significant studies on the reflective properties of snow have been done by Wiscombe and Warren (1980), Warren and Wiscombe (1980), Warren (1982), and Zeng et al. (1984). Discussion of factors influencing snow reflectance have been given by Foster et al. (1987), Winther and Hall (1999), and Winther et al. (1999). As shown in Figure 1, snow reflectance is very high in the visible and much lower in the infrared region of the electromagnetic spectrum. Reflectance of snow is influenced by various factors such as grain size, contamination, solar zenith angle, cloud cover, metamorphism and age factor, and liquid water content.

In visible wavelengths (400–700 nm), snow reflectance is quite sensitive to minor amounts of contamination like carbon soot, volcanic ash, continental dust, etc. In the near- and middle-infrared region (700–3,000 nm), snow reflectance is sensitive to the grain size. The metamorphism of the snow cover, in general, results in a decrease of reflectance. Liquid water content in the snowpack has the effect of increasing the effective grain size and thus lowering the snow albedo (Konig et al., 2001).

Reflectance of snow is anisotropic and dependent on incidence and view angle. This dependence is described by the bidirectional reflectance distribution function (BRDF) (Knap and Reijmer, 1998). However, most satellite-derived albedo studies have generally not taken into account the anisotropic reflectance behavior of snow. The effect of anisotropic reflection increases as snow metamorphoses, for example, with increasing grain size and surface melt-freeze processes that sometimes produce a highly specular surface ("firnspiegel") (Konig et al., 2001).

Recently, there have been several commendable attempts to employ satellite remote sensing for mapping and monitoring of some major characteristics (such as area, depth, volume, and albedo) of snow as these constitute vital input parameters for hydrological, climatological, and hazard prediction models. Though, remote sensing greatly facilitates the mapping and monitoring of snow cover. However, mapping snow cover from remotely sensed data may also be fraught with a number of snags, which may be data and technology dependent. The main problem with data from visible and near-infrared sensors is their weather dependency (e.g., influence of the



Digital Image Information Extraction Techniques for Snow Cover Mapping from Remote Sensing Data, Figure 1 Ground-based spectral reflectance curve of snow.

atmosphere on these data, especially the existence of cloud cover). A number of approaches have been suggested to get over the problem of cloud cover. Utilization of active and passive microwave data may overcome this problem. However, passive microwave data underestimates snow cover, perhaps due to their inability to map snow cover under forest and to distinguish wet snow from surrounding terrain. Basin-wide or large-scale snow and ice mapping has also been attempted using active microwave data obtained through Synthetic Aperture Radar (SAR) sensors since these sensors can discriminate between snow and bare ground at a spatial resolution that is compatible with topographic variation in mountainous basins. However, SAR data suffers from several limitations such as difficulties in interpretation of the recorded backscatter (Konig et al., 2001), complex image-processing requirements, and problems in distinguishing between wet snow and other smooth surfaces (Shi and Dozier, 1997). Data from different regions of the electromagnetic spectrum have also been used in combination for snow-cover mapping (Tait et al., 1999; Solberg et al., 2005; Liang et al., 2008).

Mountain shadows are also impediment to the determination of the snow line or the extent of snow-covered areas of a basin, especially in steep mountain terrains. A way out may be to combine the visible data with terrain features to minimize the effect of shadow. Alternatively, a number of ratio images and spectral indices may also be devised to map the snow cover extent (Dozier, 1989; Hall et al., 1995b).

Another problem faced in mapping of snow cover is the forest cover. A major part of the snow falling over forested areas reaches the ground after filtering through the forest canopy. Depending on the forest density, a part of fresh snowfall may stay atop the forest canopy. A dense forest cover may obscure underlying snow. Therefore, much attention is being paid to effectively determine snow-covered areas in forested regions (Klein et al., 1998; Vikhamar and Solberg, 2002, 2003; Shimamura et al., 2006). These include, using some vegetation indices such as the Normalized Difference Vegetation Index (NDVI) (Klein et al., 1998), formulating special indices for mapping snow cover under forests by using the near-infrared band (Shimamura et al., 2006) and by utilizing spectral signatures of snow cover under forests separately (Vikhamar and Solberg, 2002, 2003).

It is thus clear that mapping snow cover from remote sensing data is an intricate task and requires effective digital image information extraction techniques to extract these from a variety of aircraft- and satellite-based data acquired at varied spectral, spatial, and temporal resolutions. The use of ancillary data in this process may also not be undermined.

Digital image information extraction techniques for snow-cover mapping

A number of image information extraction techniques have been developed in view of the increasing demands for improved areal estimates of snow cover for varied applications. These techniques, as discussed in the next section, may be categorized as:

1. Manual delineation
2. Change detection–based method
3. Spectral ratios
4. Spectral indices
5. Per pixel image classification
6. Sub-pixel image classification

In order to demonstrate the implementation of these techniques and their comparison, results from a case study in mapping snow cover in a test glacier located in the Chenab basin, Western Himalaya, India, have also been presented.

Manual delineation

Manual delineation involves on-screen digitization of the satellite images based on the visual interpretation of snow-covered areas using a set of interpretation elements namely tone, texture, shape, size, association, pattern, and shadow applied individually or in combination. It has been widely used for mapping of glacial ice and snow extents, and in particular, for the estimation of retreat and deglaciation in various parts of the world (Hall et al., 1995a; Williams et al., 1997; Williams and Hall, 1993; Khromova et al., 2006; Kulkarni et al., 2007). Though being effective, the manual delineation is a very tedious and time-consuming task and may not be appropriate for mapping at operational level. Moreover, since the technique involves high degree of subjectiveness, therefore results from different sources may seldom match due to varying degrees of accuracy and bias involved.

Change detection–based method

In the change detection–based method, a snow-free satellite image is used as a reference image and is digitally compared, pixel by pixel, to record snow and non-snow-covered pixels. The brightness of the images may have to be adjusted to account for the daily and seasonal solar illumination angle differences. This method was developed initially by the U.S National Weather Station (NWS) for operational snow-cover mapping with AVHRR and Geostationary Environmental Satellite (GOES) sensors (Allen and Mosher, 1985; Holroyd et al., 1989). The method was found suitable for identification of snow in coniferous forested areas (Baumgartner and Rango, 1991). A variant of this change detection method was developed by Lillesand et al. (1982), which accounted for the inherent variations within cover types, for between-date variations within similar cover types, and for differing site characteristics (Baumgartner and Rango, 1991).

Spectral ratios

Formation of spectral ratios involves pixel-by-pixel division of the two bands of an image, which are selected in such a way that these maximize the spectral contrast between snow cover and other classes. The ratio image is then segmented using appropriate threshold values for mapping the snow cover. Band ratioing has been found to be a useful method for enhancing snow cover features in the multispectral images (e.g., Hall et al., 1987, 1988; Jacobs et al., 1997; Paul et al., 2004; Boresjö Bronge and Bronge, 1999; Williams et al., 1991). It has also been used to reduce the variable effects of solar illumination and topography besides enhancing the spectral information in the images (Justice et al., 1981; Gupta, 2003). The bands used to create ratios for mapping of snow-covered areas rely on its fundamental spectral characteristics, that is, high reflectance in visible region and strong absorption in the infrared region of the electromagnetic spectrum. Some typical spectral ratios for snow-cover mapping as cited in the literature have been compiled in Table 1.

Hall et al. (1987) used the ratio of TM4 (NIR) and TM5 (SWIR) bands to characterize snow and ice zones on glaciers using their spectral properties. Ratio values of raw Digital Numbers (DNs) (i.e., spectral response of pixels) were thresholded to generate a glacier mask by Hall et al. (1988). Rott and Markl (1989) found that spectral ratio TM3/TM5 revealed better results in shadowed areas than those obtained from TM4/TM5, whereas the latter showed better performance in mapping glacier areas facing the sun.

Jacobs et al. (1997) used atmospherically corrected spectral reflectance images obtained from TM4/TM5 and TM3/TM5, respectively, to obtain glacier mask after thresholding. Williams et al. (1991) found the TM4/TM5 ratio to be useful for discriminating glacier facies for temperate glaciers. Boresjö Bronge and Bronge (1999) found that the TM3/TM4 ratio resulted in the most accurate discrimination between blue ice and other snow types. Further, this ratio was also insensitive to the influence of thin clouds and cloud shadows. Paul (2000), while comparing various methods for glacier mapping using Landsat TM data, found that segmentation of a ratio image (TM4/TM5) with raw DNs yielded accurate glacial mapping.

Digital Image Information Extraction Techniques for Snow Cover Mapping from Remote Sensing Data, Table 1 Basic formulations of spectral ratios for snow-cover mapping

S.No.	Popular name	Formulation	Used by
1	$TM4/TM5$	$\frac{\text{NearInfrared(NIR)}}{\text{ShortwaveInfrared(SWIR)}}$	Hall et al. (1987, 1988); Rott and Markl (1989); Jacobs et al. (1997); Williams et al. (1991); Bronge and Bronge (1999); Paul (2000, 2003); Paul et al., (2002, 2004).
2	$TM3/TM5$	$\frac{\text{Red}}{\text{ShortwaveInfrared(SWIR)}}$	Rott and Markl (1989); Jacobs et al. (1997); Bronge and Bronge (1999).
3	$TM3/TM4$	$\frac{\text{Red}}{\text{NearInfrared(NIR)}}$	Bronge and Bronge (1999).

For demonstrating the snow mapping capabilities of spectral ratios, the most widely used NIR/SWIR ratio was selected in the study conducted in Chenab basin (Figure 2) and was applied to an IRS P6 AWiFS (Advanced Wide Field Sensor) image of the test glacier. The histogram of NIR/SWIR ratio image (Figure 2c) was studied for the determination of an appropriate threshold value. Snow-ice binary glacier terrain maps were generated using arbitrary thresholds of 1.5 and 2.0 (commonly used threshold; Paul, 2003) (Figure 2d and 2e, respectively). It can be seen that the ratio is unable to segregate the snow and ice class and fail to map the mixed ice and debris (MID) and supraglacial debris (SGD) classes (encircled areas in Figure 2a, 2d and 2e) toward the glacier snout. Thus, although spectral ratioing constitutes a fast and robust method for mapping snow- and ice-covered areas, the subjectivity involved in the derivation of appropriate thresholds and its inability to precisely differentiate between snow and ice zones limit its use.

Spectral indices

Besides the ratios, several empirical spectral indices have also been devised (Dozier, 1989; Hall et al., 1995b; Xiao et al., 2001; Shimamura et al., 2006; Keshri et al., 2009) for segregation and mapping of the snow and ice classes. Some of these spectral indices, their utility, and cited reference have been compiled in Table 2. Spectral indices characterize the basic spectral differences in the classes to be separated as well as assist in diminishing the radiometric effects of differential solar illumination and topography.

Normalized Difference Snow Index (NDSI), as defined in Table 2, was formulated by Dozier (1989) and Hall et al. (1995b). The basis of index is the high reflectance of snow in the visible region and a very low reflectance in the SWIR region, thereby providing high values of NDSI for snow-covered areas (Hall et al., 1995b; Nolin and Liang, 2000).

The main advantages of using NDSI are:

1. Discrimination between snow and clouds
2. Removal of mountain shadows to some extent

Winther and Hall (1999) used NDSI for snow cover area estimation to provide input for hydrological models for snow runoff modeling. Wang and Li (2003) compared NDSI with other methods and found it to be a valid and rational method for extracting snow cover areas. Kulkarni et al. (2006) employed an NDSI-based algorithm for producing snow cover products (5- and 10-day products) using data from IRS-P6 AWiFS sensor in Himalayan region.

MODIS snow-cover mapping algorithm referred as SNOWMAP is also based on the NDSI with few additional thresholds. SNOWMAP is a computationally frugal algorithm and thus is simple to implement at global scale (Hall et al., 1995b; Riggs et al., 1994; Riggs et al., 1996; Hall et al., 1998; Klein et al., 1998).

On similar lines, Xiao et al. (2001) proposed the Normalized Difference Snow and Ice Index (NDSII-1) (Table 2) for mapping snow and ice cover utilizing VEGETATION (VGT) sensor of SPOT 4. For Landsat TM data, they found that NDSII-1 yielded almost similar results as compared to NDSI. Later, NDSII-1 has also been used by them for spatial and temporal analysis of snow and ice cover over Asia and pan-Arctic zone using multi-temporal VGT sensor data.

Gupta et al. (2005) utilized NDSI along with a DEM for mapping dry and wet snow using IRS LISS-III data. The results (the area covered by dry snow) of this method were validated and compared with the area of non-melting zone from the temperature lapse method. The two were found to be in close correspondence (i.e., differences were $<15\%$).

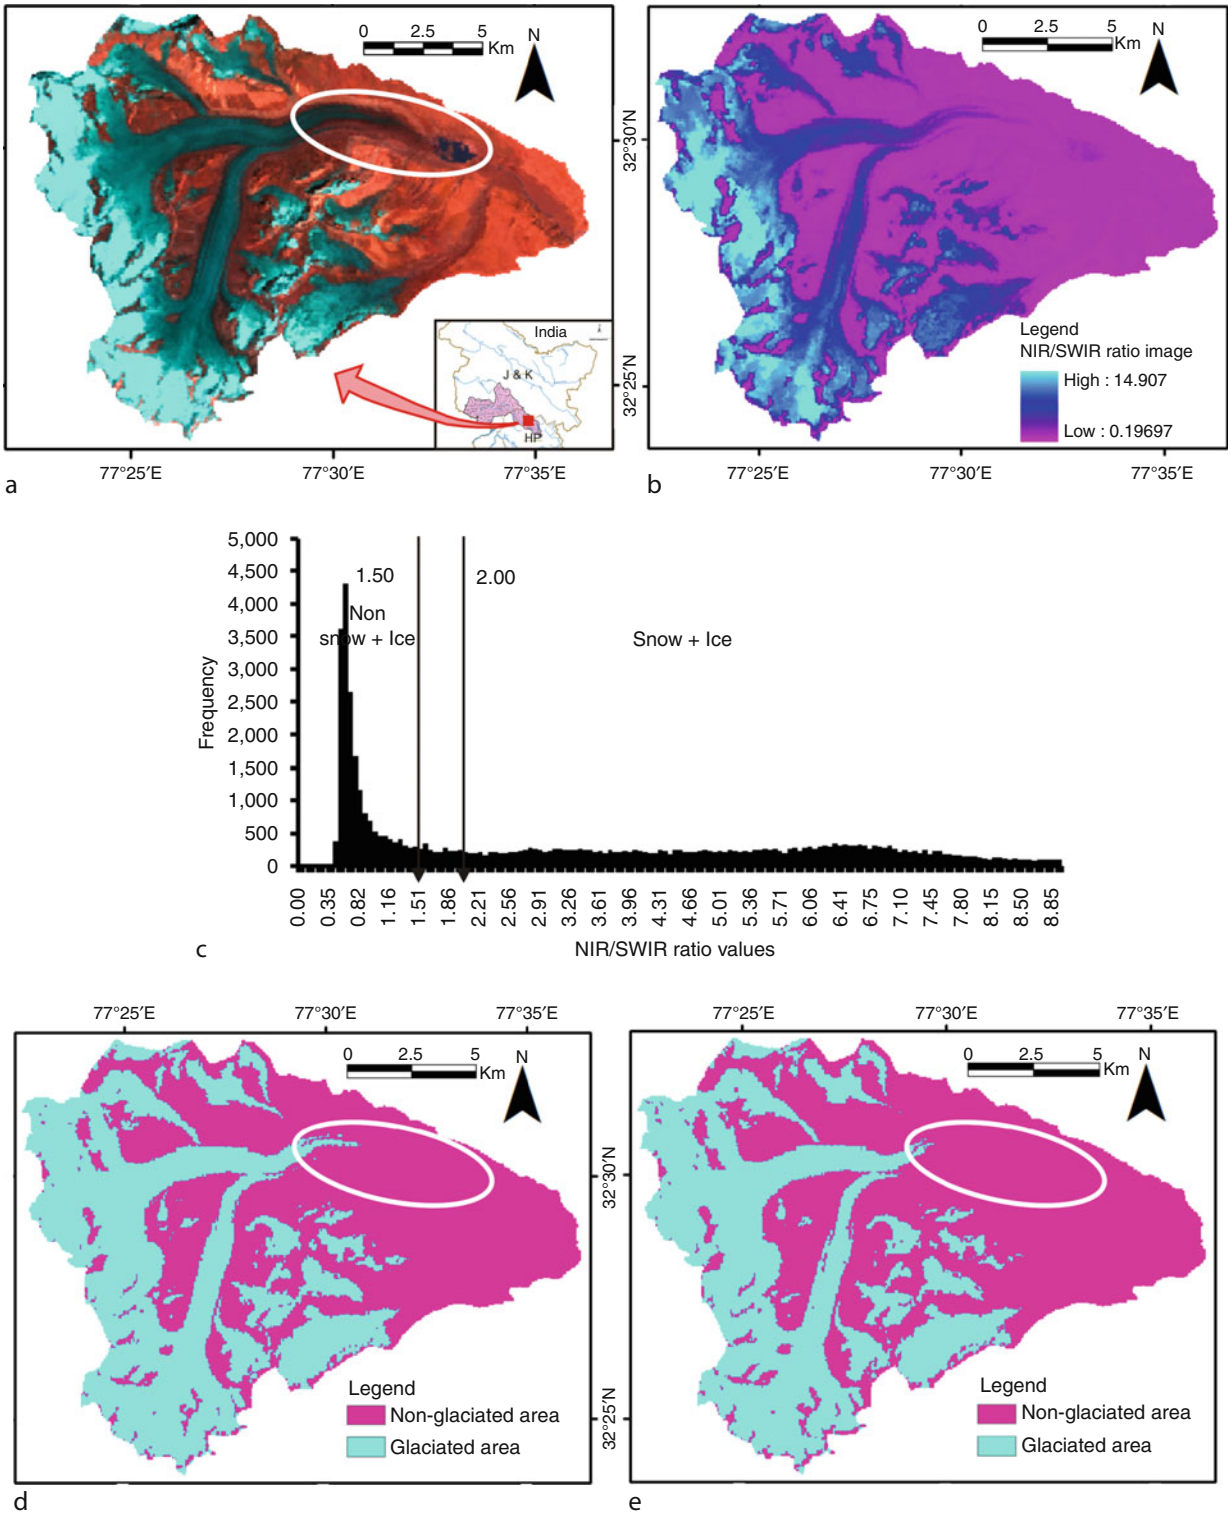
Shimamura et al. (2006) intercompared NDSI with another index S3 (initially proposed by Saito and Yamazaki (1999) for GLI sensor of ADEOS) using Landsat ETM + data and found that S3 index was advantageous for mapping snow cover under dense forests. They argued that similar to other studies while the S3 index (calculated using red, NIR, and SWIR bands) was able to map snow cover under forested areas without any reference data (e.g., NDVI image), the NDSI could not.

Keshri et al. (2009) have recently proposed two indices (Normalized Difference Glacier Index (NDGI) and Normalized Difference Snow and Ice Index (NDSII-2)) for detailed mapping of supraglacial terrain. The indices facilitate three-step discrimination. First, the snow and ice are separated from rest of the terrain using NDSI, then snow and ice from ice-mixed-debris class using NDGI, and finally snow from ice using NDSII-2.

For the case study in Chenab basin, an NDSI image was created using Green and SWIR bands of the IRS P6 – AWiFS image of the test glacier. Thereafter, its frequency distribution (Figure 3c) was analyzed and two binary glacier terrain maps (Figure 3d and 3e) were generated at 0.4 (commonly used thresholds, Dozier, 1989; Hall et al., 1995b) and 0.5 thresholds. It can be seen that on increasing the threshold value from 0.4 to 0.5 for reducing the misclassification of glacial lake water, the ice area near the snout also diminishes (Figures 3d and e). Thus, creation of empirical spectral indices, such as NDSI, may assist in quick segregation of snow and ice classes from the rest of the classes under various terrain conditions (e.g., shadow, highly rugged topography, and forest cover). However, selection of an appropriate threshold value is a crucial task, as even a slight variation in threshold values may lead to over- or underestimation of snow cover. Moreover, the thresholds may vary with different satellite sensors as well as seasons (Dozier, 1989, Hall et al., 1995b).

Digital image classification

Digital image classification is perhaps the major image-processing task for extracting useful information from remote sensing data. The aim is to produce thematic maps where each pixel in the image is assigned a class (e.g., snow) on the basis of its spectral response to produce a classification. The per-pixel (PP) classification is



Digital Image Information Extraction Techniques for Snow Cover Mapping from Remote Sensing Data, Figure 2 Snow-cover mapping using NIR/SWIR ratio. **(a)** An FCC (R = B5, G = B4, B = B3) of AWiFS image of a test glacier, **(b)** NIR/SWIR ratio image, **(c)** histogram of NIR/SWIR image, and **(d)** and **(e)** binary glacier terrain maps derived from NIR/SWIR ratio image at 1.5 and 2.0 threshold values.

Digital Image Information Extraction Techniques for Snow Cover Mapping from Remote Sensing Data, Table 2 Formulations and utility of various spectral indices

Name of the index	Cited reference	Formulation	Utility
Normalized Difference Snow Index (NDSI)	Dozier (1989), Hall et al. (1995b)	$\text{NDSI} = \frac{\text{Green} - \text{SWIR}}{\text{Green} + \text{SWIR}}$	For mapping and differentiation of snow-ice covered areas from non-snow and ice areas.
Normalized Difference Snow and Ice Index (NDSII-1)	Xiao et al. (2001)	$\text{NDSII} = \frac{\text{Red} - \text{SWIR}}{\text{Red} + \text{SWIR}}$	For mapping and differentiation of the snow-ice covered areas from non-snow and ice areas.
S3 Index	Shimamura et al. (2006)	$\text{S3} = \frac{\text{NIR}(\text{red} - \text{SWIR})}{(\text{NIR} + \text{red})(\text{NIR} + \text{SWIR})}$	For mapping snow and ice cover under forest covered areas.
Normalized Difference Glacier Index (NDGI)	Keshri et al. (2009)	$\text{NDGI} = \frac{\text{Green} - \text{Red}}{\text{Green} + \text{Red}}$	For mapping and differentiating between snow-ice and mixed ice and debris class.
Normalized Difference Snow and Ice Index (NDSII-2)		$\text{NDSII} = \frac{\text{Green} - \text{NIR}}{\text{Green} + \text{NIR}}$	For mapping and differentiating between snow and ice class.

suitable when the image pixels are pure (i.e., one pixel area is covered by a single class). However, as the spatial resolution becomes coarser, the proportion of mixed pixels (i.e., pixels containing more than one class) increases, which leads to erroneous per-pixel classification. Therefore, sub-pixel classification has been suggested. The output from a sub-pixel (SP) classification is set of fraction images (equal to the number of classes being mapped) each depicting spatial extent of a class. Both supervised and unsupervised approaches can be used to produce per-pixel and sub-pixel classifications.

Supervised classification is one of the most widely used one in various remote sensing studies, and involves four stages, as depicted in Figure 4. The salient characteristics of some of the supervised and unsupervised classifiers are given in Table 3. The following section focuses on the review of per-pixel image classifiers for mapping snow cover.

Snow-cover mapping using per-pixel image classification

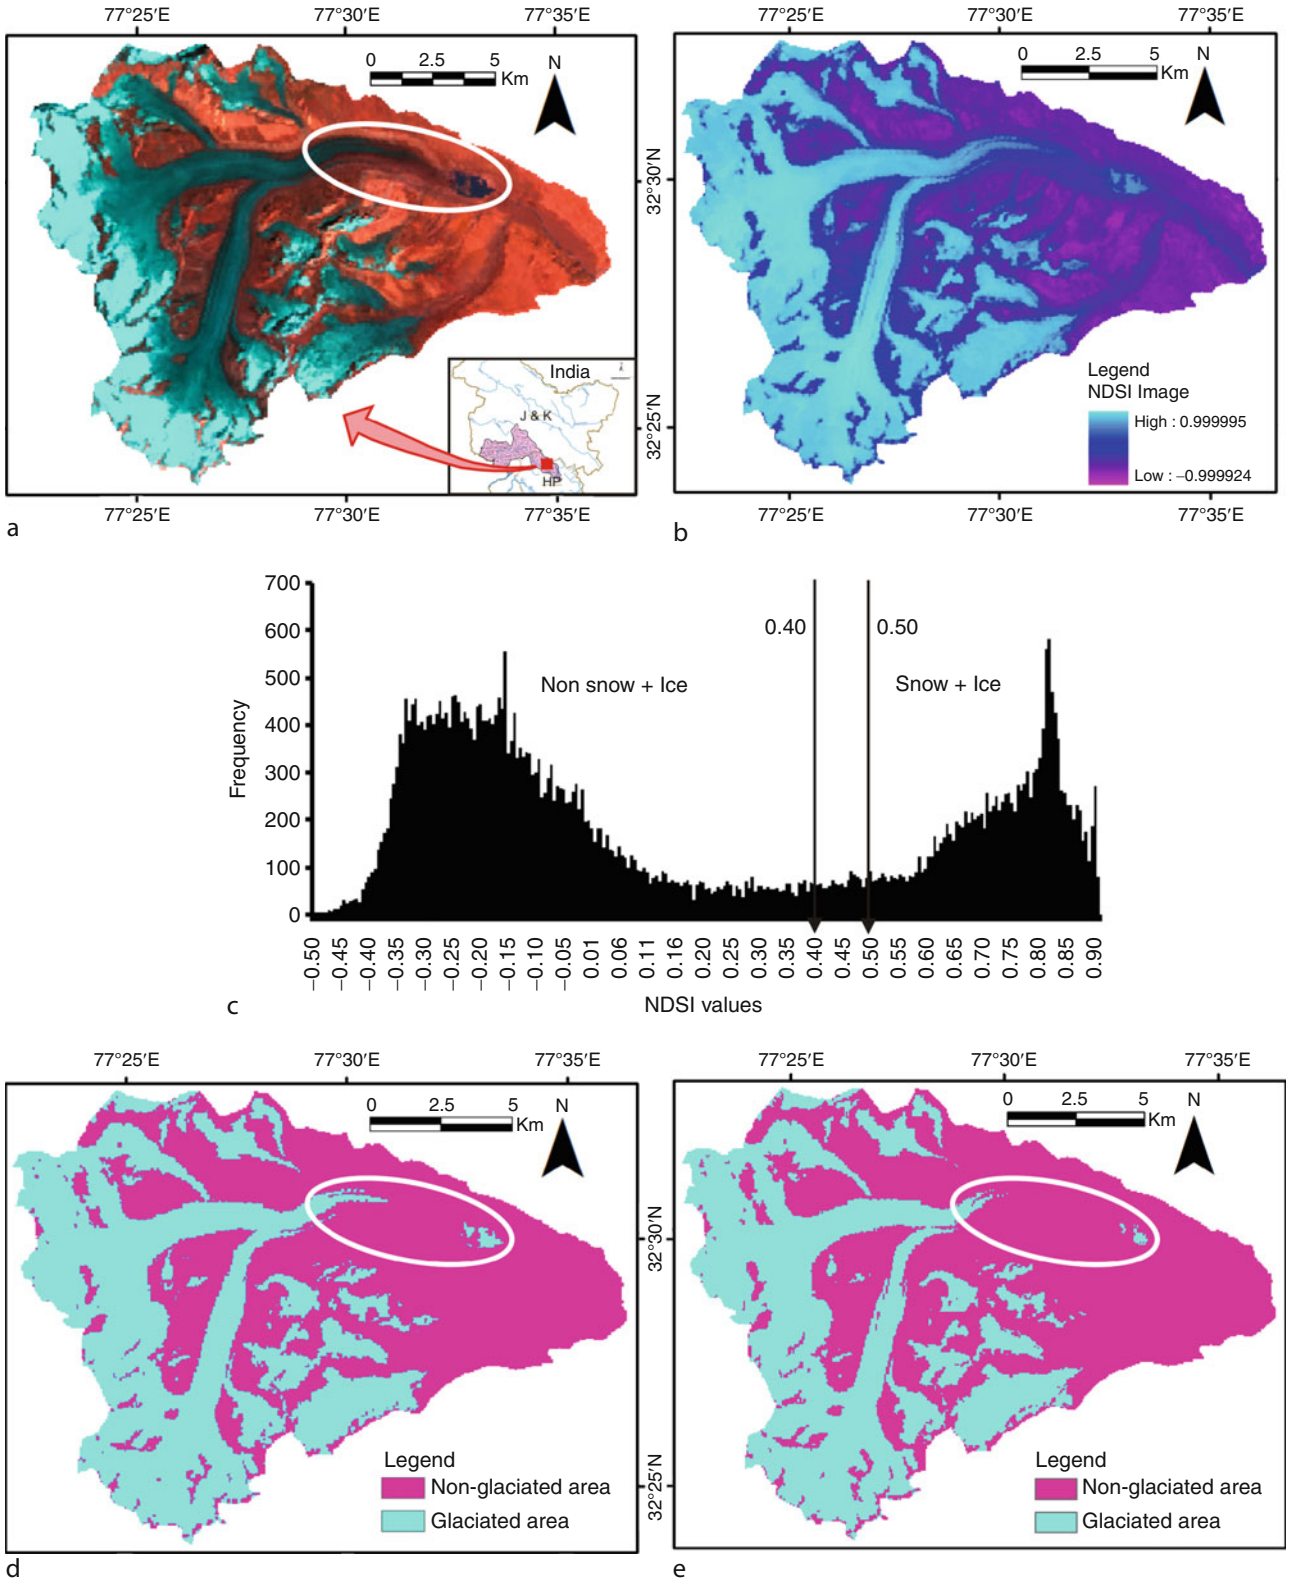
Della Ventura et al. (1983) developed a technique for automatic glacier-cover mapping (i.e., mapping of ice, snow, and other classes) using Landsat MSS data. Later, Della Ventura et al. (1987) applied a decision tree classifier and achieved more accurate results than the previous attempt. A supervised maximum-likelihood classification was applied to Landsat MSS and TM scenes by Gratton et al. (1990) to map seven classes. However, in that study, misclassification between clouds, shadows, and water, particularly in debris-covered glaciers, was observed due to which the maps had to be corrected manually. An inventory of the entire Southern Patagonian Icefield (SPI) based on TM data of year 1986 was prepared by Aniya et al. (1996) using cluster analysis (ISODATA) of TM bands 1, 4, and 5 to produce three classes (snow, ice, and rock). A parallelepiped classification was performed. In case of misclassification between ice in shade and supraglacial till, manual correction was applied (Paul, 2003).

The fuzzy set theory was used by Binaghi et al. (1997) for glacier classification. Although, a high classification accuracy was achieved, the method being technically intensive, was quite complex and moreover, debris cover on glaciers could not be mapped (Paul, 2003).

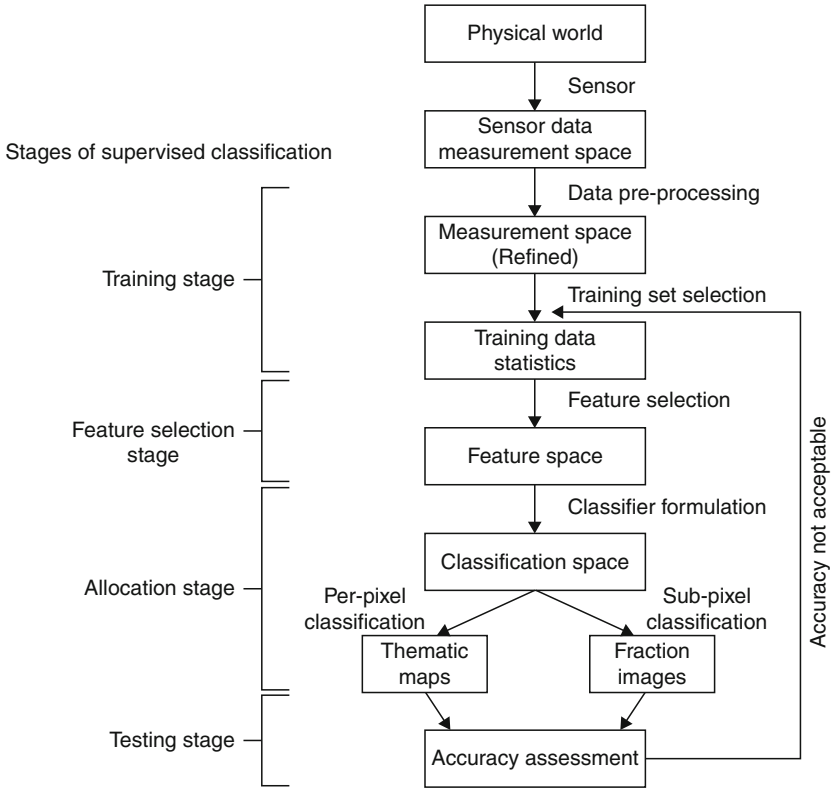
Ehrler and Seidel (1995) developed an algorithm for mapping snow and ice areas using Landsat TM and MSS and SPOT XS data via supervised classification for snow runoff modeling (SRM). The images were segmented into four illumination classes depending on the local incidence angle. Each illumination class was separately classified into bare ice, snow, transition zone, and snow free (aper). Wang and Li (2003) also performed supervised classification of images from Landsat TM, Terra MODIS, and NOAA-AVHRR to map three classes (old snow, fresh snow, and firn) using minimum distance classifier and intercompared with other snow and ice mapping techniques.

Additional information from sources other than spectral data (such as transformed spectral bands, DEM, and its derivatives) have also been utilized in the supervised classification process by some researchers either to simply augment the snow cover classifications (Boresjö Bronge and Bronge, 1999; Sidjak and Wheate, 1999).

Boresjö Bronge and Bronge (1999) applied supervised MLC to the principal components (PCs) of Landsat TM image for mapping blue ice of different characteristics as well as snow with various degrees of metamorphism. Although, the major snow and ice classes could be discerned, snow misclassifications were observed for image pixels covered with clouds and shadows. Sidjak and Wheate (1999) applied the supervised MLC using different input bands (PCs, TM4/TM5 ratio, NDSI, TM543 composite image) for mapping the glacier extent and discriminating glacier zones. The approach was able to



Digital Image Information Extraction Techniques for Snow Cover Mapping from Remote Sensing Data, Figure 3 Snow-cover mapping using NDSI. **(a)** FCC (R = B5, G = B4, B = B3) of AWiFS image, **(b)** NDSI image, **(c)** histogram of NDSI image, and **(d)** and **(e)** binary glacier terrain maps derived from NDSI ratio image at 0.4 and 0.5 thresholds.



Digital Image Information Extraction Techniques for Snow Cover Mapping from Remote Sensing Data, Figure 4 Typical flowchart of a supervised classification process (Modified after Gupta, 2003).

accommodate problems of sensor saturation and shadowed areas, and thus refining the discrimination of debris-mantled ice and ice marginal water bodies.

In order to assess the influence of ancillary data together with spectral data and their transformations in the classification process, snow-cover mapping in Chenab basin was carried out using AWiFS image via MLC. Use of three different datasets, namely, only reflectance data, reflectance data + NDSI, and reflectance data + thermal data (ASTER TIR data), was made in the classification to produce three glacier terrain maps of the area (Figure 5). Comparing these maps those produced from other snow-cover mapping methods, it can be clearly observed that MLC is able to differentiate snow from all the major glacier terrain classes in the study area and therefore, seems superior to other existing techniques.

Figure 5 shows that classification of only reflectance data leads to precise estimation of snow cover. A comparative evaluation of the three snow-cover maps reveals that while integration of data from sources (i.e., NDSI and thermal data) with reflectance data reduces the misclassification of shadow class (Figures 5b and c) and facilitates the segregation of periglacial and supraglacial debris classes (Figures 5b and d), it does not have much influence on the accuracy of snow-cover mapping.

Thus, these studies clearly demonstrate the potential of per-pixel image classification techniques for snow-cover mapping. However, in per-pixel classification, a pixel is assigned a single class, which may lead to misclassification and misrepresentation of mixed pixels especially in case of coarse spatial resolution data of sensors such as NOAA-AVHRR, Terra-MODIS, IRS-P6-AWiFS, etc. For example, MODIS snow-cover mapping algorithm SNOWMAP classifies a pixel as snow covered if it has at least 60% snow, resulting in over-estimation of snow covered area. Thus, a number of sub-pixel classification techniques for snow-cover mapping have been proposed.

Sub-pixel image classification

The output of a sub-pixel image classification is a set of fraction images equal to the number of classes being mapped. A fraction image is a grayscale image representing pixels values as the proportion of the class to which it belongs. Some sub-pixel classification techniques include MLC in soft form, spectral mixture modeling (SMM) (Settle and Drake, 1993), Fuzzy set–based methods (Bezdek et al., 1984), Evidential Reasoning (ER) (Peddle, 1993), Artificial Neural Networks (ANN) (Foody, 1995), Support Vector Machines (SVMs) (Brown et al., 1999) and Decision-tree classification (Min et al., 2005) etc.

Digital Image Information Extraction Techniques for Snow Cover Mapping from Remote Sensing Data, Table 3 Formulations and descriptions of some supervised and unsupervised image classification algorithms

Classifier	Basic formulations	Description	Supervised	Unsupervised	PP	SP
Parallelepiped Classifier	$\overline{x}_{ck} - S_{ck} \leq DN_{ijk} < \overline{x}_{ck} + S_{ck}$	It defines thresholds for each class (c) using their mean ($\overline{x}_{ck}$) and standard deviation (S_{ck}) in each band (k) and uses these to determine whether a pixel falls in that class.	✓	✗	✓	✗
Minimum Distance to Mean Classifier	Euclidean distance = $d(x,\overline{x_c}) = \left[\sum_{c=1}^{M}(x_c - \overline{x_c})^2\right]^{1/2}$ and $x \in \omega_c$ if $d(x,\overline{x_c})^2 < d\left(x,\overline{x_p}\right)^2$ for all $p \neq c$ where x is a pixel, $\overline{x_c}$ is the mean of the cth class, and ω_c is a set of spectral classes M (total number of spectral classes).	The distances between the pixel to be classified and each class center are compared. The pixel is assigned to the class whose center is the closest to the pixel.	✓	✗	✓	✗
Maximum Likelihood Classifier (MLC)	$p(x/c) = \frac{1}{(2\pi)^{n/2}\lvert\Sigma_c\rvert^{1/2}} e^{\left(-1/2\left[(\mathbf{x}-\overline{x}_c)^T\Sigma_c^{-1}((\mathbf{x}-\overline{x}_c))\right]\right)}$ where $p(x/c)$ is the probability density function of a pixel x as a member of class c, n is the number of bands, $\mathbf{x}$ is the vector denoting spectral response of pixels, $\overline{x}_c$ is the vector of class mean and $\sum_c$ is the variance covariance matrix.	It allocates each pixel to the class with which it has the highest probability of membership and requires the data to follow a normal distribution.	✓	✗	✓	✓

Artificial Neural Network Classifier (ANN)		ANN consists of several nodes arranged in three basic layers (input, hidden, and output). The neural network uses the training data to adjust the weights connecting the units until it is able to correctly identify class membership. This is achieved with the aid of an iterative learning process.	✓	✗	✓	✓
	x_i = Input pixel vector; W_{is} = weights between input and hidden l ayer node connections; net_s = net input for hidden layer nodes; O_s = is the output of the sth hidden node. O_j = is the output of the jth unit of the output layer; W_{sj} = weights between hidden and output layer node connections; E = Error function determined from training data and network output. This is to be minimized					
Fuzzy c-Means Clustering Classifier (FCM)	$J_m(U,V) = \sum_{i=1}^{N}\sum_{j=1}^{c} (\mu_{ij})^m \left\|\mathbf{x}_i - v_j\right\|_A^2$ subject to constraints, $\sum_{j=1}^{c} \mu_{ij} = 1$ for all i; $\sum_{i=1}^{N} \mu_{ij} > 0$ for all j; $0 \le \mu_{ij} \le 1$ for all i, j where $\mathbf{x}_i$ is the vector denoting spectral response of a pixel i, V is the collection of vector of cluster centers, v_j, μ_{ij} are class membership values of a pixel (members of fuzzy c-partition matrix), c and N are number of clusters and pixels respectively, m is a weighting exponent ($1 < m < \infty$), $\left\|X_i - v_j\right\|_A^2$ is the squared distance between $\mathbf{x}_i$ and v_j.	FCM measures the fuzzy membership value of data for each cluster based on the distance between the cluster center and the data in the feature space of remotely sensed imagery.	✓	✓	✗	✓

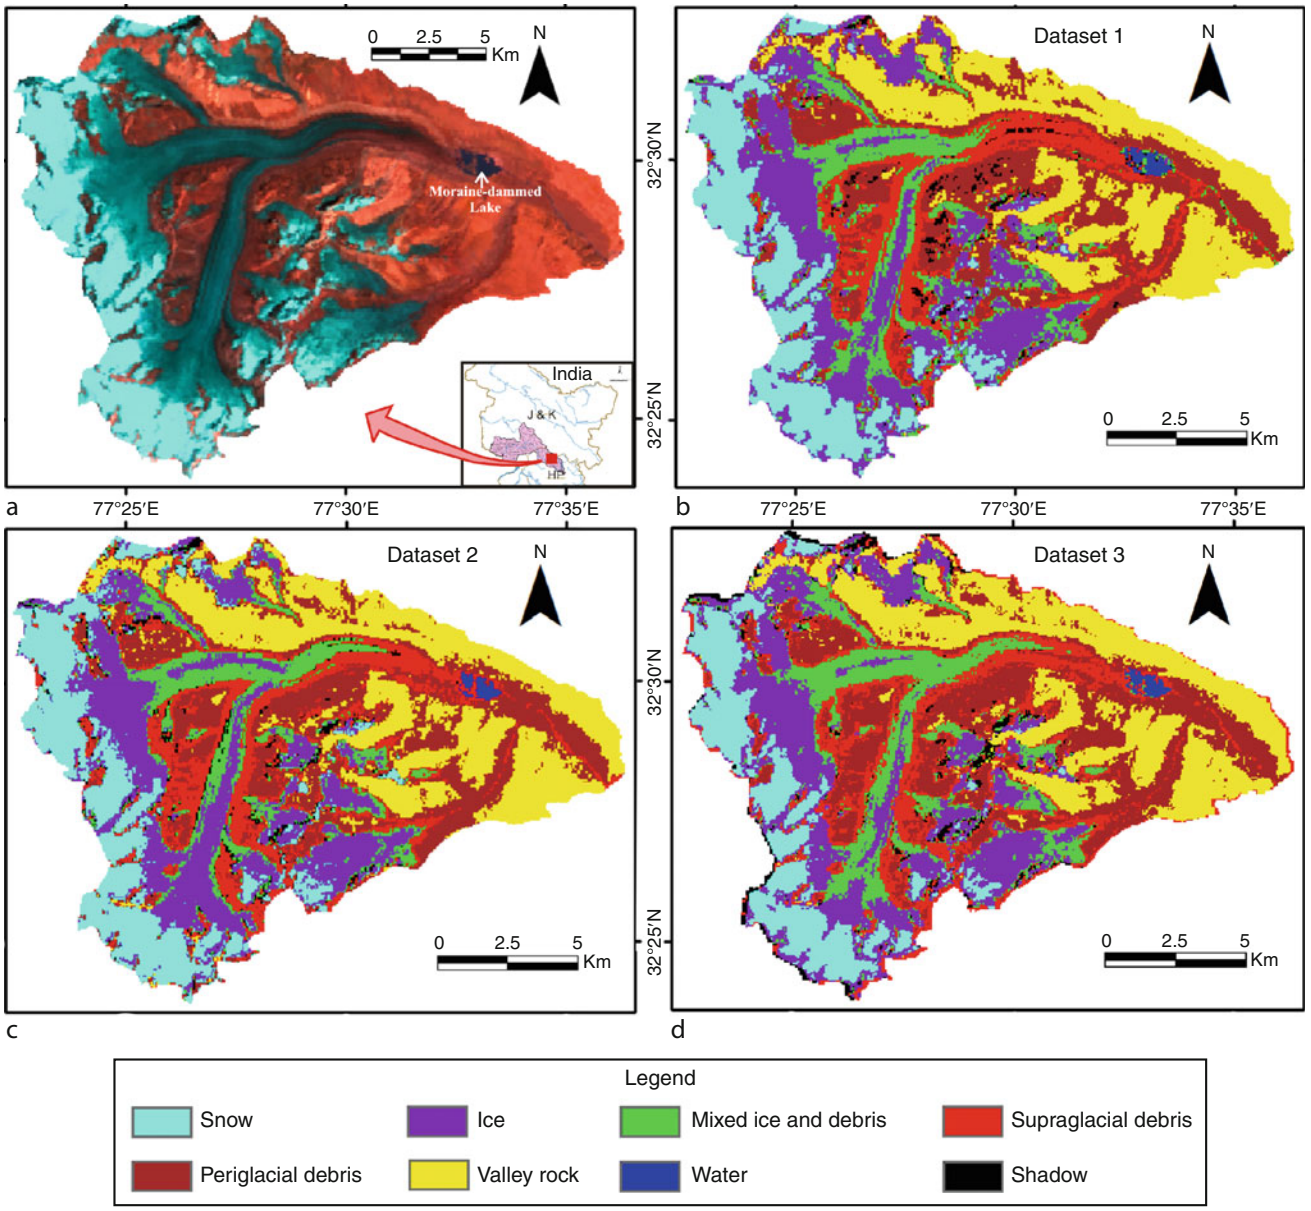
Digital Image Information Extraction Techniques for Snow Cover Mapping from Remote Sensing Data, Table 3 (Continued)

Classifier	Basic formulations	Description	Supervised	Unsupervised	PP	SP
Spectral Mixture Modelling (LMM)	$x_k = \sum_{c=1}^{n} f_c M_{kc} + e_k$ where, M_{kc} is the endmember spectra representing the mean class spectral responses of cth class in kth band, f_c are the fraction of cth class in a pixel, and the term e_k is the error term for kth band, which expresses the difference between the observed spectral response and the model derived spectral response of the pixel, respectively.	It assumes that the spectral response of an individual pixel is a linear sum of the mean spectral responses of its components (i.e. land cover classes) weighted by their relative proportions on the ground and thus calculates the proportion of each class	✓	✗	✗	✓
Evidential Reasoning (ER)	Mass function For one band, the mass function of a class c, for a DN value x is given as, $m_c(x) = \frac{\text{no. of pixels with value } x \text{ intraining sample of class } c}{\text{Total number of pixels intraining sample of class } c}$ Orthogonal summation If m_1 and m_2 are two mass functions defined on inputs from two sources, the combined mass function m_{12} is given by the equations, $m_{12}(A) = \frac{\sum_{B \cap C = A} m_1(B) m_2(C)}{1-k}$ where $A \neq \Phi$ where K is a normalization factor for ignoring conflicting evidence and is mathematically expressed as, $K = \sum_{B \cap C = \Phi} m_1(B) m_2(C)$	The mathematical theory of evidence actually refers to the Dempster–Shafer theory. The theory provides a general heuristic basis for combining information from independent sources, and can be applied to any problem where a choice is to be made from a set of well-known alternatives, based on information from various sources.	✓	✗	✓	✓

Decision Tree Classifier (DT)	 *C*(*t*)- subset of classes accessible from node *t* *F*(*t*)- feature subset used at node *t* *D*(*t*)- decision rule used at node *t*	Decision tree is a nonparametric classifier and involves a recursive partitioning of the feature space, based on a set of rules that are learned by an analysis of the training set. A tree structure is developed where at each branching a specific decision rule is implemented, which may involve one or more combinations of the attribute inputs.	✓	✗	✓
K-Means Clustering	Given a set of observations $(\mathbf{x}_1,\mathbf{x}_2,\ldots,\mathbf{x}_n)$, where each observation is a d-dimensional real vector, then k-means clustering aims to partition this set into k *(M)* partitions ($k < n$) so as to minimize the within-cluster sum of squares : $\underset{\omega}{\operatorname{argmin}} \sum_{c=1}^{k} \sum_{x_c \in \omega_c} \|x_c - \overline{x_c}\|^2$	It is an iterative clustering algorithm. First an arbitrary initial cluster mean vector is assigned. The second step classifies each pixel to the closest cluster mean. In the third step the new cluster mean vectors are calculated based on all the pixels in one cluster. The second and third steps are repeated until the “change” between the iteration is small.	✗	✓	✓

Digital Image Information Extraction Techniques for Snow Cover Mapping from Remote Sensing Data, Table 3 (Continued)

Classifier	Basic formulations	Description	Supervised	Unsupervised	PP	SP
ISODATA	Same as *k*-means with additional merging and splitting of clusters.	The ISODATA algorithm has some further refinements by splitting and merging of clusters. Clusters are merged if either the number of members (pixel) in a cluster is less than a certain threshold or if the centers of two clusters are closer than a certain threshold. Clusters are split into two different clusters if the cluster standard deviation exceeds a predefined value and the number of members (pixels) is twice the threshold for the minimum number of members.	✗	✓	✓	



Digital Image Information Extraction Techniques for Snow Cover Mapping from Remote Sensing Data, Figure 5 Snow-cover mapping using per-pixel image classification: **(a)** An FCC (R = B5, G = B4, B = B3) of AWiFS image of a test glacier, **(b)** Glacier terrain map derived from reflectance data, **(c)** Glacier terrain map derived from reflectance data + NDSI, and **(d)** Glacier terrain map derived from reflectance data + thermal data.

Among these, very few have been applied for snow cover estimation. The prevalent approaches of fractional snow-cover mapping include the techniques using empirical relationships (Andersen, 1982; Kaufman et al., 2002; Salomonson and Appel, 2004, 2006), SMM and its variations (Nolin et al., 1993; Painter et al., 2003; Vikhamar and Solberg, 2002, 2003; Sirguey et al., 2008 and 2009), and fuzzy set–based approaches (Rampini et al., 2002). Among all these, SMM has been used most widely in glaciological studies.

Empirical relationships–based snow-cover mapping

In these techniques, an empirical relationship between snow cover and some other property such as reflectance or NDSI, etc., is established, which is used to back calculate the percentage of snow cover in a pixel. Keeping in view the requirements of an operational sub-pixel snow-cover mapping algorithm, techniques based on empirical relationships have been developed (Andersen, 1982; Kaufman et al., 2002; Salomonson and Appel, 2004, 2006). Andersen (1982) developed a fractional snow-cover

mapping algorithm based on an empirical "reflectance to snow-cover" relationship. The model was calibrated by providing two points on the reflectance function: highest reflectance for 0% snow cover, and lower reflectance for 100% snow cover. This algorithm is used by the Norwegian Water Resources and Energy Directorate (NVE) to produce snow-cover maps from NOAA-AVHRR sensor.

Kaufman et al. (2002) devised an empirical technique for the estimation of fractional snow cover, based on principles of remote sensing of aerosol over the land. Both aerosol and sub-pixel snow are dark at 2.1 μm and much brighter at 0.66 μm. A relationship between directional reflectance of the non-snow areas (vegetation and soil) at these wavelengths was used to predict the reflectance at 0.66 μm. The results were validated with the snow fractions obtained from SMM (Rosenthal and Dozier, 1996) as the ground truth. The results showed a difference of only 1–2% between the snow fractions derived from the two techniques.

Salomonson and Appel (2004) conducted a study with the aim to evaluate the utility of NDSI in estimating the fractional snow cover within a 500-m MODIS pixel. For this, the data from Landsat ETM + scenes covering a wide variety of snow cover conditions was acquired as ground truth. All the Landsat scenes were classified as snow or non-snow using the current SNOWMAP algorithm of MODIS. An ordinary least squares regression approach was then applied to derive linear relationships between the snow fraction (FRA) and NDSI corresponding to the 500-m grid cells. Results from this technique proved to be superior, with lowest RMS error in the range of 0.10–0.12 and highest correlation in the range of 0.95–0.97.

Spectral Mixture Modeling

The SMM is widely used for producing class proportions within mixed pixels (Settle and Drake, 1993). SMM models the pixel spectrum with a least squares fit as a linear combination of the spectral responses of classes present within the pixel. The surface spectral responses of classes (also called as endmembers) are thus determined from other sources and the fractional cover of each class is obtained (Konig et al., 2001).

Nolin et al. (1993) were probably the first to apply SMM for mapping fractional snow cover in the mountainous regions of Sierra Nevada, California using AVIRIS data. Two multiband subset images containing 16 and 18 bands in the visible and NIR wavelengths, out of the available 224 bands were used. The SMM was run for each image to calculate the fraction images for each endmember. Deviations between the model and the data were calculated as residuals and RMS error images as well as an overall RMS error were also computed for each image. Overall RMS errors for the two subsets were found to be 3.4 Wm^{-2} μm^{-1} sr^{-1} and 3.0 Wm^{-2} μm^{-1} sr^{-1}, respectively, which are quite low. Therefore, they were able to successfully map deep snow, thin snow, shaded snow, and snow mixed with vegetation.

For operational snow-cover mapping, Rosenthal and Dozier (1996) estimated fractional snow cover using SMM for only a few representative regions and found that the technique was able to accurately identify surfaces without topographic correction (Konig et al., 2001). Recently, Sirguey et al. (2009) have presented a method for production of snow-cover maps with improved spatial resolution of 250 m, using MODIS data, at sub-pixel level. Image fusion techniques (wavelet fusion and "ARSIS" concept, Sirguey et al., 2008) were used to merge the relatively high resolution MODIS band 1 and band 2 (250 m) with MODIS bands 3–7 (500 m) data. A constrained SMM was applied on radiometrically corrected MODIS images. The eight endmembers, namely, ice, debris, rocks, medium granular snow, coarse granular snow, transformed snow, rain-forest + bush, and pasture were identified using ground measurements and photointerpretation. The accuracy of the resultant snow cover fractions was assessed against the reference snow-cover maps derived from fine-resolution ASTER data. The overall RMSE and mean absolute error (MAE) showed an improvement of 25%, while R^2 increased by 5.6% when the MODIS images with improved spatial resolution were used.

Some variations of SMM have also been reported especially in regions of rugged topography through the use of multiple snow endmembers (Painter et al., 2003). A method for sub-pixel mapping of snow cover in forests was developed by Vikhamar and Solberg (2002). The method was based on SMM of snow, trees, and snow-free ground. The focus had been on development of a physically based reflectance model that uses a forest-cover map as prior information. Later they tried to derive a simplified reflectance model suitable for operational snow-cover mapping in forests (Vikhamar and Solberg, 2003).

Although an effective technique, SMM has its own limitations such as that arisen from its basic assumption that the spectral response of a pixel is a linear weighted sum of its constituent classes. Nonlinearities are generated by the adjacency effect of bright pixels (i.e., pixels with high reflectance) next to dark pixels (pixels with low reflectance) adding some unaccounted-for path radiance and by the anisotropic distribution of reflected radiation from snow (particularly in the near-infrared wavelengths), as well as by the presence of adsorbed impurities in snow that can be adequately modeled as an intimate mixture (Nolin et al., 1993). In order to overcome the limitations of SMM, other sub-pixel classification techniques, which account for nonlinearity in spectral mixing have been proposed.

Fuzzy Set–Based Approaches

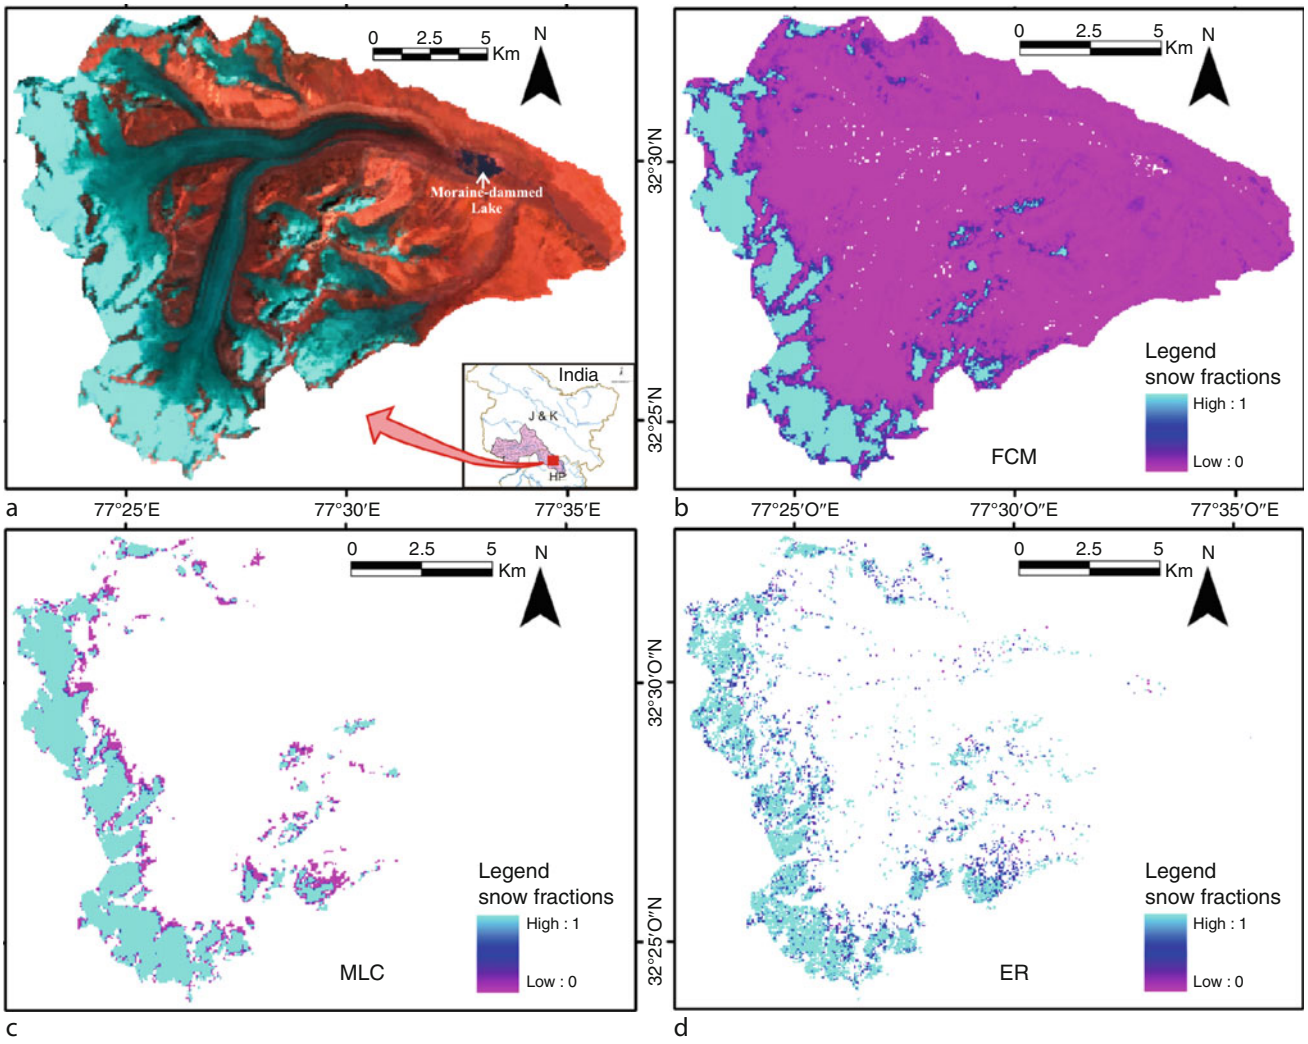
Fuzzy c-means clustering (FCM) is a popular fuzzy clustering method, which may be employed to partition pixels of remote sensing image into different class membership values or fractions. FCM measures the fuzzy membership value of data for each cluster based on the distance between the cluster center and the data in the feature space

of remotely sensed imagery and may be used in both supervised and unsupervised modes (Table 2). Rampini et al. (2002) used a supervised FCM classifier to extract eight land cover classes (snow, ice, rocks, wood, grass, lakes, clouds, and shadow) from Landsat TM and ETM + images to estimate the changes in the glacier cover from 1986 to 1999. The overall accuracy in all the classes was found to be above 90%.

In order to demonstrate the sub-pixel classification techniques, snow cover was estimated using MLC in soft form, FCM, and Evidential Reasoning (ER) from the AWiFS image in the Chenab basin (Figure 6). The SMM was ruled out due to the constraint that the number of classes to be mapped (eight in present case) should be one less than the number of spectral bands (four in present case of AWiFS data). Visual inspection of the snow cover fraction images from the three classifiers reveals that FCM has been relatively more successful in classifying snow cover as compared to MLC and ER. MLC and ER seem to underestimate and misclassify snow cover.

Summary

Mapping of snow- and ice-covered area has always been one of the major global scientific studies such as the mass balance studies, volumetric estimations of cryospheric components, meltwater runoff modeling, snow hazard prediction modeling, climatological modeling, etc. Conventional snow-cover mapping techniques include ground and aerial surveys, extrapolation of point data from weather stations, from topographic maps, and by application of temperature lapse rate method. The advances in satellite remote sensing have virtually revolutionized the global scenario of cryospheric studies in general, and



Digital Image Information Extraction Techniques for Snow Cover Mapping from Remote Sensing Data, Figure 6 **(a)** An FCC (R = B5, G = B4, B = B3) of AWiFS image of a test glacier; Pseudo-color snow cover fraction images from **(b)** FCM, **(c)** MLC, and **(d)** ER algorithms.

mapping of snow-covered areas in particular. Parallel to the advancements in the satellite sensor technology and availability of much refined data, the techniques of digital information extraction have also been enhanced. From simple change detection and manual delineation techniques to image ratios, spectral indices, and digital image classification–based mapping of snow-covered areas, there has been an exponential growth in snow-cover mapping at per-pixel and sub-pixel scales. Each technique, discussed in this chapter, has its merits and demerits. For example, while image ratioing and empirical spectral indices are appropriate for operational level tasks, the technically sound methods of digital image classification are more appropriate than others for detailed basin scale studies. Moreover, the results from digital image classification can also be augmented for further improvement by incorporation of data from sources. Moreover, work has also been carried out to exploit potential of the coarse spatial resolution data for snow-cover mapping using sub-pixel techniques, largely based on spectral mixture modeling. The utility of other techniques for snow-cover mapping at operational level needs to be explored. Besides, incorporation of ancillary data at sub-pixel level to enhance the classification accuracy and moving from sub-pixel classification to sub-pixel mapping or "super resolution mapping" of snow-covered areas constitute some areas for future research.

Conclusively, it may be stated that rapidly advancing tool of remote sensing has yet not reached its zenith and would continue to evolve and grow and in order to keep pace with it and imbibe its advantages in the field of snow-cover mapping.

DIRECT SURFACE RUNOFF

Lars Bengtsson
Department of Water Resources Engineering, Lund University, Lund, Sweden

Definition

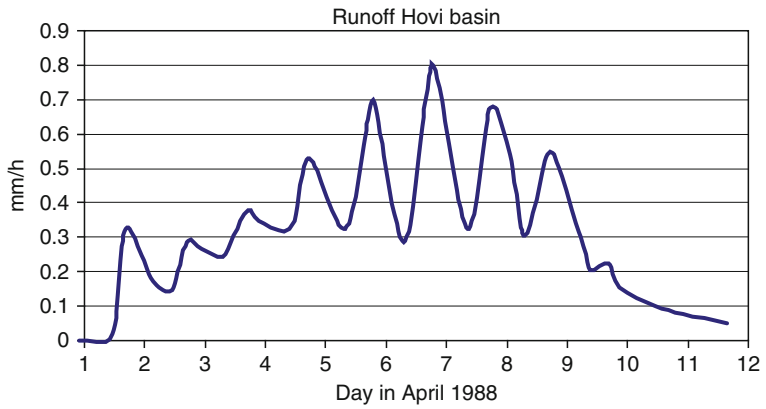
Direct surface runoff is the rain or meltwater that runs off during the rain or melt event as overland flow or in the vegetation cover above a frozen soil.

The meltwater and the rain falling onto snow or on frozen ground reach a stream along different pathways. It may be as groundwater after vertical infiltration in macropores or through the soil matrix. It may be as saturated overland flow or as Hortonian overland flow on concrete frozen soil; or as flow in cracks just below the ground surface. The water reaching a stream during or just after snowmelt or after a storm event may be old subsurface water forced forward by new water, or it may be event water, that is, meltwater or event rain water. The quality of the stream water depends on the pathways and on the interactions with the soil during the particles route to the stream.

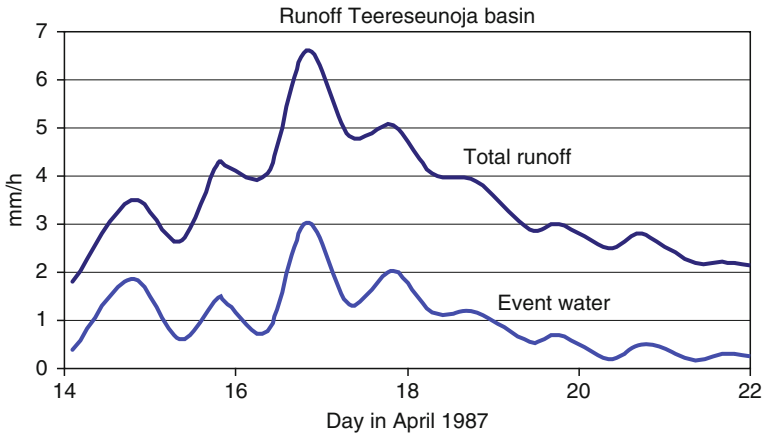
The ground under a snow cover is usually frozen. In very cold climate with thin snow cover, the frost depth is deep. When the ground is snow covered early with much snow, the snow isolates the soil and the frost depth is minor. When the ground freezes at high moisture content, the frozen soil becomes almost impermeable; while if the soil moisture is low, melt water can infiltrate into frozen soil especially into cracks and macropores. In a forest and at meadows with bushes, there is much litter and moss vegetation, many small stones, and macropores. The infiltration capacity is high. The soil seldom has high moisture content. Even when the soil is frozen, all the meltwater can infiltrate and percolate to the groundwater through the macropore system. Snowmelt occurs over extended time so the groundwater level is increasing throughout the snowmelt. At the bottom of the slopes, the groundwater reaches the surface. Saturated overland flow occurs.

In agricultural soils, there is no litter on top of the ground, macropore systems are less developed, and soils usually have clay content, all resulting in much more concrete-like frost than at forested sites. The first meltwater may infiltrate into cracks in the top ploughed soil layer, but once these are filled a saturated layer builds up and runoff occurs just below the ground surface, or if the melt proceeds over long time at the base of the snow pack. At a subdrained agricultural field, much of the water first moves horizontally in the crack-system and then vertically through drainage zones of coarse sand and gravel into the subdrains. If the soil had very high soil moisture content when the soil froze, the infiltration capacity may be almost completely reduced. Always where the ground is hard and the soil is packed, there is almost no infiltration into frozen soil, even if the soil was rather dry when the soil froze. The meltwater runs off as Hotonian flow at the base of the snow cover. The very first part of the horizontal runoff process in the snow may be considered as Darcian flow. When the melt proceeds, flow channels develop at the bottom of the snow pack. Then to match theory and observations, hydraulic conductivity 0.1–1.0 m/s may have to be used. Preferential flow takes place and the flow is faster than true Darcian flow.

Snowmelt is a slow process. Melt intensity is low compared to rainfall intensity. The velocity at which the meltwater moves in the snow is also low. Overland flow



Direct Surface Runoff, Figure 1 Runoff from the Hovi agricultural basin in Finland.



Direct Surface Runoff, Figure 2 Total runoff and runoff of Event water from the Teereseunoja forested basin in Finland.

proceeds through the night at the base of the snow pack even when melt occurs only during daytime. An example from the Hovi agricultural basin in Finland is shown as Figure 1. The distance from the top of the basin to the outlet is 400 m. The slope is about 0.01. The runoff is during the three days of most intense melt 0.7 mm/h at the end of the day and 0.3 mm/h after the night. Most of the water is snowmelt event water as determined from isotope analysis.

The diurnal runoff fluctuations are less in small forested basins compared to an agricultural one, as seen in Figure 2 from the Teereseunoja basin in Finland, mainly due to large fractions of pre-event water. In the very runoff peak of almost 0.7 mm/h, the fraction of event water is 40% but of the total runoff during melt less than 20% is event water. The ground slope towards the stream is about 10%. About one fourth of the basin is peat moor with trees. The event water contribution varies over the day in the range 0.2 mm/h in the afternoon to 0.07 mm/h in the morning and can, to a large extent, be attributed to the direct surface runoff on the moor. The diurnal runoff fluctuations are entirely attributed the event water.

Definition

Discharge. Discharge is the rate of water output resulting from melting of snow, ice, or glaciers.
Streamflow. Streamflow is the resulting rate of water flow in a stream or river draining a basin that contains snow, ice, or glacier.

Introduction

Generation of streamflow from snowmelt discharges includes processes that produce meltwater within the snowpack, those that store and delay the liquid water within the snowpack and those that channel the meltwater through watersheds to streams or rivers. Glacier-melt discharge is more complex than snowmelt discharge due to additional processes that are involved in melting of glaciers (Singh and Singh, 2001; Hock, 2005). In addition to seasonal snowpack melt, internal movement of glacier ice and the sliding of a glacier body are responsible for significant amount of melt discharge from the glaciers. Depending on elevation there are different stages within glaciers of liquid water movement from storage in firn to channel flow in the lower regions of the glacier.

Snowmelt discharge and streamflow

The depth of snow cover, the snow water equivalent, and the aerial extent of snow cover influence the amount of snowmelt runoff that will occur during the melt season. The snow water equivalent is the depth of water obtained by melting the snow cover and an estimate can be computed using the depth of snow and the density of the snowpack. The rate of snowmelt is determined by

snowpack and atmospheric conditions. The melt rate of snow is lower in the beginning of the melt season and increases in summer. Maximum snowmelt rates as high as 70 mm/day have been observed in New Zealand (Singh and Singh, 2001).

According to DeWalle and Rango (2008),

> Outflow of liquid water from a snowpack represents water from melt and rainfall and internal changes in liquid-water holding capacity due to metamorphosis. During non-rain periods, nearly all outflows are due to melting. Daily melt rates up to 2 cm d^{-1} occur frequently and maximum daily rates of 7–8 cm d^{-1} have been noted (Kuchment, 1997; Cooley and Palmer, 1997). Hourly melt rates can reach 0.1 to 0.3 cm h^{-1}. Meltwater generated at the surface of the snowpack can refreeze deeper within unripe snowpacks or be temporally stored as liquid water within the snowpack by ice layers. Thus the timing of outflow at the snowpack base can be altered considerably by storage and transmission within the snowpack.

Snow meltwater can experience significant lag in migration through the snowpack. Such conditions can occur when the liquid refreezes in subfreezing snowpacks due to significant cold content or is subjected to satisfying the liquid water holding capacity of the snowpack. Transmission of liquid water through the porous matrix of the snowpack experiences significant resistance and hence is delayed in discharging (Daanen and Nieber, 2009).

Once the discharge from snowpacks reaches the surface of the landscape, it can be rapidly transported to streamflow due to soil frost, permafrost, or saturated ground depending upon the hydraulic flow paths that are active (DeWalle and Rango, 2008). Snow that falls directly into channels or streams could discharge and flow rapidly and contributes to the initial stages of streamflow response to precipitation. Meltwater that is delivered to the soil surface in excess of the soil infiltration rate that eventually reaches a stream or river can be significant in quantity depending upon the permeability of the frozen soil or if the soil is underlain with permafrost (Semadeni-Davies, 1998; Gibson et al., 1993; Bengtsson et al., 1992; Bengtsson and Westerstrom, 1992; Kane and Stein, 1983).

DeWalle and Rango (2008) note,

> "Rapid delivery of meltwater is a particular problem in arctic basins with permanently frozen ground or permafrost (Woo, 1986). Prèvost et al. (1990) found that the low infiltration capacity of frozen soil caused overland flow and contributed to high peak streamflows during spring snowmelt at Lac Laflamme in Quebec, Canada. In an Arctic watershed, McNamara et al. (1997) found from isotope studies that runoff in spring was primarily (90%) due to event meltwater from the snowpack, but runoff in summer was typically sustained (70%) by older water released from storage by thawing of the shallow soil layer or active layer above the permafrost. A soil infiltration index was needed to account for frozen soil effects in models for accurate peak-streamflow prediction. Prediction of the depth of soil frost and the infiltration capacity of the frozen ground can be quite important to successful modeling of streamflow from snowmelt."

Streamflow hydrographs from snowmelt are strongly coupled to the energy supply for melt. The streamflow hydrograph, or time distribution of streamflow during snowmelt, depends on the physical characteristics of the drainage basin and the characteristics of the snowmelt. For example, the snowmelt discharge hydrograph for the Sierra Nevada is characterized by a *spring pulse* or the first surge in snowmelt-driven river discharge in spring, *maximum snowmelt discharge*, and *base flow* or low river discharge supported by groundwater in fall (Peterson et al., 2005). The timing of the spring pulse is primarily influenced by air temperature, but solar radiation plays a major role in mountainous terrain. The maximum daily snowmelt discharge is primarily influenced by the initial snow water equivalent. The timing of the spring pulse is mid-April, maximum daily snowmelt discharge is late May/early June, and base flow is late fall (Peterson et al., 2005).

Glacier-melt discharge and streamflow

In recent years, approximately 3,000 km^3 of water is released from the glaciers per year (Knight, 1999 and references therein). Most of the water transferred back to the hydrological system is due to ablation. Knight (1999) noted that water released from glaciers is transferred to surface streams, groundwater, directly into the ocean, or by evaporation and sublimation to the atmosphere. The discharge from a glacierized basin is characterized by a diurnal rhythm superimposed on the baseflow (Singh and Singh, 2001). This rhythm distinguishes glacier fed streams. There is also considerable baseflow in glacier fed streams during the summer. The majority of discharge from glaciers occurs during the summer months of June–August. For example, the glaciers of Alaska discharge meltwater equivalent of 2.5×10^6 m^3 of water for each km^2 of glacier during the months of July and August (Knight, 1999 and references therein).

Glaciers melt both on the surface and at the base. The surface melting occurs due to solar radiation and turbulence in the atmosphere. The basal melting occurs due to energy supplied from the bedrock underlying the glacier. Singh and Singh (2001) note, "Surface melting is seasonal and reaches a peak value usually in late summer, whereas basal melting fluctuates less markedly and generally exists throughout the entire year". They further comment that additional melting in glaciers occur due to internal movement of the glacier and the glacier sliding process when the glacier base is at pressure melting point.

Knight (1999) noted,

> Meltwater (discharge in glaciers) can be produced supraglacially, englacially, and subglacially. Supraglacial melting of snow and ice is driven by insolation, turbulent heat transfer, precipitation, and other heat sources. Englacial melting occurs due to strain heating during flow, or heat transfer into the body of the glacier. This heat transfer can occur due to percolating meltwater and by conduction from the surface or from the bed. Melting can occur at the base as a result of a variety of processes including geothermal heating, frictional heating, variations in melting point due to pressure

fluctuations during flow across the bed, heat transfer by water flowing at the bed, flow of ice between zones of different basal thermal regimes, and volcanic activity.

Timing of meltwater release from glaciers is often complicated due to different regimes of water movement with glaciers. Snowmeltwater is stored in porous snow and firn as it slowly moves toward the multiyear ice as Darcian flow. In the multiyear ice the pore structure does not support Darcian flow and most of the liquid water is stored and moves through cracks in the solid ice body. These cracks are often not connected and can therefore pond water for longer periods and even refreeze. These ponds are released when cracks and crevasses grow, which can lead to a liquid pulse release from the glacier. At the lowest stage of glacier hydrology is the channel flow where major flow paths near the bottom of the glacier funnel the water away from the glacier (Hock, 2005). These large channels tend to collect rocks and debris from the mountains and can become smaller or larger over time. These rock collection channels are also known as eskers when the glacier recedes.

Global warming has a profound effect on glacier fed stream flow, because glaciers need a long time to adjust to changing climate conditions. During a warming period glacier melt will be faster and can cause more river runoff and can offer a greater potential for hydropower generation. This trend is however not sustainable and will diminish when the glacier is reduced to a new equilibrium state. The new state is however very hard to predict and some glacier runoff may already be declining (Hock, 2005). When a new equilibrium is reached, more runoff will be generated from snowmelt during spring and rain events during the summer and much less from the melting glacier.

Summary

Discharge as a result of melt from snow and glaciers depends on a combination of snowpack and glacier physical characteristics and atmospheric conditions. Glacial melt is more complex than snowmelt due to internal movement of glacier ice and sliding of the glacier body. Snow meltwater can contribute quickly to streamflow via overland flow when the ground is frozen or saturated. Meltwater stored within the soil profile can contribute to streamflow over longer time scales. Snow melt contributions to streamflow are greatest during spring months while glacier fed streams have significant baseflow during summer months when the majority of glacial discharge occurs. Glacial melt occurs at both the surface and the base of the glacier with the timing of meltwater release complicated due to different regimes of water movement within glaciers.

Runoff Observations

DISTRIBUTARY CHANNELS

Anju Chaudhary
Water Resources System Division, National Institute of Hydrology, Roorkee, India

Definition

Distributary channel is a stream that carries water away from the main river channel and distributes it to other area. Distributary channel has bifurcating channels that persists relatively independent of the parent stream. However, they may rejoin the parent channel or each other. Distributary channels are a common feature of river deltas.

Distributaries are usually formed as a stream nears the lake or the ocean, but they can occur inland as well. In some cases, a minor distributary can take so much water from the main channel that it can become the main route. The opposite of a distributary is a tributary.

DIURNAL CYCLE OF RUNOFF

Darrel A. Swift
Department of Geography, University of Sheffield, Sheffield, UK

Definition

Runoff. The flow of surface water, derived from snow melt, glacier melt, precipitation, or other sources, from a defined drainage area, such as a glacierized basin.
Diurnal cycle. The daily rise and fall of discharge/streamflow that is characteristic of runoff derived from snow and ice melt, most notably in glacierized basins.

Introduction

The important contribution of snow and ice melt to runoff from mountainous or glacierized basins causes *Discharge/Streamflow* (qv) to exhibit a distinctive diurnal cycle. The rate of melting of snow and ice is determined predominantly by the intensity of solar radiation (qv *Melting Processes*), such that runoff from these sources rises and falls daily, with diurnal maxima (i.e., daily peak flow) occurring shortly after the diurnal peak in melt. The form of the diurnal cycle varies as a result of both seasonal and spatial variations in the sources of melt, the efficiency with which solar energy is converted into melt, and the efficiency with which the resulting runoff is routed to the glacier or basin terminus (qv *Specific Melt Rate*; *Snow Hydrology*; *Glacier Hydrology*).

Diurnal cycle characteristics and their significance

Discharge Observations (qv *Discharge/Streamflow*) in mountainous or glacierized basins commonly demonstrate marked diurnal changes in discharge/streamflow superimposed on a *Base Flow/Groundwater Flow* (qv) that changes more slowly (Paterson, 1994). Diurnal changes are most obvious during fine summer weather when they are dominated by changes in the volume of runoff from snow and ice melt that has followed hydraulically efficient flow pathways (e.g., via open channels); this results in a strong diurnal runoff cycle where diurnal maxima occur only a few hours after the peak in melt. Base flow comprises snow and ice melt plus water from other sources, including groundwater, that has at least in part followed less hydraulically efficient flow pathways (e.g., via seepage through the snowpack itself, qv *Snow Hydrology*); as a result, such runoff takes a great many hours or days to reach open channels. The volume of the base flow component is typically estimated from diurnal minima (i.e., daily minimum flow). Key features of the diurnal cycle – notably, the diurnal minima and maxima, separated by periods of rising and falling (or recessional) discharge – are evident from *Hydrographs* (qv).

Discharge records from glacierized basins at the peak of the melt season demonstrate very pronounced diurnal runoff cycles (e.g., Elliston, 1973) because a number of factors maximize both the efficiency with which solar energy is converted into melt and the efficiency of flow pathways that connect runoff sources to the glacier terminus. Firstly, because the *Albedo* (qv) of glacier ice is very low in comparison to that of fresh snow, the exposure of large areas of glacier ice – as a result of the melting of accumulated winter snowfall – produces large volumes of ice melt with a highly-peaked diurnal cycle (e.g., Gordon et al., 1998). Secondly, because glacier ice is effectively impermeable at intermediate scales, runoff from ice melt is routed rapidly across the glacier surface, typically in open channels. Thirdly, highly-peaked glacier surface runoff has been shown to result in the evolution of hydraulically-efficient subglacial channel networks (e.g., Nienow et al., 1998), such that runoff from ice melt that accesses the glacier bed via moulins is also routed rapidly to the glacier terminus. Diurnal variation in discharge/streamflow may cease temporarily if summer snowfalls re-cover the glacier surface, and the cessation of surface runoff over winter allows hydraulically efficient subglacial channel networks to close.

Runoff cycle evolution in glacierized basins

The diurnal cycle of runoff from glacierized basins evolves during the melt season, from low and steady base flow with no superimposed diurnal cycle, to high base flow with highly peaked superimposed diurnal cycles whose diurnal maxima may be two or more times greater than the diurnal minima (e.g., Elliston, 1973). Base flow is initially low and stable because runoff is derived largely from Bottom Melting or Undermelt (Ice Shelf) (qv *Bottom Melting or Undermelt (Ice Shelf)*), groundwater, and the slow release of water from temporary englacial and/or subglacial storage (qv *Meltwater Storage*). As the melt season begins, base flow increases as a result of snow and ice melt following hydraulically inefficient supraglacial and subglacial flow pathways, while the diurnal cycle increases in amplitude simultaneously largely as a result of an increasing proportion of runoff being derived from ice melt, and to a lesser extent snow melt, that is able to follow hydraulically efficient flow pathways. Base flow volume is also influenced by the length and form of the recession curve from the previous diurnal peak (qv *Recession of Discharge*), which itself reflects the efficiency with which runoff from various sources is routed through the glacier (e.g., Gurnell, 1993).

The ease with which *Discharge/Streamflow* (qv) can be obtained has resulted in the characteristics of the diurnal cycle and their relationship with meteorological variables – for example, the lag times between diurnal

maxima in runoff cycles and air temperature or incident radiation, and the relative magnitudes of the diurnal and base flow components – being used widely to characterize the hydrological evolution of glacierized basins (e.g., Gurnell et al., 1992; Fountain, 1992; Hodson et al., 1998). Most recently, the controls on diurnal runoff cycle evolution have been explored using statistical analyses of hydrograph form (e.g., Hannah et al., 1999, 2000; Swift et al., 2005a). For example, Swift et al. (2005a) statistically classified diurnally-peaked hydrographs from Haut Glacier d'Arolla, Switzerland into three types that demonstrated systematic evolution of the diurnal cycle that is characteristic of many temperate glacierized basins (e.g., Elliston, 1973; Lang, 1973; Gurnell et al., 1992; Fountain, 1992; Raymond et al., 1995); however, the timing and extent of runoff cycle evolution varied significantly between melt seasons as a result of the influence of the glacier-surface snowpack on the sources of melt and the routing of the resulting runoff (cf. Willis et al., 2002).

A notable feature of diurnal cycle evolution is the appearance of progressively earlier diurnal maxima, and therefore an increasingly rapid rise to peak discharge from the diurnal minima, which Elliston (1973) suggested reflects the more efficient routing of runoff as a result of the enlargement of subglacial channels. However, Fountain (1992) has argued that channel size should have a negligible effect, since the delay between peak melt and peak runoff should be a function of the time required for a pressure wave to propagate over the same distance. Swift et al. (2005a) therefore suggested that the timing of diurnal maxima may be affected by changes in glacier-surface characteristics that effect the efficiency of melt production and the routing of the resulting runoff – for example, changes in albedo as melting concentrates englacial debris on the ice surface, and the development of more efficient (i.e., less tortuous and better-connected) supraglacial, englacial, and subglacial drainage networks – as the melt season progresses (cf. Seaberg et al., 1988; Hock and Hooke, 1993; Fountain, 1996).

The glaciological factors that control the evolution of the size of the diurnal cycle relative to base flow are also poorly understood. Observations at many glaciers indicate that the amplitude of the diurnal cycle at the peak of the melt season may be only 50% of the volume of base flow (e.g., Elliston, 1973; Lang, 1973; Raymond et al., 1995), perhaps because a large proportion of runoff from ice melt that accesses the glacier bed does so in areas of hydraulically inefficient subglacial drainage. This theory is given support by observations at Haut Glacier d'Arolla that are consistent with the corollary; in other words, moulins at Haut Glacier d'Arolla that allow surface runoff to reach the glacier bed are located largely above preferential subglacial drainage axes (Sharp et al., 1993), and diurnal maxima at the peak of the melt season are typically in excess of two times base flow volume (Swift et al., 2005a). Nevertheless, it might be possible for channel flow to elevate base flow if diurnal maxima are sufficient to force channel flow into adjacent areas of hydraulically inefficient subglacial drainage (cf. Hubbard et al., 1995) and/or delay flow within the inefficient system from entering arterial channels (Swift et al., 2005a).

Significance of the runoff cycle for glaciology

The form of runoff cycles in glacierized basins is highly significant because the large amplitude of runoff cycles produced by ice melt have been shown to drive the evolution of hydraulically efficient subglacial drainage systems (e.g., Gordon et al., 1998; Nienow et al., 1998) and to dictate water pressure variations within such systems (cf. Hubbard et al., 1995) that influence glacier motion (cf. Willis, 1995; Nienow et al., 2005) (qv *Dynamics of Glaciers*; *Glacier Sliding*). Such diurnal water pressure variations will increase in amplitude with the increasing peakedness of the runoff cycle, and, should increasingly peaked runoff cycles result in open flow conditions in subglacial channels for longer periods of the diurnal cycle (cf. Sharp et al., 1993), adjustments in the cross-sectional area of channels should further increase water pressures at peak flows (Swift et al., 2005a). Swift et al. (2005b) have shown that the peakedness of the diurnal cycle also appears to control the efficiency of basal sediment evacuation by subglacial drainage, presumably because high water pressure variation promotes extreme discharge gradients within subglacial channels and a strong diurnally-reversing hydraulic gradient between channels and adjacent areas of hydraulically inefficient drainage (cf. Hubbard et al., 1995) (qv *Subglacial Drainage System*).

Summary

Diurnal cycles in runoff are common in mountainous and glacierized basins, but are especially pronounced in glacierized basins during fine summer weather at the peak of the melt season, when large areas of exposed glacier ice generate large volumes of ice melt that is efficiently routed to the glacier terminus by hydraulically efficient subglacial channel networks. The form of runoff cycles is also influenced by the sources of melt and the efficiency with which melt is produced, such that the removal of accumulated winter snowfall from the glacier surface during the summer is a critical control on the timing and extent of runoff cycle evolution, as well as being a significant source of base flow as a result of flow through the snowpack being highly inefficient. The amplitude of the diurnal cycle is critical in many important glacial processes, including the evolution of hydraulically efficient subglacial channels, and rates of basal sliding and sediment evacuation. Nevertheless, as a result of the compexities of runoff sources, the processes that generate melt, and the routing of the resulting runoff, the controls on the form and evolution of key components of the diurnal cycle remain poorly understood.

DIVERGING ICE FLOW

Gulab Singh, Farjana S. Birajdar
Centre of Studies in Resources Engineering, Indian Institute of Technology Bombay, Powai, Mumbai, India

Definition

Diverging ice flow represents the slow-moving ice flow. The divergence of glacial flow is directly linked to ice velocity and sediment transport to the glacial terminus. Slow-flowing areas of ice sheets (or glaciers) are often associated with divergent flow line gradient, little basal erosion, and low sediment supply to continental slope. Diverging flow occurs where flow lines diverge and lateral stresses are tensional results in decrease in forward velocity. Diverging flow occurs at locations where there is a transverse gradient in the slope of the ice (e.g., zone of ablation in a valley glacier). Under such conditions, streaming ice becomes unconfined. On the other hand, converging flow where flow lines converge and lateral stresses are compressive results in an increase in velocity. This type of flow is observed in the accumulation zone of an alpine glacier or where unconfined flow becomes

confined or channeled into a valley. The significance of *divergent ice flow* direction can be probably linked to the mode of deglaciation.

DRIFT GLACIER/ICE/SNOW

Gulab Singh, Farjana S. Birajdar
Centre of Studies in Resources Engineering, Indian Institute of Technology Bombay, Powai, Mumbai, India

Definition

Drift Glacier is movement of glacier which results in transportation of rock material by glacial ice. Glacial drift occurs as scattered rock fragments, as till, and as outwash. The erosive action of glaciers generates considerable amount of sediment. Drift could be deposited by ice, by a combination of melt water and ice, or reorganized completely by melt water. Mainly, the material transported by glaciers is gravel, sand, or clay.

The drift ice is defined as the movement of ice fields or floes in water bodies caused by wind or currents, whereas drift snow is a deposit of snow created by wind into a mound during snowstorms.

DRY AND WET SNOW LINE/ZONE

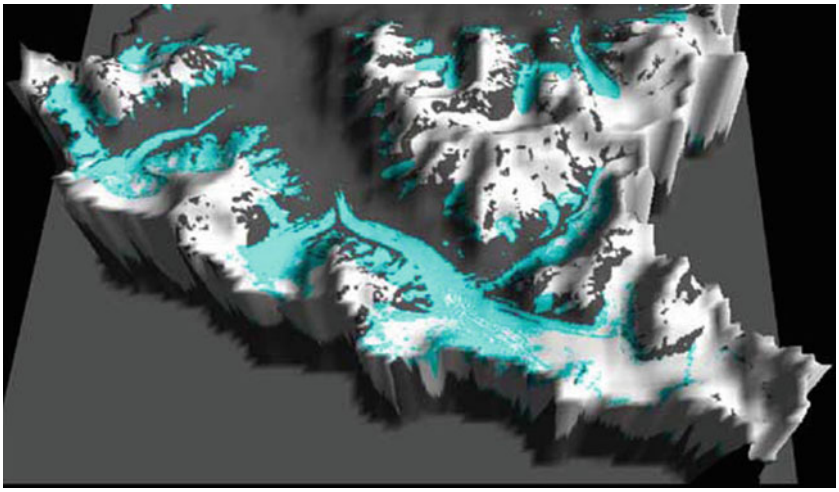
Ravi P. Gupta
Department of Earth Sciences, Indian Institute of Technology Roorkee, Roorkee, UA, India

Definition

Dry and wet snow line/zone essentially separates that part of the snow cover in the mountain basin where snowmelt arises (wet) from that where no snowmelt arises (dry).

Dry and wet snow line/zone

1. Dry and wet snow line/zone essentially separates that part of the snow cover where snowmelt arises (wet) from that where no snowmelt arises (dry). Snow at the time of precipitation from clouds has a dry granular-flaky form with soft and open structure and possesses low relative density. With the onset of melting season as the environmental temperature rises and crosses the melting point (0°C), the snow starts to melt, and almost invariably at this time undergoes repeated cycles of partial melting (day) and refreezing (night). This leads to development of bigger recrystallized ice crystals with increased density and this forms the typical melting seasonal snow.
2. Sun is the main source of heat energy leading to the melting of snow, and the intensity of solar radiation reaching the individual snow-covered topographic slope/facet is the most important factor in the snow-melting process. Therefore, the dry and wet snow line/zone is influenced by a complex interplay of various factors, such as sun direction and angle vis-à-vis local topographic slope and aspect, time of the day, latitude–longitude, besides various atmospheric–meteorological factors. Thus, the dry and wet snow line/zone could vary in altitude/location within a basin.
3. Further, the dry and wet snow line/zone is a transient feature that changes position with time within a basin. It exhibits a systematic gradual movement toward higher elevation with time as the snowmelt season advances. The boundary between dry and wet snow is gradational and fuzzy; therefore, in field the term zone is more appropriate, whereas on small-scale maps, it may appear as a line.
4. Snowpack constitutes an important source of fresh water in many parts of the world. Melting seasonal snow, most of which is névé, is relatively less recognized and described in literature, but is of great importance as snowmelt is concerned. Out of the entire snow-cover area in a basin on a particular date, snowmelt is generated only from the snow-cover area that lies below the dry and wet snow line/zone, as the snow-cover area above it remains essentially dry and does not produce any melt. Snowmelt runoff models (SRMs) are developed to predict snowmelt runoff in the ensuing summer melting season on a daily basis, and it is very important to map dry/wet snow line/zone for estimating snowmelt runoff.
5. Field investigations for mapping of dry and wet snow line/zone are very difficult to carry out and may be tedious, arduous, and too time consuming. On the other hand, the position of the line/zone rapidly changes with time. Therefore, satellite remote sensing systems are most optimally suited to collect synoptic data for mapping of dry and wet snow line/zone. The melting seasonal snow consists of small snow-ice crystals, possibly with moisture film during the daytime. This leads to a reduced near-infrared reflectance as compared to the dry snow (Dozier and Painter, 2004; Hall et al., 1992) (Figure 1). Thus, on satellite sensor images, the wet snow is characterized by marked reduced reflectance in the near-infrared part of the spectrum in comparison to the dry snow, which exhibits very high reflectance, facilitating their mutual discrimination.
6. Although, wet snow and glacial ice appear similar on remote sensing satellite images, the two can be differentiated from each other on the basis of shape, site,



Dry and Wet Snow Line/Zone, Figure 1 Boundary and relative distribution of dry snow (*white*) and wet snow (*cyan-blue*) in the Gangotri basin (the origin of the Ganges river), Himalaya. Dry snow occurs at higher altitudes and is fringed by the melting seasonal wet snow on relatively lower altitudes. Perspective view generated by draping IRS-satellite image over the digital elevation model (Gupta et al., 2005).

and repetivity in occurrence on different temporal images. The ice body occurs only in glacial valley, is lingulate, has a sharp boundary and a permanent position, i.e., is repeatedly shown at the same place in various images, whereas the wet snow occurs as a fringe adjoining the dry snow all over on hill slopes and valleys, and this fringe changes position with time in the melting season, i.e., appears at different heights/places on images of different dates (Gupta et al., 2005).

7. Anomalous local deviations in dry and wet snow line/zone, e.g., late occurrence in the accumulation season and advance presence in the melting season, may indicate local higher geothermal gradients, e.g., due to hot springs.

Summary

In summary, it may be stated that dry and wet snow line/zone is basin morphology dependent, fuzzy, and transient. Its delineation is extremely important for various purposes such as water resources modeling and management. As field investigations are tedious, arduous, and too time consuming, satellite remote sensing techniques are most optimally suited for such resources applications.

Dry Snow

DRY SNOW

Ravi P. Gupta
Department of Earth Sciences, Indian Institute of Technology Roorkee, Roorkee, UA, India

Definition

When snowfall occurs in a condition such that the temperature of the troposphere (the lowermost layer of the earth's atmosphere which contains most of the atmospheric water vapor) and the temperature of the earth's surface, both, are below freezing point, then in that condition the snow falling on the earth's surface is crystalline, granular, flaky material with dendritic or highly branched crystals possessing very low relative density. This is essentially dry snow. Such conditions of snowfall generally occur during winter months at high altitudes and high latitudes. The dry snow comprises of solid crystals with no melt or moisture film on crystal surfaces and has a minimal amount of water content. Snow is considered wet or dry based on the water content, that is, "snow to liquid equivalent," a ratio used to indicate the amount of liquid water produced as snow melts. Wet snow has this ratio as usually 10:1 (means 10 cm of snow produces 1 cm of melt water), whereas for dry snow the ratio could 30:1, implying presence of more air pockets in the (dry) snow medium. Dry snow has a very high reflectance, reflecting more than 90% of the incident solar radiation. Further, it is not "sticky" or cohesive, and can be hardly

used for making snowballs or snowmen. Being non-cohesive, it is also susceptible to avalanches. The dry snow zone is the region where no melt occurs and is great for skiing.

DYE TRACER INVESTIGATIONS OF GLACIER HYDROLOGY

Peter Nienow
School of Geosciences, University of Edinburgh, Edinburgh, UK

Definition

Dye tracing. Dye tracing involves the input of a fluorescent dye into a hydrological system and subsequent detection of the dye after it has flowed through the system under investigation. Analysis of the dye breakthrough curve enables inferences to be made concerning the structure and flow conditions of the hydrological system that has been traced.

Introduction

Salt and dye tracers have been used for over a century to investigate glacial drainage systems. These tracers provide direct information on water flow characteristics between an input site, usually a freely-draining, ice-surface moulin or crevasse (Figure 1), and a detection site located on the proglacial stream close to the glacier snout. If detection of an internal drainage connection is the sole aim of a tracer test, the hydraulic properties of the tracer are unimportant. However, if the tracer is to be used for estimation of flow velocity or other quantitative parameters, it is essential that the hydraulic behavior of the tracer is equal or very similar to that of the water itself (Hotzl, 1990). Most modern applications of dye tracing are concerned with the quantitative analysis of dye breakthrough curves and therefore require advanced fluorometric equipment. Fluorescent dyes such as rhodamine and fluorescein are the most commonly used tracers, since they can be detected by a fluorometer at concentrations below 1 ppb upon emergence in the proglacial stream. Water samples are collected either manually or by pump or gravity-driven continuous flow (Fountain, 1993; Sharp et al., 1993). With the latter technique, dye concentration is usually recorded at regular intervals using automated data loggers. Dye concentration breakthrough curves can be analyzed to yield a number of parameters that can be related to the character of the glacier hydrological system that has been traced.

Hydrological flow parameters derived from tracer tests

Subglacial and englacial drainage systems are largely inaccessible. Glaciologists have therefore developed a range of remote techniques for determining the character of these systems including dye tracing in addition to investigations of bulk meltwater discharge and chemistry, proglacial bedrock characteristics, and borehole studies (Hubbard and Nienow, 1997). Dye tracing has been used to investigate glacier hydrology across a variety of glacial environments including temperate glaciers in the Alps (e.g., Behrens et al., 1975) and polythermal glaciers in the High Arctic (Bingham et al., 2005) and Greenland. Extensive tracer campaigns conducted over the course of a melt-season can be used to infer both temporal and spatial variations in subglacial drainage system characteristics (Hock and Hooke, 1993; Nienow et al., 1998). The parameters that can be derived from a suite of dye tracer tests to infer the structure and flow characteristics of glacier hydrological systems are outlined below:

Dye Tracer Investigations of Glacier Hydrology, Figure 1 Rhodamine dye flowing into a moulin during a tracer experiment on a glacier near the margin of the Greenland ice sheet.

- Internal drainage connections

  The simplest application of any fluid tracer is to provide positive evidence of the existence of a hydrological connection between a point of injection and a point of detection. Tracing of water for this purpose is clearly only of value when the routing of the water is unobservable. For these reasons, tracers have been used for many years to determine hydrological

connections in karst, groundwater, and subglacial drainage systems (Ford and Williams, 1989).

The earliest attempts to study glacial drainage connections using dye tracers involved the injection of dye into moulins and relied on the visual detection of dye emerging from portals at the glacier snout (Forel, 1898; Vallot and Vallot, 1900). This method of detection has been used more recently when advanced fluorometric equipment has been unavailable or when more than one dye has been used (e.g., Theakstone and Knudsen, 1981; Burkimsher, 1983). This simple technique allows a basic reconstruction of subglacial drainage pathways. If multiple streams are discharging water from a glacier and each is sampled for dye after an injection, it is possible if multiple injection sites are used, to determine whether the glacier is underlain by a number of discrete drainage catchment basins (Stenborg, 1969; Willis et al., 1990; Fountain, 1993; Sharp et al., 1993).

- Dye flow velocity

  A minimum estimate of the mean flow velocity of water during a tracer test can be obtained from the time elapsed between dye injection and peak concentration at the detection site and the straight-line distance between these two sites. The flow velocity through the englacial and subglacial drainage system is dependent on the character of the flow pathways via which the water has travelled. Return velocities from tracer tests made into moulins and boreholes have varied between 0.0031 m s^{-1} for a winter trace at Findelengletscher, Switzerland (Moeri and Leibundgut, 1986) and 1.8 m s^{-1} at Austre Okstindbreen, Norway (Theakstone and Knudsen, 1981).

  Rapid transit velocities of greater than 0.2 m s^{-1} are interpreted in terms of flow through hydraulically efficient channelized drainage systems (e.g., Stenborg, 1969; Behrens et al., 1975; Burkimsher, 1983). In contrast, lower through-flow velocities have usually been interpreted in terms of flow through an inefficient "distributed" hydrological system such as a linked-cavity configuration, a thin basal water film, or a permeable basal sediment layer (Theakstone and Knudsen, 1981; Iken and Bindschadler, 1986; Kamb, 1987; Willis et al., 1990). In some studies, velocities of less than 0.1 m s^{-1} have also been interpreted as flow through highly sinuous hydraulically inefficient anabranching channels (Seaberg et al., 1988: Hock and Hooke, 1993; Fountain, 1993).

- Velocity–discharge relationships

  If water discharge is monitored, then the mean cross-sectional area of a drainage system can be calculated by dividing that discharge by the mean flow velocity derived from a tracer test. With this cross-sectional area information, it is possible to use turbulent flow theory to calculate the expected flow velocity through a variety of alternative drainage configurations (Seaberg et al., 1988; Kohler, 1995). By comparing the predicted velocities with those determined from dye tracer experiments, inferences can be made about the likely character of the drainage pathways followed. Furthermore, by analyzing the relationship between velocity and discharge, inferences can be made about both the hydraulic geometry and the flow conditions in a drainage system (Leopold and Maddock, 1953; Seaberg et al., 1988; Willis et al., 1990; Hock and Hooke, 1993; Fountain, 1993; Nienow et al., 1996a; Schuler et al., 2003).

- Percentage dye recovery

  The percentage of dye recovered during a tracer test can be determined by multiplying the integral of the dye breakthrough curve by the proglacial stream discharge. Recoveries of less than 50% typically indicate storage of the tracer within the glacier's hydrological system (Theakstone and Knudsen, 1981). These returns are more likely in a hydrologically complex drainage system, since efficient channels route water rapidly, as a concentrated slug of dye, with little potential for storage. However, a number of non-hydrological variables may result in erroneous estimates of dye recovery and caution must be exercised when using this parameter for interpreting glacial drainage systems (Nienow, 1993). For example, loss of dye may result from sorption onto sediment surfaces (Bencala et al., 1983) while certain suspended sediments fluoresce at the same wavelength as the tracer causing a spurious increase in fluorometer reading resulting in apparent overestimation of the volume of dye recovered (Smart and Laidlaw, 1977).

- Dye dispersion

  The shape of a dye return curve is determined by dispersive processes that spread dye out during its passage through a flow system (Taylor, 1954; Fischer, 1968). This dispersion results from two main mechanisms: (i) advection in the fluid flow (mechanical dispersion) and (ii) molecular diffusion. Since these processes are controlled by flow hydraulics, which are themselves controlled by the structure of the flow path, the shape of a dye return curve may be interpreted in terms of the structure of the flow pathways followed by that water. An increasingly dispersed dye cloud can result from two main characteristics of flow: (i) an increase in the variation of flow velocities within the drainage routeway and (ii) an increase in the volume of storage locations or immobile zones along the course of the drainage routeway. In all glacial flow systems, both characteristics cause dispersion of a dye cloud although in general, dispersion resulting from variations in flow velocity dominates, particularly in channelized systems, while dispersion resulting from storage retardation becomes increasingly significant in hydraulically inefficient flow systems.

While the shape of a dye return curve can provide a wealth of information on the structure of the drainage system which has generated the curve, visual interpretations of return curve shapes are highly subjective. An objective

method of describing the properties of return curves requires physically meaningful and empirically reproducible results. The most commonly used parameter derived from the shape of breakthrough curves is *dispersivity* (d), in m, which represents the rate of spreading of a tracer cloud (described by the *dispersion coefficient, D,* in $m^2\ s^{-1}$) relative to the rate of advection of the dye or salt during transit through a flow system (u), in $m\ s^{-1}$ (Fischer, 1968; Seaberg et al., 1988; Hock and Hooke, 1993):

$$d = D/u \tag{1}$$

The most commonly adopted form of D in glaciology is that derived by Brugman (1986) as:

$$D = \frac{\left(x^2(t_m - t_i)^2\right)}{(4t_m t_i \ln(2(t_m/t_i)^{0.5}))} \tag{2}$$

In general, more dispersed tracer returns ($d > \sim 10$ m) reflect inefficient drainage pathways (e.g., Seaberg et al., 1988; Nienow et al., 1998), while highly-peaked, less dispersed ($d < 10$ m) curves are interpreted in terms of flow through efficient channels (e.g., Burkimsher, 1983). Irregularities on the rising or falling limbs of breakthrough curves (including the occurrence of multiple tracer peaks) are interpreted in terms of flow divergence in the drainage pathways (Collins, 1982).

The interpretation of dye return curve shapes is the most complex area of dye tracer analysis and the one most susceptible to conflicting interpretations between different workers. However, to ensure that the parameters derived from the return curves are accurate and comparable between tests, a minimum sampling interval should be used which is no greater than *tm*/16 where *tm* is the time to peak dye concentration (Nienow et al., 1996b).

Tracer investigations in the snowpack and firn

While dye tracing techniques have been most commonly used in glacial environments for investigating the routing and flow characteristics of englacial and subglacial drainage systems, the same methods can be applied for investigating the hydrology of the snowpack (Gerdel, 1954; Schneebeli, 1995, Kattelmann and Dozier, 1999) and firn. Observations of the movement of dye-stained water through an alpine snowpack reveal qualitatively the complexity of flow patterns and the influence of ice layers and preferential flow zones in controlling percolation through the snowpack, and fluorometric techniques can be used to yield flow rates for percolation through the snowpack of between 0.13 and 0.49 $m\ h^{-1}$ (Campbell et al., 2006). The changing form of dye-return curves can also be used to determine changes in percolation rates over the course of a melt season and thus in the efficiency with which the snowpack transmits meltwater (Campbell et al., 2006).

A more recent application of tracers has been to determine, through visual observation of shallow ice cores, the depths to which summer meltwaters percolate before refreezing in the percolation zone of the firn on a High Arctic ice cap. Rhodamine dye was spread over the surface of the snowpack in spring, and cores were retrieved in Autumn down to depths of ~3m to visually determine the depths to which the surface meltwaters had percolated prior to refreezing (Bell et al., 2008).

Summary

Dye tracing provides a simple, inexpensive, and valuable technique for investigating glacial drainage systems which is today usually reliant on the use of a fluorometer which can detect dye in concentrations as low as 0.05 ppb. This equipment provides the potential for obtaining extremely detailed information on both the routing of water through and flow conditions within a glacial drainage system. The raw data which can be obtained from tracer tests enable the investigator to determine (i) the portals at which dye emerges from the system; (ii) the water flow velocities through the system; (iii) the shape of the dye return curves emerging from the system; and in conjunction with discharge; (iv) the proportion of dye recovered after an injection into the system; and (v) the hydraulic geometry and the flow conditions in the drainage system.

From these data, a considerable amount of information can therefore be gained about the drainage conditions through and under a glacier. Furthermore, since dye can be injected at any point where water enters the englacial drainage system, extensive spatial coverage can be provided by tracer tests on any given glacier. Tests can also be carried out over the course of a melt-season to provide evidence for the temporal evolution of subglacial drainage systems (Hock and Hooke, 1993; Nienow et al., 1998; Bingham et al., 2005). Despite this excellent spatial and temporal resolution, however, dye breakthrough curves can only be interpreted in terms of the net influence of the flow pathways separating the injection and detection sites. The technique therefore provides only limited evidence for spatial variability in the flow pathways followed by dye clouds.

Definition

Dynamics of glaciers are the resulting ice flow processes caused by the interplay of the physical mechanism causing a glacier to move (gravity) and forces resisting this movement (e.g., friction). Alternatively it can be defined as a glacier's response to climate change or to other external or internal forcings.

Internal deformation (or *creep*) is the movement of an ice mass through the deformation of glacier ice itself.

Basal motion is the movement of ice relative to the substrate, either through basal sliding or through bed deformation of a soft sedimentary substrate (till), or both.

Basal sliding is the movement of ice along the bed, as a result of *enhanced creep*, *regelation* (melting of basal ice under higher pressure on the upstream side of bed obstacles, and refreezing of this ice in the lower pressure regime on the lee side of these obstacles), or complete *decoupling* from the bed.

Soft bed deformation is the movement of the subglacial sediments (substrate) causing some of the forward motion of a glacier or ice sheet.

Normal stress is the force per unit area that is applied perpendicular to a plane. In the case of glacier dynamics, the normal stress is usually considered the stress acting on the ice through vertical loading.

Shear stress is the force per unit area that is applied parallel or tangential to a plane. In the case of glacier dynamics it is most often the force that is applied to glacier ice due to the ice surface slope.

Yield stress is the stress at which a material begins to deform plastically. At stresses equal or higher than the yield stress the deformation is instantaneous and irreversible, and the resulting stress is limited to the yield stress. The yield stress is dependent on the *yield strength* of a material: yield strength of glacier ice is generally much higher than that of till (100 ± 50 kPa and 2–90 kPa, respectively: Paterson, 1994; Murray, 1997).

Longitudinal stress is the force per unit area that is pushing or pulling on an ice mass in the along-flow direction.

The *constitutive relationship* relates applied stress to deformation rate (also called stress–strain relationship). This relationship is dependent on the rheology of the specific material. The *rheology of ice* is the way glacier ice responds (deforms/strains) to applied stress.

Anisotropy is the property of ice that causes the deformation rate to differ, depending on the direction of applied stress. Anisotropy mainly results from the stress loading history, which can orient individual ice crystals. Anisotropy results in so-called ice *fabric* (preferential orientation of the ice crystals).

Ice overburden pressure (or normal pressure) is the force exerted by the ice on the substrate due to its weight (expressed as ρgH: ice density × gravitational acceleration × ice thickness).

Hydrostatic pressure is the magnitude at which the basal water pressure exactly counteracts the ice overburden pressure. If the basal water pressure exceeds the hydrostatic pressure, the ice can be lifted off its bed (effectively floating the glacier).

Introduction

Glaciers are like large rivers of ice that slowly make their way downslope under the pull of gravity. They move because the surplus ice mass from years of accumulation in the upper parts of the glacier (the accumulation area) needs to be compensated by outflow of ice to the lower parts of the glacier (ablation area), where ice loss through melting and calving needs to be replenished by the inflow of ice. If this redistribution of ice mass would not take place a glacier would become steeper infinitely. Theoretically, glaciers discharge ice from the accumulation area to the ablation area through movement in order to maintain a steady-state glacier profile: this is the balance flux. The corresponding velocity, the balance velocity, is controlled by mass balance conditions and glacier geometry (Clarke, 1987a). However, because glacier motion is a delayed effect of the amount of accumulation received, with individual glacier response time depending on glacier type and size, mass balance fluctuations result in asynchronous, filtered and time-lagged decadal to century-long velocity fluctuations and corresponding advance and retreat rates (e.g., Jóhannesson et al., 1989). Although ice masses often flow with speeds corresponding to their balance velocities, in some glaciers the balance flux is much lower or higher than the measured fluxes. If this occurs over a prolonged time, glacier depletion (mass wasting) or pulsating behavior with sudden switches between slow and fast flow can occur. Pulsating glaciers include unstable tidewater glaciers, ice streams, and surge-type (Clarke, 1987a).

The velocity and motion in glaciers and ice sheets is determined by the geometry of the ice (ice thickness, surface slope) and by its physical properties (temperature, impurities, density), by the valley shape or lack of valley walls in the case of ice sheets, by the conditions at the glacier bed (frozen versus thawed bed, hard bedrock versus soft deformable substrate, type of subglacial drainage system), by the amount of ice that is floating in adjacent water (lake, sea or ocean) as a floating tongue or an ice shelf, and by the average accumulation and ablation rates (the surface mass balance, or net amount of snow received and melted over several years). Dependent on all of these factors, average ice flow velocities for valley glaciers are generally less than a few hundreds of meters per year (m a^{-1}) and for outlet glaciers up to several kilometers per year (Paterson, 1994). Most glaciers have seasonal velocity fluctuations, with the faster flow occurring in the early melt season when the available large quantities of meltwater cannot be discharged efficiently yet because the subglacial drainage systems have not been fully developed. An enigma that has been part of research into glacier dynamics for a long time is the behavior of pulsating glaciers, and in particular that of surging glaciers and ice streams (Meier and Post, 1969; Harrison and Post,

2003). Glacier surging is a quasi-periodic oscillation between long periods (tens to hundreds of years) of slow flow or quiescence, and shorter periods of typically 10–1,000 times faster flow or surge. During a surge, the flow velocity increases abruptly, and fast flow is maintained over some time and over a wide area. The switch from slow to fast flow is an internally triggered ice flow instability, reflecting sudden changes within the glacier system. These changes can sometimes be associated with external factors (e.g., weather, climate, and earthquakes), but only if the glacier system is already close to a critical threshold.

Because glaciers move, they scrape and pluck the landscape causing bedrock erosion. This material is then transported by the glaciers and deposited hundreds of meters to over a thousand kilometers downglacier, leaving layers of glacial sediment (till), which are sometimes molded or pushed up into pronounced landforms (e.g., moraines, flutes, etc.). Moving ice is therefore a geomorphological agent altering the landscape. Additionally, glaciofluvial, glaciolacustrine and iceberg calving action can alter the landscape as well. Further, thick ice masses (from hundreds of meters to several kilometers in thickness for present and past ice sheets) isostatically depress the asthenosphere and overlying lithosphere up to about one-third of the ice thickness, which is followed by isostatic rebound of the crust after the ice thins or completely melts away. This effect is lagging behind the growth and shrinkage of ice sheets, and regions under the former Pleistocene ice sheets still experience differential uplift, affecting relative sea level in those regions.

Historical perspective

The first scientist to measure the movement of a glacier was Franz Josef Hugi, who built a rock hut on the medial moraine of Unteraargletcher in the Swiss Alps. Hugi visually observed his hut to have moved several hundreds of meters between 1827 and 1836 (Clarke, 1987b). In 1938, Louis Agassiz started a field campaign drilling holes in the ice of Unteraargletcher, and in 1842 James D. Forbes, who had joined Agassiz in the field in 1941 but with whom he had fallen out after he had published his results independently, had started his measurements using a theodolite on Mer de Glace, France. Both Agassiz and Forbes, as well as eighteenth- and nineteenth-century physicists, mathematicians, chemists, and geologists, including Horace de Saussure, John Tyndall, Lord Kelvin, William Hopkins, and Harry Reid, speculated about the mechanisms of movement, and several theories were developed (Clarke, 1987b). Although most of these theories were untenable, important observations included that (a) ice behaves both in a brittle and viscous way, (b) ice is layered, (c) ice velocity at the surface of a glacier may be submergent or emergent rather than parallel to the ice surface, (d) ice moves both through plastic deformation and sliding along the base, (e) the force driving glacier movement is opposed by a resisting shearing force, and (f) ice deformation is temperature dependent (e.g., Mathews, 1870).

Although several early twentieth century scientists worked on the properties of ice, it was not until the mathematical work by Nye (1951, 1957) and experimental work by Glen (1952, 1955) that a generalized flow law was developed for the creep, or internal deformation, of glacier ice. This law, known as "Glen's Flow Law" is to this day being used by glaciologists, although it has been adjusted for cases outside the temperature and stress regimes that it was originally tested for, as well as to account for a range of glacier ice properties (impurities, water, and anisotropy) (see Marshall, 2005). Also in that period, Shumskii (summarized in Shumskii, 1964) extensively studied the geochemistry and geophysics of glacier ice, Weertman (1957) and Lliboutry (1958) recognized the two main processes of basal sliding (regelation and enhanced creep) and developed a "sliding law," and Ahlmann (1948) executed field studies to link climate change to glacier fluctuations. Not until a decade later, the important roles of water pressure and cavitation in the process of sliding were identified (Lliboutry, 1968), which led to mathematical theories on how switches in the subglacial drainage system control sliding speed and related flow instabilities (Iken, 1981; Bindschadler, 1983; Kamb, 1987). A *paradigm shift* (Boulton, 1986) in thinking about ice flow elucidated the importance of motion within subglacial soft deformable substrate (till) in the overall motion of glaciers and ice sheets (Blankenship et al., 1986; Alley et al., 1986), and led to the development of a first (viscous) till rheology (Boulton and Hindmarsh, 1987). While laboratory experiments and field observations have now led to the development of a plastic till rheology, the viscous rheology is still occasionally used because of its simplicity. We now also have a much better understanding of the mechanical and hydraulic properties of till (Clarke, 1987c), of till discontinuity and heterogeneity causing sticky spots (Alley, 1993), of the effects of frozen till on ice flow (Murray et al., 2000), and some have observed that till deformation is not as widespread and pervasive as originally proposed (e.g., Piotrowski et al., 2001 and 2004).

On a larger scale, the flow and response of glaciers, and in particular ice sheets, have been explored using mathematical and numerical (computer) models, starting with the work of Nye (1965) through works of Budd (e.g., Budd and Jenssen, 1971) using numerical techniques, and Oerlemans (1980) and Pollard (1982) on glacial cycles, and continuously involving more complex processes, including fast flow in ice streams, flow of marine ice sheets and ice shelves, the role of shear margins, calving, subglacial lakes, and the role of thermomechanical coupling and longitudinal stresses in ice flow (overviews in Hutter, 1983; Hindmarsh, 1997; Hughes, 1998; Van der Veen, 1999; Hindmarsh, 2004; Marshall, 2005; Pattyn et al., 2008). Lastly, the developments and increased use

of remote sensing and geophysical techniques in glaciology over the last half century have led and continue to lead to a more detailed understanding of glacier dynamics (see e.g., Clarke, 1987b; Bingham et al., 2010).

Basic principles: force balance and constitutive relationship

Glaciers flow due to the force of gravity pulling them down because of their weight. The rates of ice flow are dependent on the stresses that act on a glacier, on the way in which ice can deform (creep) and whether or not, and how, a glacier can slide over its bed. Glacier flow can be described with a force-balance equation (as accelerations are negligible), where the gravitational driving stress is balanced by a resistive stress (or stresses). The gravitational driving stress is determined by the gravitational acceleration, the average density of glacier ice, and the ice thickness and surface slope of a glacier. Thickening of the accumulation area and thinning in the ablation area result in a steeper surface slope, increasing the gravitational driving stress. Glacier flow is therefore intricately related to a glacier's surface mass balance. On most (grounded) glaciers, resistive stresses act mainly at the base of the glacier in the form of *basal drag*, but can also include *lateral drag* from the valley walls or shear margins (in the case of ice streams in an ice sheet), and *dynamical resistance* to flow through pulling and pushing due to longitudinal stress gradients within the ice.

In the most simple case, the gravitational driving stress of a glacier is compensated by the basal shear stress (basal drag). This basal shear stress, τ (in Pa), is related to glacier thickness, the steepness of the surface slope, and the shape of the glacier valley, which for a rectangular section in a glacier equals:

$$\tau = f\rho g H \sin\alpha, \tag{1}$$

where ρ is the density of ice (830–917 kg m^{-3}: the maximum in this range is usually taken as a standard and represents bubble-free glacier ice at depth), g the gravitational acceleration (9.8 m s^{-2}), H the ice thickness (m), α the ice thickness gradient (dH/dx) which equals the ice surface slope on a horizontal bed, and f a dimensionless shape factor related to the glacier profile and valley shape (Paterson, 1994). Typical values for basal shear stress are ~10 kPa for ice streams and ~100 kPa for valley glaciers (Paterson, 1994). The shape factor (f) is a dimensionless term included to represent friction along the bed as a fraction of the net basal drag, which is one of the driving stresses. In valley glaciers, however, part of the driving stresses is resistance by lateral drag or friction along the valley walls. Therefore, f can be expressed as the ratio between the "hydraulic radius" (defined as the cross-sectional area of the glacier divided by the "wetted perimeter" or the length of the glacier/ground interface), and the centerline ice thickness (Nye, 1965). Theoretically f can be between 0 and 1, but the usual range is between 0.7 and 0.9 for valley glaciers. A shape factor of $f = 1$ is for an infinitely wide glacier (an ice sheet), while a very low ratio (e.g., $f = 0.6$) is for a glacier in a deep narrow valley. Shape factors can be easily calculated from the ratio (W) between the half-width of a glacier and its ice thickness at the centerline, and a range of values are given in Paterson (1994).

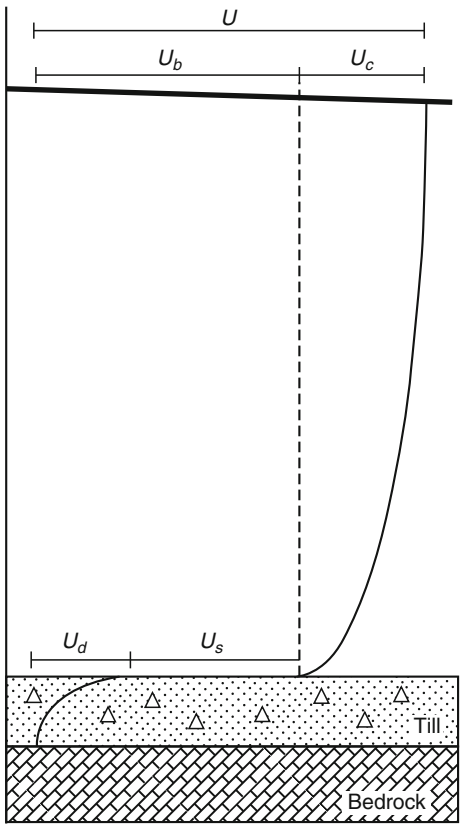
There are some extrapolations to this simple case of the force balance, to account for cases where the gravitational driving stress is not balanced by the basal shear stress alone. For scales where basal shear stress is calculated from ice thickness and surface slopes averaged over distances equal or larger than the ice thickness (the so-called shallow ice approximation or SIA: see e.g., Paterson, 1994), Equation 1 is a good approximation. However, for shorter distances, longitudinal stresses that act within the glacier system need to be included. If these longitudinal stresses are unbalanced (i.e., they are "pushing" or "pulling"), then the basal shear stress can be significantly larger or smaller than in Equation 1.

The three major components of ice flow

In response to the driving stress, glaciers can move due to three independent ice flow processes: (1) internal deformation (creep), (2) basal sliding, and (3) soft bed deformation. These components contribute, sometimes in ensemble, to the overall movement of a glacier. While all glaciers move due to creep flow, only glaciers that are not frozen to their beds (temperate and polythermal glaciers) demonstrate sliding as a major component, and only glaciers that are underlain by soft deformable substrate (till) experience bed deformation. Where sliding and/or bed deformation are activated, these factors often contribute well over 50% of the total velocity measured at the glacier surface, and are orders of magnitude greater than internal deformation velocities (e.g., Boulton and Hindmarsh, 1987). The net ice flow measured at the glacier surface (U) can be described as the sum of deformation velocity (creep velocity), sliding velocity, and bed deformation velocity (Figure 1: $U = U_c + U_s + U_d$), where the last two terms are sometimes combined as basal motion (U_b). Where glaciers move predominantly through internal deformation, the velocity decreases as a fourth-order polynomial with depth, from a maximum velocity at the glacier surface to almost zero at the base (Figure 1: U_c). For glaciers dominated by internal deformation, the transverse velocity profile (velocity distribution across the glacier) has a parabolic shape (with maximum velocities in the center of the valley and tapering off toward the valley walls; Figure 2), whereas for glaciers dominated by basal motion, a more uniform (flat) transverse velocity profile results. The extreme case of the latter is called "plug flow" (Sharp, 1988), and has well-defined shear margins on either side at the transitions between stationary rock/ice and moving ice (Figure 2). Plug flow is common in tidewater glacier tongues and glaciers that are surging. The descriptions of the different flow mechanisms that follow will help explain these differences in velocity profiles.

Internal deformation

Glacier ice is polycrystalline and behaves as a nonlinear visco-plastic material in the stress regime commonly found in glaciers. If large stresses are applied rapidly glacier ice can break, which results in crevasses (this is clearly visible in many glaciers and ice sheets, as well as in icebergs that are breaking off, and in rifts that form in ice shelves). However, if glacier ice is subject to stresses that are applied slowly and over a long time, as is the case inside a glacier, then the ice becomes permanently deformed in a plastic rather than a brittle way. The range of stresses experienced in normal glacier flow is 50–200 kPa (Paterson, 1994). The ice deformation rate (or shear strain rate) under a constant shear stress is initially high but then tapers off to a constant value, also called the secondary strain rate. The exact value of the constant shear strain rate is dependent on the amount of stress applied, on the ice temperature, on the stress history, and on impurities within the ice.



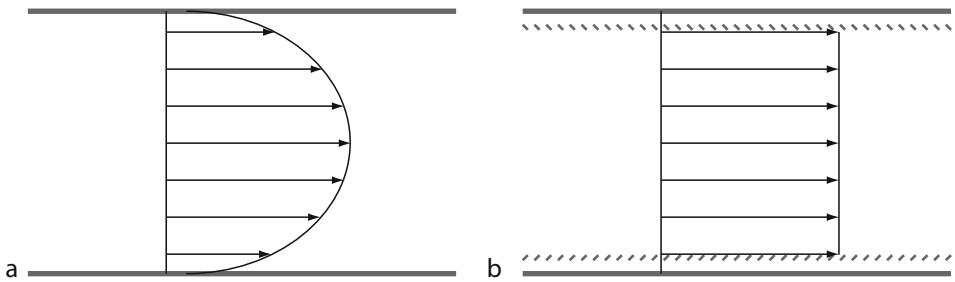
Dynamics of Glaciers, Figure 1 Cross section of vertical velocity distribution and surface velocity (U) in a glacier with the three components of ice motion: internal deformation (U_c), basal sliding (U_s), and bed deformation (U_d). U_s and U_d combined can also be denoted as basal motion (U_b).

Stress–strain relationship: Glen's Flow Law

Through laboratory experiments where the deformation rate was measured in a block of ice subject to a range of stresses and a range of temperatures, Glen (1955) derived the constitutive relationship of glacier ice (the relation between secondary shear strain rate, $\dot{\varepsilon}$, and applied stress, τ). This empirical flow law for ice, known as *Glen's Flow Law,* in steady-state ice creep, is expressed as:

$$\dot{\varepsilon} = A\tau^n, \tag{2}$$

where A is the ice "*softness parameter*" depending on ice temperature and activation energy according to the Arrhenius relation (Glen, 1955). Rigsby (1958) showed that parameter A is not affected by hydrostatic pressure, provided that the temperature is taken relative to the freezing point (hydrostatic pressure depresses the freezing point). A ranges from 10^{-14} to 10^{-17} s^{-1} kPa^{-3} and decreases log-linearly with temperature for temperatures well below the freezing point, but at a higher rate close to the freezing point (Paterson, 1994). The exponent n is a constant that depends on applied stress and is in the range $1.5 < n < 4.2$ with a mean of $\sim$3 for temperate valley glaciers (Paterson, 1994). Thus, for temperate valley glaciers the deformation rate is proportional to the vertical shear stress cubed, which is a function of depth. However, from laboratory experiments, borehole deformation measurements, and ice sheet models it was derived that for the low stress (<40 kPa) environments in central regions of polar ice sheets the exponent n is closer to 1 or 2 (e.g., Pettit and Waddington, 2003). The temperature dependence of A and n reflects the fact that ice is stiffer at lower



Dynamics of Glaciers, Figure 2 Diagrams of two end-members of transverse velocity profiles in glaciers (**a**) Approximate parabolic flow, and (**b**) plug flow. Hatched lines represent shear margins.

temperatures: cooling ice from −10°C to −25°C reduces the internal deformation by a factor of 5 (Paterson, 1994). Instead of parameter A, some use B or β, where $B = A^{-n}$. Because it is now well known that complex microscale processes influence ice deformation, recent advances have been made to improve on Glen's Flow Law and to include anisotropy, grain size evolution, recrystallization, grain-boundary migration, and the deformation rate of glacier ice outside the commonly tested stress and temperature ranges. See Pettit and Waddington (2003) and Schulson and Duval (2009) for overviews of these efforts.

Deformation velocity (creep)

By adding up (integrating) the shear strain throughout the thickness of a glacier, a deformation velocity profile can be produced. The sum of all these layers of ice deforming is expressed as the velocity at the glacier surface. The vertically averaged horizontal deformation (creep) flow velocity (U_c) can be described as:

$$U_c = c_I H \tau^n, \tag{3}$$

where the constant c_I depends on the values for A and n from Glen's Flow Law (Equation 2), H is ice thickness, and τ is basal shear stress (Equation 1) (Kamb and Echelmeyer, 1987). The geometrical controls in this relationship are clear: steeper and thicker glaciers have a larger internal deformation rate than thin ones with shallow slopes. It can also be seen that the relation between applied stress and glacier flow is nonlinear, and approximately proportional to the fourth power of ice thickness (H^4) and the third power of ice surface slope (α^3). Therefore, if the surface mass balance of a glacier changes that glacier's ice thickness or surface slope, or both, very large changes in ice flow solely due to the mechanism of internal deformation can result.

Basal sliding

When glaciers are not frozen to the substrate (bedrock or sediments) additional movement may occur through glaciers sliding over their beds.

Sliding without cavitation

Two processes, first recognized by Weertman (1957), are fundamental to the mechanism of glacier sliding without cavitation or ice-substrate separation: enhanced creep and regelation. Enhanced creep is the result of bedrock protuberances causing a local increase in stress on the upstream side of these bumps, which can increase the amount of creep around such obstacles. The process of regelation results from local increases in pressure on the upstream sides of bedrock bumps that lower the melting point and cause some ice to melt, which then moves to the leeside of the bump where the pressure is lower and where refreezing occurs. While enhanced creep is most efficient for large bedrock obstacles, regelation is most efficient with small obstacles. Bed roughness is therefore an important factor controlling this process.

Sliding with cavitation

Enhanced creep and regelation can occur without bed separation. However, high water pressures can cause cavities (voids) to form on the leeside of obstacles. This cavitation can cause sliding with bed separation if the water pressures in these cavities are high enough to lift the glacier partly off its bed, which drastically reduces basal friction. The importance of cavitation in controlling sliding velocity was emphasized by Lliboutry (1968). He postulated that glacier sliding would be a multivalued function of the basal shear stress and effective pressure. A multivalued sliding law has two "modes" of sliding for the same basal shear stress. According to present understanding, the "slow mode" is for subglacial drainage through conduits (Röthlisberger channels), and the "fast mode" for drainage through linked cavities. Given the water pressure–water flux relation of conduit systems is inverse and that of linked-cavity systems is direct, the effective pressures are generally low in conduit systems, but can be close to overburden pressure in linked-cavity systems, lifting the glacier off its bed causing bed separation (Kamb, 1987). Switches in these two subglacial drainage systems can therefore cause sudden changes in sliding velocity that are directly related to the amount of bed coupling (Lliboutry, 1968; Bindschadler, 1983; Kamb, 1987). These types of switches have been observed as a result of seasonal changes in water input to the glacier (Iken, 1981) as well as in the sudden changes in flow velocity related to glacier surging (Kamb et al., 1985; Kamb, 1987).

Sliding velocity

Basal boundary conditions for the sliding velocity (U_s) are the basal shear stress (τ) and the effective pressure (N_e), which is the difference between ice overburden pressure ($p_i = \rho g H$) and water pressure (p_w). Water pressure is dependent on the pressure–flux relations in the subglacial drainage system. Efficient fast draining Röthlisberger channel systems generally have low water pressure while discharging large volumes of water, while slow distributed subglacial drainage systems (e.g., linked-cavity systems) have high water pressure and low water flux. The lower the effective pressure the higher the sliding velocity. At water pressures exceeding the ice overburden pressure the glacier can start to "float," which means that complete ice-bed decoupling occurs. A general form for the sliding velocity flow law is:

$$U_s = \frac{k \tau^m}{N_e} \tag{4}$$

where k and m are constants (k is a function of bed roughness, and $m > n$) and N_e is the effective normal pressure (Bindschadler, 1983). However, the commonly used sliding relationships neither take into account realistic hard bed morphologies (bumps of different sizes and shapes) nor sliding over soft beds (e.g., Tulaczyk, 1999). Recent attempts have been made to improve the mathematical description of sliding over irregular beds, where both

drowning of bed features and cavitation play a role in the sliding velocity (e.g., Schoof, 2005). This work has also confirmed the theoretical upper limit to sliding velocity, the "Iken's bound" (after Iken, 1981), for general bed geometries. Further complications to the general sliding laws, such as Equation 4, are that they ignore the effects of frictional forces between rock particles frozen in the basal ice and the underlying bedrock (Hallet, 1981; Iverson et al., 2003), and the effects of chemical reactions in bedrock or in impurities within the basal ice due to melting and refreezing (Hallet, 1976). Additionally, the sliding speed itself controls the amount of basal sliding, as faster flow produces more frictional heat.

Soft bed deformation

Subglacial till is a non-sorted to poorly sorted mixture of unconsolidated sediments, ranging in size from boulders to clay. Thicknesses of till in the order of 1–20 m have been inferred under ice streams, outlets from ice caps, and glaciers. Because the finer sediments (clay to sand) lack cohesion and are almost frictionless, they can readily deform under applied shear stress if a large fraction of their pore space is filled with water under high pressure. Ice underlain by matrix-supported till is therefore likely to have soft bed deformation as a proportion of its basal motion. Where a glacier is underlain by such a soft deformable substrate, then, if the basal shear stress exceeds the yield strength of the till, some or all of the shear stress can be accommodated by bed deformation. The yield strength of till is highly dependent on the grain size distribution, the fractional water content and the water pressure within the till, and its deformation history. Low yield strength (as low as 2–10 kPa) has been reported for tills underlying present and past ice streams and outlets from ice caps (especially in Iceland), and the fast flow velocities of these ice masses at relatively low basal shear stresses (<50 kPa) have by some been attributed to the soft bed deformation mechanism in these subglacial tills (Alley et al., 1986; Blankenship et al., 1986). Although rapid bed deformation generally occurs under warm bedded glaciers, bed deformation can also play a role under polythermal glaciers, where the till can be partly or temporarily thawed (Murray, 1997).

Ice flow through bed deformation

Ice flow over a soft bed is often a combination of basal sliding and bed deformation, where the latter can be (a) pervasive and deep-seated (an entire till layer is involved), (b) through plowing at the ice-sediment or the sediment-bedrock interface, or (c) along internal stratigraphic boundaries (Fischer and Clarke, 1994; Murray, 1997; Kjær et al., 2006; Fleisher et al., 2006). The type and amount of bed deformation is dependent on till thickness, till composition, and water pressure. Because these factors can vary temporally as well as spatially, till is a complex and highly heterogeneous material and it is quite difficult to construct a constitutive relationship or general flow law for soft bed deformation. Most soft bed deformation flow laws assume an average deformability of till of a certain composition, which can be based on field measurements of till properties combined with ice flow velocities (e.g., Boulton and Hindmarsh, 1987), on empirical laboratory experiments with till samples (e.g., Iverson et al., 1998), or on mathematical treatments of till physics with specific designated properties (e.g., Fowler, 2003).

Although subglacial till is not a viscous material, a quasi-viscous constitutive relationship was proposed by Boulton and Hindmarsh (1987) ("the B–H rheology") on the basis of sparse field observations. This B–H rheology was later modified by Fowler and Walder (1993). The modified viscous B–H rheology is still occasionally used because of its simplicity, but laboratory experiments and field studies have proven that till behaves almost like a perfectly plastic material, but one where the deformation rate is dependent on the amount of stress (Iverson et al., 1998; Tulaczyk et al., 2000). This is sometimes expressed as an exponential quasi-viscous flow law of the form

$$\dot{\varepsilon} = A_2 \mathrm{e}^{\frac{\tau}{b\tau_0}}, \tag{5}$$

where A_2 is a constant related to a reference strain rate, b a constant that is dependent on pre-consolidation stresses and texture of the till, and τ_0 the stress taken at a reference shear strain rate (larger than the Mohr–Coulomb yield strength) (Hooke, 2005). This relationship implies that small increases in shear stress should result in large increases in till deformation, which is often related to unstable runaway flow of glaciers over soft deformable beds which in extreme cases could result in surges.

Piotrowski et al. (2001, 2004) recently argued that till deformation is not as widespread and pervasive as originally thought, and that so-called "sticky spots" appear to be the norm rather than the exception, at least under ice sheets. Sticky spots are patches where till is frozen or of increased stiffness or absent (e.g., bedrock protrudes), and influence the proportion of forward motion contributed to soft bed deformation (Alley, 1993; Murray et al., 2000; Kjær et al., 2006). These sticky spots are sometimes considered ephemeral in nature (i.e., that they can be created and destroyed in response to variations in subglacial water pressure, temperature, or through redistribution of till). An additional factor in the heterogeneity of soft bed deformation is the fact that cavitation over soft deformable sediments plays an important role both in the overall soft bed deformation velocity and in basal sliding over soft beds (e.g., Schoof, 2007).

Dynamic adjustments to variations in driving forces

Deviations from balance velocity result from changes in the driving forces and the resistive forces. Small perturbations in the driving forces such as in accumulation rate, basal conditions, subglacial hydrology (especially fluctuations in volume, pressure and distribution of meltwater), nonuniformities in the deformation rate and calving events

can initiate stress irregularities which may lead to short-term perturbations in flow speed (e.g., Hutter, 1983). Short-term perturbations in surface mass balance, for example, excess accumulation over some winter seasons, can be transmitted downglacier more rapidly in the form of "kinematic waves," which are topographic waves (bulges) that travel through the ice at rates much higher than the overall ice flow velocity. Kinematic wave theory was first applied to glaciology by Nye (1963), and further developed and used by many. At longer timescales, changes in driving forces can be caused by variations in surface mass balance related to a change in climate. This mechanism is called "climate forcing." As the adjustment to climate forcing is not instantaneous, but occurs according to a specific response time, glaciers are constantly adjusting to the large-scale variability in mass balance conditions and are in disequilibrium with their present mass balance. It is therefore complicated to deduce changes in surface mass balance (or indeed a climate signal) from changes in length of glaciers of different shapes and sizes worldwide (e.g., Oerlemans, 2005).

Ice flow adjustment to calving events and breakup of ice shelves can be quite instantaneous and significant, but can also have long-term effects. Floating ice, with virtually no basal shear stress, has a surface gradient approaching zero. This implies that stresses in ice shelves are generally low (<40 kPa, Paterson, 1994). The driving stress is partly compensated by the back pressure exerted by the frictional drag on the ice shelf edges (most ice shelves are confined in an embayment) and by basal drag on islands in the embayment (ice rises) (Menzies, 1995). Rapid changes in these systems have resulted in sudden collapse of ice shelves. Collapse of ice shelves in the Antarctic peninsula region due to regional warming of surface and ocean temperatures has lead to rapid adjustments upstream by increasing ice flow of the land-based glaciers that were once buttressed by those ice shelves, and has in some cases resulted in rapid retreat of these glaciers (Rignot, 2006). Through positive feedback, this retreat can then lead to sea-level rise, which may destabilize large parts of the (marine) West Antarctic ice sheet, which will lead to further retreat of the ice sheet. Reversely, positive feedback effects involving resistive stresses can also slow down glaciers: Catania et al. (2006) found from geophysical field measurements with ice-penetrating radar that the sudden stagnation of Kamb ice stream (Ice Stream C) was due to changes in basal conditions where reduced basal lubrication in the subglacial tills related to negative changes in water input and subsequent refreezing of the ice stream to its bed.

Because changes in mass balance influence ice thickness and glacier slope, glaciers respond dynamically to these changes. Dynamic adjustment to changes in mass balance due to climate forcing is important to understand because it can determine how sensitive a glacier is to climate change, and how fast it adjusts to such a change (response time).

Response time

Response time is the observed delay in the dynamic response of glaciers and ice sheets to longer-term changes in climate and is usually measured as length and/or volume adjustment to a new perturbed state. Response time is usually expressed as the sum of reaction time, or delay between the change in mass balance and initiation of a change, and adjustment time, the subsequent time it takes to adjust to the change in mass balance. Response times generally range from a few decades to a century for alpine glaciers and from centuries to millennia for ice sheets. In general, glacier with a steeper mass balance gradient (e.g., temperate maritime glaciers) have higher balance velocities (or turnover rates) than glaciers in continental regions where the precipitations rates are much lower (if their ablation rates are not extreme), and glaciers with higher turnover rates tend to respond faster to a given climate forcing. Further, glaciers with contrasting hypsometries (e.g., top-heavy, equidimensional, bottom-heavy) appear to have intrinsically different response times (Furbish and Andrews, 1984), and it is also clear that thermal regime can directly affect glacier response (e.g., Hutter, 1993). Therefore, glaciers with different geometry show different net balance histories for the same climate forcing. These observations led to research in individual response time of glaciers of different sizes and types, using principles of the kinematic wave theory (Nye, 1965), and the requirement of mass continuity and the height mass balance feedback (Jóhannesson et al., 1989; Oerlemans, 1989; Haeberli and Hoelzle, 1995). This research is done both by analytical and numerical modeling and by using direct observations of glacier length and/or volume changes in a variety of regions around the world. Response time determined from modeling is usually a dynamic adjustment to a step-change in climate, whereas climate forcing in nature causes glaciers to respond to a complex history of climate variability. Therefore, glacier response time determined from both methods might elucidate slightly different combinations of controls on response time.

Instrumental mathematical research by Jóhannesson et al. (1989) showed that volume response time can be expressed in terms of the ratio between the characteristic glacier thickness and the balance rate at the glacier terminus, in which case the response time is independent of terminus dynamics, which is contrary to that originally suggested using the kinematic wave theory (Nye, 1965). Subsequent research into volume and length response times has included the influence of bed slope, balance gradient, glacier size, and average surface elevation (e.g., Bahr et al., 1998; Harrison et al., 2001; Oerlemans, 2008). Generally, large glaciers, with gentle slopes and small balance gradients have longer response times than small glaciers with steep gradients and large balance gradients, thus response time is inversely proportional to both bed slope and balance gradient (Oerlemans, 2008). Therefore, arctic glaciers have a longer response time than

mid-latitude glaciers, and maritime glaciers a shorter response time than continental glaciers of the same size. Further, when large spatial and temporal scales are considered (>50 years) temperature is a much more important driving force than precipitation, and response time can be scaled according to glacier length, slope, and average annual precipitation (Oerlemans, 2005).

Response time research based on observed glacier terminus and area behavior has revealed many of the controls mentioned above. On the basis of three typical response patterns of glaciers in the North Cascades since the Little Ice Age, Pelto and Hedlund (2001) concluded that glacier slope, terminus velocity, average thickness, and accumulation rate determine response time and climate sensitivity. In their dataset, the reaction time, or delay between the change in mass balance and initiation of a change, was 4–16 years, while the response time or full adjustment to that change was 20–100 years, where glaciers with steeper slopes were on the lower end of this range, and glaciers with shallower slopes on the upper end. Hoelzle et al. (2003) showed that specific combinations of glacier size and slope (proxies for basal shear stress) in the Swiss Alps determined response to climatic forcing, with small steep glaciers showing high frequency variability with low amplitude, and large shallow glaciers showing low frequency response with high amplitude. This concurred with the terminus behavior of glaciers worldwide, where glaciers larger than 8 km with shallow slopes show greater retreat than smaller glaciers (Hoelzle et al., 2003). Using data from the World Glacier Inventory and assuming that glacier area is always symmetrically distributed around the ELA (here ELA = median elevation) Raper and Braithwaite (2009) suggest that the volume response time depends directly upon the mean glacier thickness, and indirectly on glacier altitude range and vertical mass balance gradient. They therefore relate response time to glacier hypsometry, as was already suggested by Furbish and Andrews (1984). Raper and Braithwaite (2009) further show that the type of relation between volume response and glacier area is not straightforward, but rather dependent on geographical region: in the Arctic the relation is positive (response time increases with glacier area), in wet maritime regions it appear to be inverse, and in maritime subarctic regions they found that glacier area (size) is not related to response time.

A separate type of glacier response is that of glacier survival (Schwitter and Raymond, 1993; Pelto, 2010), which is the viability of a glacier to cease to exist under a certain climatic condition. Glacier survival response is dependent the ratio between glacier thinning in the accumulation zone and thinning at the terminus, where when this ratio is approximately 0.2–0.4 the glacier is thinning much more rapidly at the terminus than in the accumulation area and the glacier is retreating to a new stable position. However, if the ratio approaching 1 then the glacier is thinning at an equal rate everywhere and the glacier is unlikely to survive under unchanged climate conditions (Pelto, 2010).

Modeling ice dynamics

Many modern numerical glacier and ice sheet models include full thermomechanical coupling to calculate ice flow and response to mass balance. Although most models include the ice dynamic processes and mechanisms as outlined above, many are still based on the shallow ice approximation (SIA) and do not include longitudinal or transverse stress gradients or other complex mechanisms. Longitudinal and transverse stress gradients are particularly important for transition zones (e.g., between ice sheet and ice shelf flow or at the onset regions of ice streams). A relatively easy way to solve this has been to include an enhancement factor representing these longitudinal stresses (Marshall, 2005). However, models that include higher-order stress gradients (including longitudinal stresses), called higher-order models, are becoming more common. Some of these models apply the Full Stokes solution to resolve the stress field, following pioneering work by Blatter (1995). An additional improvement of application of the Full Stokes models to model the behavior of glaciers and ice sheets over time is that in the SIA models the response of glaciers to a climate forcing is almost immediate, whereas in Full Stokes models it is delayed, which is more realistic (Oerlemans, 2008). Efforts are also underway to couple models of subglacial hydrology directly with ice sheet models (see Marshall, 2005), and to understand and model the stability and ice flow over large Antarctic subglacial lakes, where lake drainage is a common feature (e.g., Wingham et al., 2006). Further, calving and the flow in ice shelves can now be incorporated in ice dynamics models of tidewater glaciers and ice sheets. Most of these models resolve the strain rate at the calving front that determines the fracture propagation of crevasses, while some include a calving criterion, such as the height of the calving cliff above the water or crevasse depth (e.g., Benn et al., 2007).

Summary

Glaciers move as a result of the gravitational driving force, and the processes of movement include internal deformation (usually expressed as secondary plastic creep), basal sliding, and soft bed deformation. Although these three processes can act in ensemble, the activation of the basal motion components is dependent on specific conditions such as temperature at the base of a glacier, bed morphology, subglacial water volume and pressure distribution (related to surface melt and configuration of the subglacial drainage system), as well as the presence, properties, and distribution of till. Therefore, with the same driving stress, glaciers can flow with vastly different speeds, ranging from a few meters per year to kilometers per year. It is obvious that subglacial water pressure, the volume and the distribution of water under a glacier or ice sheet, and in its underlying till, are of crucial importance in glacier dynamics, as these can reduce basal friction, and are directly linked to glacier sliding and bed deformation.

All in all, glaciers are complex systems and glacier dynamics are dependent on the properties of all materials involved (glacier ice, water, till, and bedrock), as well as on the configuration of the subsystems within, under, or in front of a glacier. Many of these factors exhibit temporal and/or spatial variability, such as ice temperature, hydrology, bed configuration, and till properties and distribution. Most relationships in glacier dynamics are nonlinear and therefore small changes in certain properties can have large "runaway" effects on the glacier movement. The dynamic adjustment of glacier geometry, as well as of other subsystems, to this movement can further rapidly change other properties, and can cause positive or negative feedback effects in the dynamic response of glaciers. It is therefore not surprising that individual glaciologists often specialize in specific aspects of the glacier system. A combination of field and remote sensing observations and measurements of glacier (sub)systems, empirical laboratory experiments (ice and till properties), and conceptual, mathematical analytical, and numerical models of glaciers and ice sheets is needed for the advancement of understanding of glacier dynamics. This understanding will then provide us with the tools to model and predict recent and future changes in these glacier systems, as well as to understand past ice sheet behaviour.

For a more detailed treatment of many aspects of the dynamics of glaciers, I refer to the following books, ranging from early expositions on ice flow to very advanced treatment of the physics of glaciers, and mathematical and numerical modeling of glaciers and ice sheets (Shumskii, 1964; Hutter, 1983; Drewry, 1986; Sharp, 1988; Paterson, 1994; Menzies, 1995; Hughes, 1998; Van der Veen, 1999; Hooke, 2005; Schulson and Duval, 2009).

ELONGATION RATIO

Vijay Kumar
National Institute of Hydrology, Roorkee, India

Definition

Elongation ratio is one of the main areal properties of basin. Areal properties express the overall plan form and dimensions of the basin. The elongation ratio (R_e) is defined by Schumm (1956) as the ratio of the diameter of a circle with the same area as that of the basin to the maximum basin length:

$$R_e = \frac{D_c}{L_b}$$

where

D_c, diameter of the circle with the same area as that of the basin
L_b, maximum basin length

The value of R_e approaches 1.0 as the shape of a drainage basin approaches to a circle. The ratio varies from 0.6 to 1.0 over a wide variety of climatic and geologic regimes. Typical values are close to 1.0 for regions of very low relief and are between 0.6 and 0.8 for regions of strong relief and steep ground slope.

The elongation ratio has important hydrological consequences because, in contrast to more circular catchments, precipitation delivered during a storm in highly elongated basins has to travel a wide range of distances to reach the basin outlet. The resulting delay in the arrival of a proportion of the storm flow consequently leads to a flattening of the storm hydrograph. Statistical analyses of the glacio-morphometric parameters of glaciers of Indian Himalayas by Ahmad et al. (2004) indicated that the higher relief area gradient and higher elongation ratio are the favorable morphometric condition for surviving the glaciations for a glacier. Elongated body is more influenced by surrounding reflected diffuse energy and vice versa.

ENGLACIAL CONDUIT

D. P. Dobhal
Wadia Institute of Himalayan Geology, Dehradun, Uttarakhand, India

Definition

Englacial conduits are the primary water transporting system from the surface of glacier to the base of a glacier. Supraglacial melt water either flows over the ice surface or descends vertically into the ice via holes called Moulin, where the water connects in the form of pipes or conduits of the englacial system. Moulin can go all the way to the bottom of the glacier. Englacial melt water is often connecting to sub-glacier flow system at the base of the glacier. Geometry and hydraulics of englacial conduits depends on the structure of the glacier.

ENGLACIAL PROCESSES

Andrew G. Fountain
Department of Geology, Portland State University, Portland, OR, USA

Definition

Englacial processes refer to the body of the glacier, or that region between the surface and the bed. In practice it refers to the ice, as opposed to firn, part of the englacial region away from the surfaces. Although no formal distance away from the surface is adopted, the term generally implies that portion of the ice body which is not directly affected by the atmosphere. In this view, the englacial region starts below average crevasse depth from the atmosphere-ice interface. At the bed, no implicit or explicit distance away from this interface exists.

Characteristics

The englacial region is generally considered to be entirely composed of ice, although rock debris, water-filled voids (in temperate glaciers), and air-filled voids may be present. Other impurities that may be scavenged by precipitation descending through the atmosphere, or that may be blown onto the snow surface in the accumulation zone become incorporated in the englacial region (Cuffey and Paterson, 2010). Ice sheets, and to some degree polar glaciers, are generally free of large englacial inclusions, as revealed by ice radar. Instead, reflecting horizons in ice sheets are common and can be followed for hundreds of kilometers (Figure 1; Siegert and Hodgkins, 2000; Welch and Jacobel, 2003). These horizons are thought to result from changes in snow (ice) chemistry due to volcanic or other dust events that cover the snow surface for long distances (Fujita et al., 1999). In contrast, temperate glaciers exhibit many reflectors and are thought to be water-filled inclusions of unknown origin (Figure 2; Murray et al., 2000). Indeed, the number density of these reflectors were such that early versions of ice radar technology could not penetrate significant distances into the ice and it wasn't until the application of long wavelength radar that the bottom of the glacier could be detected.

For the remainder of this discussion, we focus on the englacial characteristics of temperate glaciers. Investigations of the englacial region have relied strongly on theoretical considerations, and on three empirical approaches. First, ground penetrating radar, often called "ice radar," has been employed with great success in the polar ice sheets to explore the stratigraphic horizons (Figure 1). Application to temperate glaciers has been less successful due to the large number of radar-scatters in the ice, as previously discussed. The hope has been to unambiguously map the location and extent of englacial conduits and other hydraulic features with only a few successful efforts to date. Better success has been achieved in estimating the water fraction within the ice; however, this has not been independently tested. The second approach is to inject tracers using the travel time and dispersion to infer the geometry of the flow system. However, the tracer is typically routed through subglacial pathways before exiting the glacier clouding interpretations of englacial hydraulics. Finally, the most direct approach is to drill a borehole into a glacier and examine the englacial region directly using submersible video cameras. In addition, hydraulic tests can be conducted to measure the permeability of the region. Ground penetrating radar antennas have also been lowered in boreholes to better detect deep englacial structures.

In temperate glaciers the englacial region contains significant volumes of water. At the microscopic scale water is present along the grain boundaries where three or more ice crystals meet (Raymond and Harrison, 1975). Given that the ice is near its melting temperature in such glaciers,

thermodynamics considerations predict the presence of water at the boundaries. It was once thought that a network of passageways through the grain boundaries routed water from the glacier surface to bottom; however, the presence of air bubbles and the surface tension of water precludes significant water flux rates (<1 m s^{-1}) (Lliboutry, 1976). Nearly all rain and surface meltwater enters the body of the glacier through crevasses and moulins (e.g., Stenborg, 1973). Crevasses are the most important avenue for water because they are more numerous than moulins and are found over the entire glacier, whereas moulins are generally restricted to the ablation zone. Water-filled crevasses are not common, indicating that they efficiently route water into the body of the glacier. This conclusion is supported by Stenborg's (1973) work showing that moulins develop from crevasses. Neither the nature of hydraulic links between crevasses and the body of the glacier nor the formation of such links is well understood.

Conventional wisdom envisions englacial water flow in semi-circular ice-walled conduits (Fountain and Walder, 1998). The mechanics of steady flow in englacial conduits have been described theoretically. These conduits exist if the tendency for closure, from the inward creep of ice, is balanced by the melt enlargement resulting from the energy dissipated by flowing water. Englacial conduits should form an upward branching arborescent network, with the mean flow direction oriented steeply down-glacier, as determined by the gradient of the total potential (gravity and ice pressure) driving the flow. Observations of englacial conduits, with typically shallow slopes, near a glacier terminus and lower ablation zone are relatively common (Figure 3). In a particularly nice study of conduit geometry Gulley and Benn (2007) showed that conduits that developed from debris-filled crevasses exhibit a wide variety of cross-sectional geometries and formed a sinuous flow path. Empirical results based on the dispersion and travel time of numerous tracer injections in crevasses support the arborescent-network hypothesis. Most of the information bearing on the distribution and geometry of englacial passageways or on englacial water pressures and flow rates comes from boreholes drilled to the glacier bottom using a jet of hot water. About half of all such boreholes drain before the glacier bed is reached, indicating that they intersect englacial. Measurements of water level, water quality, and flow direction in boreholes and measurements of tracers injected into boreholes strongly suggest the presence of englacial passageways. However, the hydraulic inferences are contaminated by the hydraulic connections between the englacial passageway and a subglacial connection at the bottom of the borehole. Therefore, distinguish variations in flow/pressures in the subglacial connection versus that in englacial connections cannot be separated with certainty.

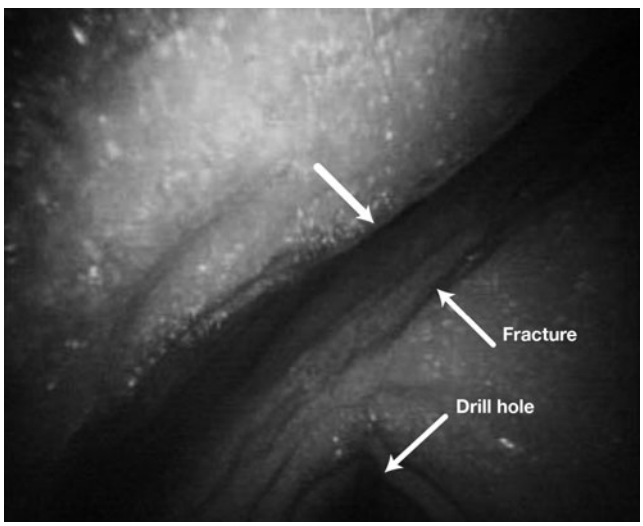
A number of direct measurements of englacial passages exist including englacial voids with typical vertical extents of ~0.1 m, and small (~mm in radius), arborescent, passages, but whether these voids or passages were part of an active hydraulic system was unclear. (Void is used here to mean a water-filled pocket in the ice, which may or may not be part of the englacial hydraulic system. Isolated voids are known to exist.) Englacial conduits have been observed where they connect to subglacial tunnels. Video cameras lowered into boreholes revealed multiple englacial voids through nearly the entire ice thickness. Voids that intersected opposite sides of the borehole wall were interpreted as englacial conduits; typically, one or two such features were encountered in each borehole, with diameters typically ~0.1 m (e.g., Harper and Humphrey, 1995). Pohjola (1994) determined that water was flowing in a few englacial conduits and estimated a flow speed in one of 0.01–0.1 m/s, the same range estimated by Hooke et al. (1988) using dye tracers. Fountain et al. (2005a) intersected two adjacent semi-circular

Englacial Processes, Figure 3 An exceptionally well-developed englacial conduit with incised floor in Ngozumpa Glacier. Taken from Gulley and Benn (2007).

englacial conduits at a depth of about 42 m. The diameters were 0.03 m and 0.1 m and within the conduit water flow speeds were about 0.1 m s^{-1}. Most conduits seen by borehole video seemed to be nearly horizontal.

In the search for englacial conduits Fountain et al. (2005b) found water-filled hydraulically connected fractures conveying englacial water to be ubiquitous in the ablation zone of an alpine glacier. Conduits were not encountered until the search included a small region around moulins. The fracture aperture openings averaged about 4 cm and were found from near surface to 96% of the local ice depth. Water flow speeds in the fractures were 1–2 cm s^{-1}. The fractures were near vertical in orientation and associated with clear ice. From this they inferred that the fractures are probably partly refrozen crevasses. That these features were also found near the bottom of the glacier points to a possible subglacial origin for deep fractures. Surface fractures/crevasses can be propagated deep into a glacier through hydrofracturing (Boon and Sharp, 2003; van der Veen, 2007) if it is water filled. The common occurrence of englacial fractures and the lack of conduits contest the traditional hypothesis that englacial conduits route surface water through the englacial region of temperate glaciers. Englacial conduits may be limited to regions down-glacier of moulins and fractures may convey most of the water up-glacier of moulins (Figure 4).

The multiple radar reflections and ubiquity of fracture observations suggests that the englacial region of a glacier may be quite heterogeneous and rather than a solid mass of ice and a few conduits it is highly fractured with water-filled fractures. The implications for glacier hydrology are clear; however, how such a composition affects glacier motion is less obvious.



Englacial Processes, Figure 4 Englacial fracture in Storglaciaren, Sweden. The view is looking vertically downward, note the drill hole at the bottom. Width of the fracture at the *arrows* is approximately 4 cm. Taken from Fountain et al. (2005b).

Understanding how water is routed through the englacial region is of key importance for understanding the motion of temperate glaciers and glacier hydrology. Water routing to the bottom of a glacier is an important control on the basal hydrology and therefore basal drag and glacier motion. Basal water pressure partially offsets ice pressure on the bed reducing sliding friction. In addition, the presence of basal water bodies transfers the bulk shear stress to areas

of ice-substrate contact. The influence of englacial routing on subglacial hydraulics can be argued as follows. Where large fluxes of surface water are focused to a few crevasses, we presume efficient flow pathways, moulins and englacial/subglacial conduits, develop to route the water. In regions where input is much smaller and more disperse among numerous crevasses, other pathways can accommodate the water flux and a different configuration of subglacial hydraulic features can develop.

Temperate glaciers can store and catastrophically release water impounded in ice-dammed lakes or stored internally, presumably in englacial or subglacial regions. Although the evolution of ice-dammed flooding behavior has been well-outlined theoretically and largely explains the observations, the processes of storage and release are essentially unknown. Outburst floods are an important hazard in many alpine regions, particularly in the Himalaya Hindu-Kush region. Also, temperate glaciers play an important role in alpine hydrology, particularly during the hot-dry summer months when rainfall is a minimum. Understanding glacier controls on stream flow variations is a relevant concern for dams and other human infrastructure in such regions. In some alpine regions of Norway and Switzerland, water is drained from beneath some glaciers to drive hydroelectric facilities.

ENVIRONMENTAL ISOTOPES

Bhishm Kumar
Hydrological Investigation Division, National Institute of Hydrology, Roorkee, Uttarakhand, India

Definition

Environmental isotopes may be defined as those isotopes, both stable and radioactive, which occur in the environment in varying concentration over which the investigator has no control (Payne, 1983).

These can be stable or unstable isotopes. Some examples of stable isotopes include ^{2}H, ^{3}He, ^{6}Li, ^{11}B,^{13}C, ^{15}N, ^{18}O, ^{34}S, etc., and some unstable or radioactive isotopes are ^{3}H, ^{14}C, ^{36}Cl, ^{137}Cs ^{210}Pb, etc. These are principal elements of hydrological, geological, and biological systems. The stable isotopes of these elements serve as tracers of water, carbon, nutrient, and solute cycling. Radioactive environmental isotopes are also important in hydrogeology. The environmental radioisotopes, whether naturally occurring due to cosmic ray interaction with various gaseous molecules or anthropogenically produced and become the part of hydrological cycle, are safe in normal conditions and do not pose any threat to human health. Environmental radionuclide such as ^{14}C and ^{3}H decay with time so that they can be used to estimate the age or circulation of groundwater.

Uses

Since glaciers are known to preserve the precipitation of the past in an unbroken sequence, it might seem that they are especially well suited for the study of the isotopic composition of precipitation and its variation with time. Dansgaard (1964) first proposed that the ^{18}O and D contents in glacier ice might reflect climatic conditions of the past. The other applications include study of accumulation rates, run-off ratio, dating of the ice-core, ice-flow pattern, drifting sea ice, and paleoclimates (Clark and Fritz, 1997).

EPIGENETIC ICE

Chelamallu Hariprasad
Centre for Studies in Resource Engineering, IITB, Mumbai, Maharashtra, India

Definition

The ground ice refers to all types of ice formed in freezing and frozen ground. Broadly ground ice can be categorized as epigenetic and syngenetic. Epigenetic ground ice forms in situ as permafrost aggrades while syngenetic ground ice forms in combination with deposition. Thus Epigenetic is a type of ground ice, formed in situ under conditions of permafrost in the subsoil. In general, frozen ground or permafrost represents the area which existed below 0°C for over few years (at least 2 years).

EPIGLACIAL MORPHOLOGY

Claudio Smiraglia, Guglielmina Diolaiuti
Department of Earth Sciences "A. Desio", University of Milano, Milano, Italy

Synonyms

Epiglacial environment; Epiglacial landscape; Epiglacial system; Supraglacial morphology

Definition

Epiglacial or supraglacial. Processes acting or features being evident at the glacier surface.

Epiglacial morphology. Complex of features deriving from processes active at the glacier surface, such as differential ablation or meltwater flow.

Introduction

Epiglacial morphology due to the large amplitude of topographical features plays a crucial role in determining the distinctive landscape of glacial system; in addition it creates the actual epiglacial environment which is well known to trekkers, alpine climbers, and mountain travellers (Benn and Evans, 1998). Crevasses and ice falls, supraglacial lakes and water ponds, medial moraines and debris-covered glacier snouts are among the best-known features belonging to the glacial landscape.

By analyzing the main epiglacial morphology features it is possible to deepen the knowledge on ice flow and strain rate and on debris transfer through the glacial system.

A large number of processes, which are different in complexity and mutual relations, are driving the epiglacial morphology giving a large amplitude of forms. For sorting the epiglacial forms and describing their development and evolution, a basic and qualitative classification can be applied: (1) forms related to glacier motion and flow, (2) forms related to epiglacial meltwater, and (3) forms related to differential ablation.

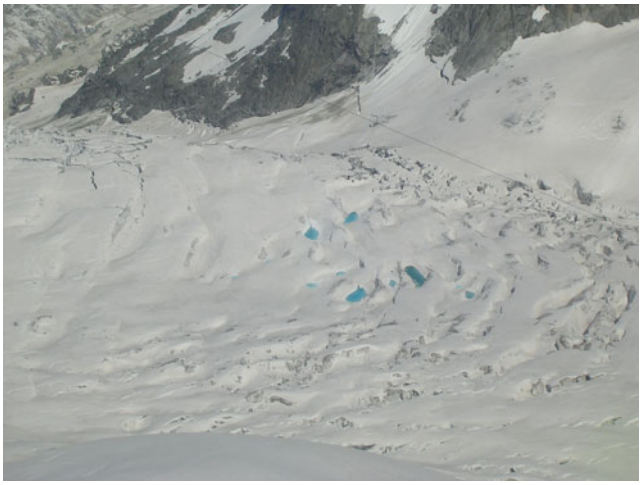
The above classification, although useful for describing the main features of epiglacial morphology, is not fully exhaustive, since the largest part of epiglacial forms is polygenic and actually results from the interactions among different processes which create a unique complex morpho-dynamic system where glacier flow, epiglacial drainage, and differential ablation are connected by several positive and negative feedback mechanisms.

The driving factors shaping the glacier surface and determining the different types of epiglacial forms are well expressed on temperate glaciers. In the following sections we will focus on this glacier type. It is also important to consider the brief time span covered by epiglacial form evolution: they generate, develop, and end in a short time frame, thus being considered ephemeras forms which, in particular on the lower sectors of glacier ablation tongues, may fast change their shape or disappear after a few days.

Epiglacial forms related to glacier motion

Crevasses are glacier fractures which can be listed among structural forms. Glacier fractures occur when ice cannot creep fast enough to allow a glacier to adjust its shape under stress. Crevasses are fractures formed where ice is pulled apart by tensile stresses; these fractures are fairly superficial features because at depth creep rates are higher and ice will flow faster than it can split (Figure 1). On *temperate* glaciers, characterized by "soft" ice, they rarely extend deeper than 30–40 m, whereas on polar and *cold* glaciers they may be much deeper. Crevasses are surely the most prominent and well-known features related to glacier flow, since they represent the most serious hazards

Epiglacial Morphology, Figure 1 Crevasses in the Mont Blanc area (Alps, at the boundary between France and Italy).



Epiglacial Morphology, Figure 2 Crevasses with some epiglacial ponds (Glacier du Geant, French Alps).

faced by mountaineers; they are present at the surface of several glacier types ranging from small cirque glaciers to ice sheets.

Generally, crevasses are grouped into a well-defined set as it occurs on valley glaciers (Nye, 1952) and from their analysis several types of information on glacier ice stresses can be derived.

Chevron crevasses are among the more common cleft patterns; they are linear breaks with an oblique orientation from the boundaries to the inner glacier sector aligned approximately at 45° to the valley walls; they originate from friction between mountain walls and glacier ice which makes ice velocity increase in the central glacier sector.

In the case of valley glaciers under extending flow conditions, which make glaciers accelerate, *transverse crevasses* occur; the main strain results to be parallel to ice flow and breaks open perpendicularly to the central flow line, slightly bending down valley (Figure 2).

When ice flow becomes compressive, that is the case of lower glacier sectors, *splaying crevasses* take place; they are curved and quite parallel to the ice flow direction in the inner glacier area, instead close to the margins they become bending at a smaller than 45° angle.

Bergschrund is a special crevasse type, a deep transverse one that occurs at the head of a glacier and can be also several hundreds of meters long.

Crevasses, after their genesis, flow down within the glacier reaching areas with different stress conditions which may cause their closure; in this latter case they leave linear scars named *crevasse traces,* layers of blue ice made by regelation of melting water inside the crevasse (before it closes off), or levels of white bubble ice made by snow filling the crevasse before its closure (Hambrey, 1994).

When glaciers flow on very steep slopes they increase their velocity (the acceleration can reach values up to ten times speedier than the normal ones), break in a chaotic totally broken surface, and give rise to *ice falls* with ice

Epiglacial Morphology, Figure 3 Seracs on a tributary of Forni Glacier, the widest Italian valley glacier (Alps).

towers named *séracs* (Figure 3). Generally these towering and unstable blocks of ice convince climbers to find an alternative route. In the areas where ice falls occur, large explosive sounds are not infrequent to be heard as house-size chunks of ice break off and collapse. The Khumbu Icefall on Mount Everest is a classic zone of unstable ice that climbers are forced to traverse.

At the base of ice falls, where ice flow becomes compressive, the most striking glacier structures, *ogives,* occur. These forms are curving bands or waves convex downflow each usually several meters wide, alternating bands of dark and light ice; they (sometimes called *Forbes bands*) are formed annually and each dark-light pair represents 1 year of glacier movement. They reflect the alternate season passage of dirty ice (in summer) and snow-covered ice (in winter) along the ice fall (Nye, 1958). *Layered structures*

are also present at the glacier surface, in any case the driving processes are different in the accumulation area with respect to the ablation one.

When a layered structure (*sedimentary stratification*) develops in the accumulation basin, it reflects yearly accumulation with layers generally parallel to the glacier surface. Layering consists of two kinds of alternating single stratum: thicker strata of coarse-grained white or light blue bubble ice (compacted winter snow and converted to ice by pressure) and thinner strata of dark blue dirty ice (layers saturated with water, that concentrates wind-blown dust, and afterward refrozen). In the ablation area, instead, the ice is characterized by *foliations,* a new layered structure with layers closer and less continuous derived by deformation of sedimentary stratification. The foliation orientation depends on the arrangement of primary stratification and on the sequence of deformations occurred during glacier flow.

Meltwater flow and related epiglacial forms

Meltwater derived from surface ablation is important, together with that derived from basal melting, not only because it influences glacier behavior and geomorphological processes (e.g., flow rate and basal sliding depend on the presence and distribution of liquid water), but also because it may form very peculiar epiglacial features. During the early summer, the winter snow packs may become saturated with water that accumulates in the snow and in the low-relief areas may form zone of *snow swamps* or *slush swamps*.

When on the glacier surface a slope is found, melt water drains away thus originating rills and giving rise to an actual glacier drainage system; the latter develops in the ablation areas like a surface stream network due to the low primary permeability of glacier ice.

The development of epiglacial meltwater streams (named *bédières*) depends on many ice factors (temperature, ablation rate, strain rate) and on features as crevasse occurrence and distribution, or foliation presence and pattern.

The drainage network characterizing epiglacial meltwater streams shows similarities with the ones occurring outside glacier areas (i.e., on glacial sediments or on rock surfaces); nevertheless some differences are present: on glacier surface the drainage density is stronger and higher order streams are absent due to ice flow and ablation that inhibit the development of an integrated drainage network; moreover on glacier surface the drainage pattern shows several subparallel channels which reflect the structural control (mainly crevasse distribution and foliations); the channel density is diminishing in the upper sectors (which is strongly different from the situation found on drainage networks outside glaciers) due to decreasing meltwater production at higher elevations; the channel patterns are fast changing since ablation processes are continuously shaping and modifying the glacier surface. In addition, new crevasses can develop, thus interrupting and intercepting the drainage network (Sugden and John, 1976).

The epiglacial streams are characterized by different depths, from a few centimeters in the case of small rills to several meters in the case of huge canyons which can represent giant obstacles to be traversed by climbers and mountaineers. Glacier streams show smooth sides which offer small resistance to water flow. The epiglacial drainage systems can easily develop on slow moving or stagnant glaciers not strongly crevassed and with small or absent surface moraines. Under these conditions, streams may form a dendritic pattern or a meandering with great regularity of wavelength and amplitude and with the concave slope of their bends characterized by steep gradient walls (Figure 4).

Crevasses are also found to be factors driving the development of peculiar epiglacial forms which are able to reach the inner and deeper glacier sectors. In fact, crevasse traces and/or developing crevasses produce planes of weakness which allow melt water to create vertical holes in the ice called *glacier mills* or *moulins,* analogous to pothole in the limestone of the karst countries. They have a diameter from less than a meter to more than 10 m and may penetrate deep into the glacier for many tens of meters; they in fact form the most important way for the glacier surface meltwater to reach the bed or the internal drainage network. Investigations and descents of moulins by means of speleological techniques have been performed since the end of nineteenth century (J. Vallot in 1898 explored the moulins of the Mer de Glace on Mont Blanc Massif), nevertheless only at the end of the twentieth century investigations became systematic and a new branch of glaciology saw the birth (i.e., glacio-speleology).

From field investigations it results in the higher sector of moulins to be generally vertical and regular, the deeper zone, instead, results to be inclined downvalley and quite always water filled. The water level of glacier moulins shows intense and fast changes and when more water enters the system with respect to the one drained by the englacial and subglacial network (as it occurs during periods of fast melting or after strong rainstorms) the

Epiglacial Morphology, Figure 4 Epiglacial meltwater streams (*bédière)* on the tongue of Dosdè Glacier (Italian Alps).

higher water level is found. The persistence of active moulins is driven by forms related to glacial flow; in the case a crevasse develops at higher elevations than a moulin, it can capture the drainage thus giving the rise, on the same supraglacial stream, of a new moulin at higher elevations (Holmlund, 1988).

Surface meltwater is not only flowing at the glacier surface or in glacier moulins, it may also be temporarily stored up in *epiglacial lakes* or *water ponds* (Figures 2–8). These forms are newly witnessing the complexity and the synergic action played by glacier processes which create epiglacial morphology. Generally epiglacial lakes develop on glacier lower areas like closed-off remnants of crevasses or inactive partially filled moulins. They form during the ablation period and in subpolar regions or wherever ice is below the pressure melting point, and can persist all the melt season due to the impossibility of melt waters to penetrate into the inner ice layers. On temperate glaciers the epiglacial lakes are more ephemeral (a proper example could be the *Effimerous Lake,* which developed in 2001 on Belvedere Glacier, Monte Rosa, Italy), they normally form early in the ablation season but rapidly drain when the drainage network becomes more active or the accelerating glacier flow forms new crevasses (Benn and others, 2001).

A peculiar type of epiglacial lake is spread where glaciers are covered by large amounts of debris (i.e., on debris-covered glaciers) and their development is caused by differential melting or ablation. In this case lakes and water ponds act as increasing glacier absorption of incoming energy (water albedo is lower than ice one, moreover water heat capacity is high and convective fluxes occur) and thus rising glacier ablation. In several cases they are found to enlarge their size, to become coalescent, and they may give rise to GLOF phenomena.

Differential ablation processes

The most impressive and diffuse features of epiglacial morphology derive from differential ablation processes. Differential ablation is defined as the ratio between the melt rate of bare or debris-free ice and the melt rate occurring at debris-covered ice at the same elevation. Supraglacial debris cover plays a key role in determining rates and magnitudes of buried ice ablation (Østrem, 1959; Nakawo and Young, 1982). The debris influence on ice ablation is due to its different albedo, generally lower than the one of bare ice, thus increasing the absorption of incoming solar radiation and ice ablation. Differently, supraglacial debris, whenever thicker than the *critical* value (Mattson et al., 1993), reduces the magnitude and rates of glacier ice ablation; the melt reduction in the case of thick debris layer is due to the prevailing insulating effect played by rock debris. On the glacier surface, especially in the lower part, during the ablation season, an amount of debris ranging in grain size from fine material as silt or sand to rubble or huge blocks of rock is visible. This supraglacial debris derives from different sources: (1) mass movements from adjacent mountain slopes, (2) wind-blown dust, (3) volcanic eruptions, (4) salt and microorganisms from sea-spray, (5) meteorites, and (6) pollutants from human sources (Hambrey, 1994; Kirkbride, 1995; Benn and Evans, 1998). The weight played by the different source types depends on the geographic setting: on areas where volcanic activity is important (e.g., Island) volcanic ash and tephra play the major role; on ice sheet surfaces (e.g., Antarctica) far from rock exposures the main debris sources are volcanoes and meteorites; on mountain glaciers nested by rock walls and with the occurrence of *nunataks* and rock exposures the main debris sources are slope processes (e.g., rock-falls and rock-slides, snow and ice avalanches, creep, debris and mud flows).

There are also several mechanisms of debris transport: supraglacial cover can receive material from subglacial glacier sector; in this case debris transport occurs in the basal shear zone of glaciers (*active transport*, Boulton, 1978). Then debris comes upwards the glacier surface in the ablation zone; debris may also be transported in supraglacial and englacial positions (*passive transpor*t, Boulton, 1978), in the latter case debris reaches the glacier surface when ablation of the nesting ice occurs.

Summarizing, the effect of a debris cover on the ablation rate of the underlying ice depends on the thermal conductivity of the debris, the ice density, the latent heat of ice melting, the surface debris temperature, and most of all, if the other factors are constant, the debris layer thickness.

Differential ablation features

The complex pattern and distribution of epiglacial debris, which may alternate areas with coverage thicker than the critical value or large boulders and areas with debris layer thinner than this threshold, give rise to different epiglacial features. In the case of thin and fine debris cover, ablation tends to form depressions, such as small and a few centimeters deep holes that riddle ice giving it a honeycombed appearance (at the bottom of the holes is well visible the small pebble or the dust that promotes melting). In some situations, where the surface melting waters are able to collect and accumulate a thin deposit of small particles, many water filled holes, on the average 10–20 cm long and large and a few centimeters deep, with the bottom covered by a few millimeters thick black fine debris layer are developed in large numbers (*cryconites*). When the fine debris collected in a hollow by surface stream becomes thicker than the critical value, differential ablation tends to remove more ice from surrounding areas than below the debris layer, producing an upstanding dirt mound; it is called *dirt cone*, formed by a relatively thin veneer of debris, almost sand, covering a cone of ice (Figure 5). Where on the glacier surface, isolated large boulders, even many decimeters thick, are diffused, the rock protects the ice from melting and as a result it tends to be perched on the top of a pedestal of ice that in some large Asian glaciers can more than a man be tall (*glacier table*) (Figure 6).

Epiglacial Morphology, Figure 5 A dirt cone on the surface of Forni Glacier.

Epiglacial Morphology, Figure 7 The ablation tongue of Forni Glacier: a bigger medial moraine (ISI type) is visible together with some thinner moraines (AD type). Ice seracs, transverse and chevron crevasses, rock outcrops are appreciable as well.

Epiglacial Morphology, Figure 6 Glacier table with glaciologists on the Morteratsch Glacier (Switzerland).

The narrow stripes, sometimes sinuous, of the *medial moraines* are among the most striking and spectacular features of valley glaciers due to differential ablation. They are formed by a long dark ridge of coarse debris, a few centimeters thick, that hides the underlying ice and overhangs even for some meters the ice free glacier surface. They may derive from a glacier confluence and be the morphological expression of the merging of two epiglacial lateral moraines; in that case a glacier composed by the confluence of two basins will have one single medial moraine, whereas the basins are three the medial moraines are two. This kind of moraine is called *ice stream interaction* (ISI). When the debris forming the moraine derives from emerging through melt-out of englacial material, the moraine is defined *ablation-dominant* (AD). In the case the debris derives from a rock fall event, the moraine is defined *avalanche-type* (AT) (Eyles and Rogerson, 1978) (Figure 7).

Penitentes are the most fascinating epiglacial features due to differential ablation; they are pinnacles of snow or ice which grow over all glaciated and snow-covered areas in the Dry Andes above 4,000 m (Lliboutry, 1954). They range in size from a few centimeters to over 5 m (Naruse and Leiva, 1997). They take the form of tall thin blades of hardened snow or ice closely spaced with the blades oriented toward the general direction of the sun. Penitentes were first described by Darwin (1839) during his travel from Santiago de Chile to Mendoza (Argentina). Darwin described *penitente*s as features formed by the strong winds of the Andes; this explanation had persisted until the recent times when deeper investigations on these epiglacial features were performed. Lliboutry noted that the key climatic condition for the differential ablation that leads to the formation of *penitentes* is that the dew point is always below freezing. Thus, snow will sublimate, which requires higher energy input than melting. Once the process of differential ablation starts, the surface geometry of the evolving *penitente* produces a positive feedback mechanism, and radiation is trapped by multiple reflections between the walls. The hollows become almost a black body for radiation, while decreased wind leads to air saturation, increasing the dew point temperature and the onset of melting. In this way peaks, where mass loss is only due to sublimation, will remain, as well as the steep walls, which intercept only a minimum of solar radiation. In the troughs ablation is enhanced, leading to a downward growth of *penitentes* (Betterton, 2001; Corripio and Purves, 2005).

Epiglacial Morphology, Figure 8 The debris-covered tongue of Baltoro Glacier (Karakoram). An epiglacial lake is visible as well.

Debris-covered glacier snout features

In some glaciarized areas, where a high relief mountain environment dominates, many glaciers have a continuous debris mantle covering most of their ablation tongue with maximum thickness usually present in the lower part of the glacier. Some typical examples can be seen in Karakoram, Himalaya, Alps of New Zealand, where a large volume of debris is delivered on the glacier surface by rock-falls and other mass wasting processes (Figure 8). The great spatial variability in debris thickness and grain size favors the differential ablation processes that produce a strong gravitational and meltwater reworking of the former debris-covered surface. The flanks of dirt cones and of medial moraines become gradually more steep, the abundance of debris and water produces debris flows and sliding, all processes that redistribute sediments on the glacier surface, change the pattern of differential ablation and create in the deglaciation phases very characteristic and distinctive features. The final phase of the gravitational reworking is the development of a low-relief topography on the very thick debris mantle that reduces strongly ice ablation rates. On actual debris-covered glaciers the larger ice losses are mainly concentrated at the debris-free areas such as the walls of open crevasses and other holes on the glacier surface and steep marginal areas. Ablation proceeds by the preferential melting and retreat of such slopes in a process known as *backwasting* (Eyles, 1979). This process enlarges holes and produces a chain of a circular depression filled with water, favors the collapse of the roofs of englacial and subglacial water conduits (Kirkbride, 1993); the process results in a sequence of landscapes similar to the evolution of karst features on limestone terrains and thus defined as *glacier karst* (Clayton, 1964).

Summary

Epiglacial morphology includes all the forms and features characterizing the glacier surface. Among the most important factors driving epiglacial forms are: glacier flow and dynamics (generating crevasses and foliations), melt water drainage (originating *bédières* and *moulins*), and differential ablation (creating giant forms, medial moraines, or small morphologies – glacier tables).

On the ablation tongue of temperate and subpolar glaciers, where supraglacial debris creates continuous mantles, the most impressive epiglacial forms can be found: supraglacial lakes and water ponds fast changing their shape and giving rise to coalescence features, ice collapse, backwasting. The landscape morphology in such areas resembles the one belonging to the karstic system and is frequently reported as *glacier karst.*

Definition

The equilibrium-line altitude (ELA) marks the area or zone on a glacier separating the accumulation zone from the ablation zone and represents where annual accumulation and ablation are equal.

Introduction

The equilibrium-line altitude (ELA) on glaciers is the average elevation of the zone where accumulation equals ablation over a 1-year period. The ELA can rarely be observed as a line at the same elevation across the entire width of the glacier due to local topographic and climatic variations in accumulation and ablation (Figure 1). Thus, the ELA is the average altitude of the equilibrium line. The ELA is very closely related to the local climate, particularly winter precipitation and summer air temperature. Variations in the ELA can therefore commonly be attributed to changes of these two variables. This can best be illustrated by its relationship to the net balance. The term net mass balance is the net gain or loss of ice and snow. The mass balance is highly dependent on the climate conditions. If the annual mass balance of the glacier as a whole is negative, the ELA rises, and when the balance is positive, the ELA falls. The steady-state ELA is defined as the ELA when the annual net balance is zero, as the glacier mass and the geometry are in balance with climate. The concept is very useful because it provides a measure of the climatic means related to certain glacier positions and geometries. The climatic ELA is the average ELA over a 30-year period (corresponding to a climate "normal" [30-year mean] period). Variations in ELA and net mass balance have been measured for many glaciers worldwide (e.g., Storglaciären in Sweden (since 1946) and Storbreen in Norway (1947). For details, see www.geo.unizh.ch/wgms). These time series underpin how fluctuations in the ELA provide an important indicator of glacier response to climate change and allow reconstructions of former climates and the prediction of future glacier behavior. Although the ELA is determined by local weather conditions, it is a good indicator of regional climate because glacier mass-balance fluctuations are commonly strongly correlated over distances of c. 500 km (Letreguilly and Reynaud, 1989).

Climate influencing the ELA

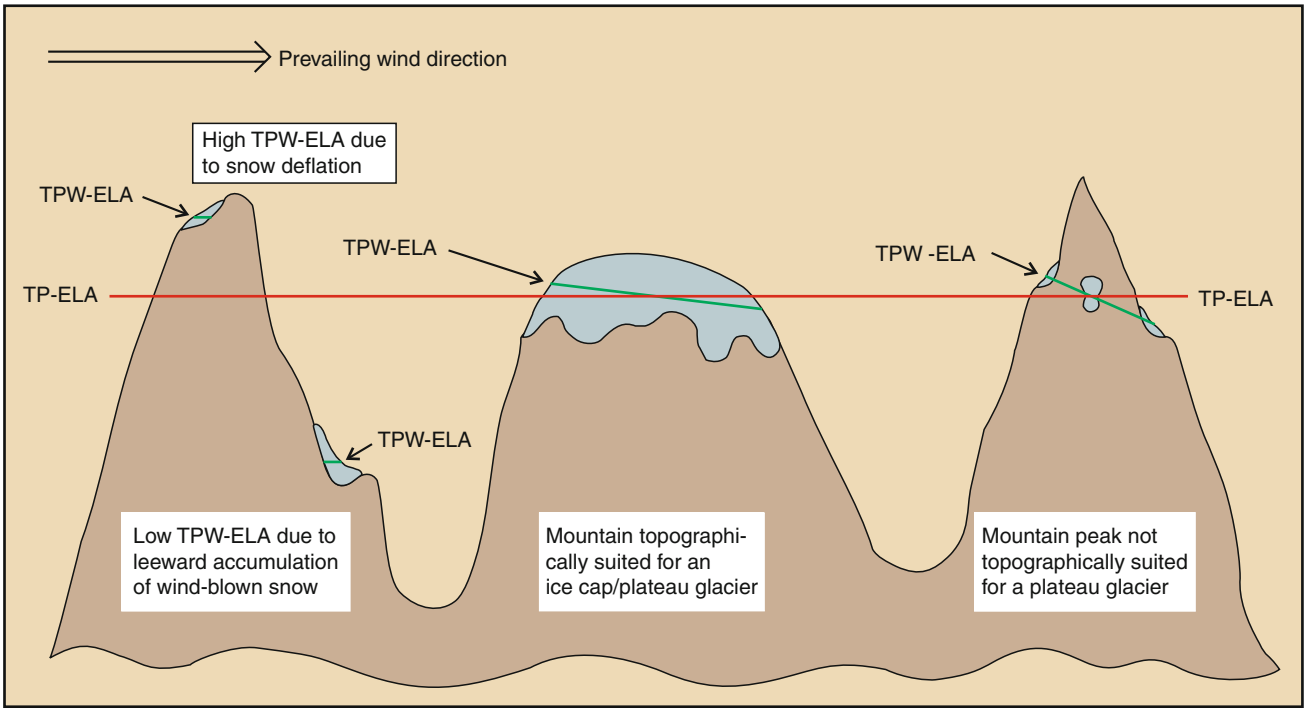
The accumulation on a glacier includes all materials that add mass to the glacier, such as snow, refrozen slush, hail, rain, and avalanched snow and ice. The ablation includes direct ice melt, iceberg calving, wind erosion/deflation, and sublimation. On most glaciers, accumulation is dominant in the winter months, whereas ablation mainly occurs during the summer. Where an ice sheet or glacier terminates in water, however, iceberg calving may occur throughout the year. Commonly, accumulation exceeds ablation on the upper part of a glacier, whereas ablation is larger than the accumulation in the lower parts. For a "regular" glacier fed by snowfall in its accumulation area and that loses mass by melting of "clean" ice in its ablation area, altitudinal mass-balance gradients are approximately linear, with ablation gradients tending to be steeper than

Equilibrium-Line Altitude (ELA), Figure 1 The southern part of the Folgefonna glacier in western Norway. The ELA can be seen as a meandering line between snow and blue ice (Photo: Jan Rabben).

accumulation gradients (Schytt, 1967; Furbish and Andrews, 1984). The links between climate and glacier mass changes have also been investigated by using mathematical models to find the climatic combinations required to "grow" or "melt" glaciers of a known size in a specified time frame. The most detailed models calculate accumulation and ablation totals by considering changes in all contributions to accumulation input and energy balance within defined time window (e.g., Gruell and Oerlemans, 1986; Kuhn, 1989; Braithwaite and Olesen, 1990). Depending on their complexity, these models incorporate a number of meteorological input parameters and simulate the temporal evolution of mass-balance terms (accumulation and ablation) in the course of a year or over several years (Oerlemans, 2001). The atmospheric forcing is usually provided by weather station data near to or on the glacier surface, which are interpolated to the required horizontal resolution of the mass-balance model. In addition, glacier characteristics (i.e., extent and a digital elevation model [DEM]) are needed as input to the model. More simple models integrate the climatic controls into two or more easily calculated parameters such as annual effective precipitation, mean temperature during the ablation season, or ablation–altitude relationships (e.g., Budd and Smith, 1981; Laumann and Reeh, 1993; Reeh, 1991). Such models can easily be used to calculate ELA also on reconstructed glaciers based on e.g., dated terminal moraines.

Wind influencing the ELA

Climate processes influencing the ELA on glaciers involve ablation (mainly controlled by summer temperature, T) and direct snowfall (precipitation, P), giving the TP-ELA. In addition, wind (W) transport of dry snow is an important factor for the glacier mass balance, in particular during the accumulation season. On plateau glaciers, snow deflation and drifting dominate on the windward side, whereas snow accumulates on the leeward side. By calculating the mean ELA in all glacier quadrants on a plateau glacier, the influence of wind on plateau glaciers may be negligible. The resulting ELA is therefore defined as the TP-ELA (temperature/precipitation ELA). The TP-ELA reflects the combined influence of the accumulation-season precipitation and ablation-season temperature (Dahl and Nesje, 1992). On wind-exposed mountain plateaux, the snow may deflate and accumulate in lower cirques and valleys, either by direct accumulation on the cirque/valley glaciers, or by avalanching from the mountain slopes. The accumulation on the cirque/valley glaciers may therefore be significantly higher than the local precipitation indicates (Figure 2) (Dahl and Nesje, 1992). The mean ELA on a plateau glacier therefore defines the TP-ELA, whereas the ELA on a cirque glacier, commonly influenced by wind-transported snow, gives the TPW-ELA. Therefore, the TPW-ELA is commonly lower than the TP-ELA. Leeward accumulation of windblown snow, including avalanching from the cirque walls, is an important factor influencing the mass balance of cirque glaciers. Due to the potential upslope transport of dry snow by wind, the additional accumulation of snow in a cirque is commonly difficult to estimate. One possible approach to this problem is to calculate the ratio between the catchment area above the TPW-ELA (D) and the reconstructed glacier accumulation area (A) as a rough measure of the potential for additional of snow by wind transport and avalanching in cirques (Dahl et al., 1997). Another approach to calculate this ratio is to define the prevailing wind direction and calculate the area in quadrants upslope and upwind of the glacier surfaces, including plateaux, all



Equilibrium-Line Altitude (ELA), Figure 2 The effect of windblown snow can on some glaciers contribute with a large amount of snow. Therefore, the term temperature-precipitation-wind (TPW) ELA can be useful when describing the altitudinal distribution of glaciers in an alpine terrain (Dahl and Nesje, 1992).

glacier-facing slopes and all other plateau-edge slopes with gradients $<5^{o}$ irrespective of orientation (Benn and Ballantyne, 2005). Further, to take into account snow avalanching, all slopes $>25^{o}$ overlooking the glaciers are calculated. As the two categories frequently overlap, the results must be combined into a single snow-contributing area factor (Ballantyne, 2006). This factor can then be subtracted when calculating the regional ELA in an area. When studying the ELA distribution along a western transect in Scotland during Loch Lomond stadial, the above approach was applied by Ballantyne (2006).

Relationships between precipitation/temperature and the ELA

There is a very close connection between the ELA and local climate, in particular winter accumulation (snowfall), summer temperature, and wind strength causing transport of dry snow during the accumulation season. The ELA is therefore sensitive to perturbations of these variables; high winter snowfall combined with low summer temperatures the following summer gives a low ELA, whereas low winter accumulation followed by a warm summer yields a high ELA. Fluctuations in the ELA over time are therefore an important indicator of climate change and commonly allow reconstructions of past climates. Thus, palaeoclimatic reconstructions based on former glacier extent commonly make use of reconstructed ELAs. Data on past variations of ELAs therefore provides an important source of proxy palaeoclimatic data in glaciated regions around the world.

Relationships between temperature and precipitation at ELAs on glaciers have been established by statistical/analytical approaches (e.g., Liestøl in Dahl et al., 1997; Nesje and Dahl, 2000; Ohmura et al., 1992; Shi et al., 1992; Sissons, 1979). The positive correlation between these two variables for a wide range of glaciers reflects the fact that higher values of mass turnover at the ELA require higher ablation (higher summer temperatures) to balance the annual specific mass budget. The approaches of Ohmura et al. (1992) and Nesje and Dahl (2000), however, deviate significantly for temperature and precipitation $>4°C$ and $>3{,}500$ mm, respectively. Some of the discrepancy may be explained by the fact that Ohmura et al. (1992) used winter accumulation plus summer precipitation at the ELAs, whereas Nesje and Dahl (2000) used only winter (1 Oct–30 Apr) precipitation.

The temperature-precipitation relationship also explains the regional rise in glacier ELAs with increasing distance from moisture sources. In areas of lower precipitation, the temperature required to melt the annual accumulation at the ELA does not need to be as high as in areas of high precipitation. Consequently, ELAs tend to be at higher elevations in areas with low ablation-season temperatures than in areas with higher ablation-season temperatures. If palaeo ELAs have been reconstructed and if palaeotemperatures

are reconstructed from independent proxies (pollen, faunal remains, etc.) nearby, former winter or total precipitation at the ELA can be calculated from temperature-precipitation relationships (e.g., Dahl and Nesje, 1996). Regional variations of glacier ELAs can be used to infer former precipitation gradients that may allow prevailing moisture sources and circulation patterns to be reconstructed (Lehmkuhl, 1998; Lehmkuhl et al., 1998; Miller et al., 1975). In addition, reconstructed ELAs of former glaciers have been used to correlate moraines in mountain regions (e.g., Maisch, 1982). The term ELA has, however, been applied to several altitudinal indices calculated for past glaciers. The relationship between some of these indices and climate has, however, not been firmly established. Palaeoclimatic reconstructions based on these indices may therefore be inaccurate (Benn and Lehmkuhl, 2000). In some high mountain regions, however, the relationship between climate and glacier ELAs may be complicated due to avalanches and debris cover on the glacier surface. It is also complicated by different types of accumulation cycles where the most important types are: (a) winter accumulation type, with a well-defined winter accumulation season and summer ablation season; (b) summer accumulation type, with maxima in accumulation and ablation occurring simultaneously during the summer months: and (c) year-round ablation type, with one or two accumulation maxima coinciding with wet seasons.

Based on the "Liestøl-equation," three equations derived from a close exponential glacier-climate relationship at the ELA of Norwegian glaciers were implemented in a geographical information system (Lie et al., 2003). The equations enable calculation of (1) the minimum altitude of areas climatically suited for present glacier formation, (2) quantification of the glacial build-up sensitivity (GBS) in an area, and (3) calculation of the theoretical climatic temperature-precipitation ELA (TP-ELA) (based on temperature and precipitation data from meteorological stations in southern Norway) in presently non-glaciated areas by combining GBS with terrain altitude. The approach is primarily intended for reconstruction of palaeo ELAs in areas with no present glaciers.

Identifying ELA on modern glaciers

The ELA for any given year can be identified by observing the distribution of snow and ice on the glacier surface at the time of year when glacier mass is at a minimum (in the end of the accumulation season). Commonly, the ELA coincides with the transient snow line. This information can be obtained by field survey or from any photographic source (e.g., aerophoto, satellite images). On temperate glaciers, the ELA can give immediate information of the state of the glacier in relation to the last mass-balance year, and also the longer term state of the glacier. Paterson (1994) lists the following situations that give signs of the relationship between the glacier and climate over the last year(s):

1. A low snow line possessing a sharp boundary with bare ice indicates a positive net balance (the glacier is growing).
2. A similar boundary but at a high altitude indicates that a period of accumulation has interrupted long period of negative balance.
3. A snow line separated from bare ice by an area with old firn indicates a more negative balance than the preceding few years.

Approaches of calculating palaeo ELAs

When calculating the ELAs when a glacier was larger than at present, or when the glacier was melted completely, several approaches for calculating/estimating the ELAs of former glaciers from geomorphological evidence have been developed (see review by Benn and Lehmkuhl, 2000; Gross et al., 1976; Meierding, 1982; Torsnes et al., 1993). Former variations in ELA are a valuable palaeoclimatic proxy as it is also possible to isolate the winter component of the proxy (see above). The concepts of the different methods vary significantly, as do their reliability and ease of use. Some approaches are based on detailed evaluation of mass balance and glacier hypsometry (distribution of glacier area over its altitudinal range). Others are based on the large-scale morphology of the glacier catchment, the altitude of marginal moraines, and the cirque floor. A literature survey indicates that ELA depressions from modern values during the last glacial maximum, Younger Dryas and the "Little Ice Age" were typically in the range of 1,000 $\pm$ 300 m, 500 $\pm$ 200 m, and 100 $\pm$ 50 m, respectively. It is likely that many of the methods discussed below will be redundant by simple mass-balance models for calculation also of former ELAs.

The maximum elevation of lateral moraines (MELM)

Due to the nature of glacier flow toward the center above the ELA and toward the margin of the glacier below the ELA, lateral moraines are theoretically only deposited in the ablation zone below the ELA. As a result, the maximum elevation of lateral moraines should ideally reflect the corresponding ELA. This method is considered best suitable for long valley glaciers with large, continuous lateral moraines. There are, however, several problems with this approach. First, englacial material may not reach the glacier surface immediately below the equilibrium line. Thus, lateral moraines may not form at, but below the actual ELA. Second, it is difficult to assess whether or not a lateral moraine is preserved entirely in the upper part due to degradation on steep slopes. Consequently, ELA estimates derived from eroded/degraded lateral moraines may be too low. Third, the valley sides may be too steep for deposition of lateral moraines, giving estimates of the former ELA that are too low. Finally, if initial glacier retreat is slow, additional moraine material could be deposited in the prolongation of the former steady-state

lateral moraine. The MELM approach is, despite the problems, considered the most reliable method where former glaciers were covered by debris and the mass-balance gradient is poorly or not known.

The median elevation of a glacier (MEG)

This approach places the ELA half altitudinal difference between the glacier front and the top of the glacier. Empirical evidence from modern glaciers, however, suggests that the MEG overestimates the ELA. In addition, this method fails to take into account variations in valley morphology, which strongly affects the area-elevation distribution of a glacier. However, it works reasonably well for small glaciers with an even area/altitude distribution. The main problem is commonly to define the headward limit of a former glacier.

The toe-to-headwall altitude ratio (THAR)

This method assumes that the ELA lies at a fixed proportion of the vertical distance between the highest and lowest part of a former glacier. A ratio between the maximum and minimum altitude of a glacier (toe-to-headwall altitude ratio [THAR]) has been used as a quick estimate to calculate the ELA. Ratios of 0.35–0.4 were used by Meierding (1982) for glaciers in Colorado. Values of 0.4–0.5 were used by Porter et al. (1983) for "clean"-ice glaciers. The THAR approach is considered a rough way of estimating former ELAs because it does not take into account glacier hypsometry and mass balance. In addition, a major problem is to define the headward limit of a former glacier. The THAR approach allows rapid estimates of former ELAs in remote areas with poor or inaccurate maps.

Toe-to-summit altitude method (TSAM)

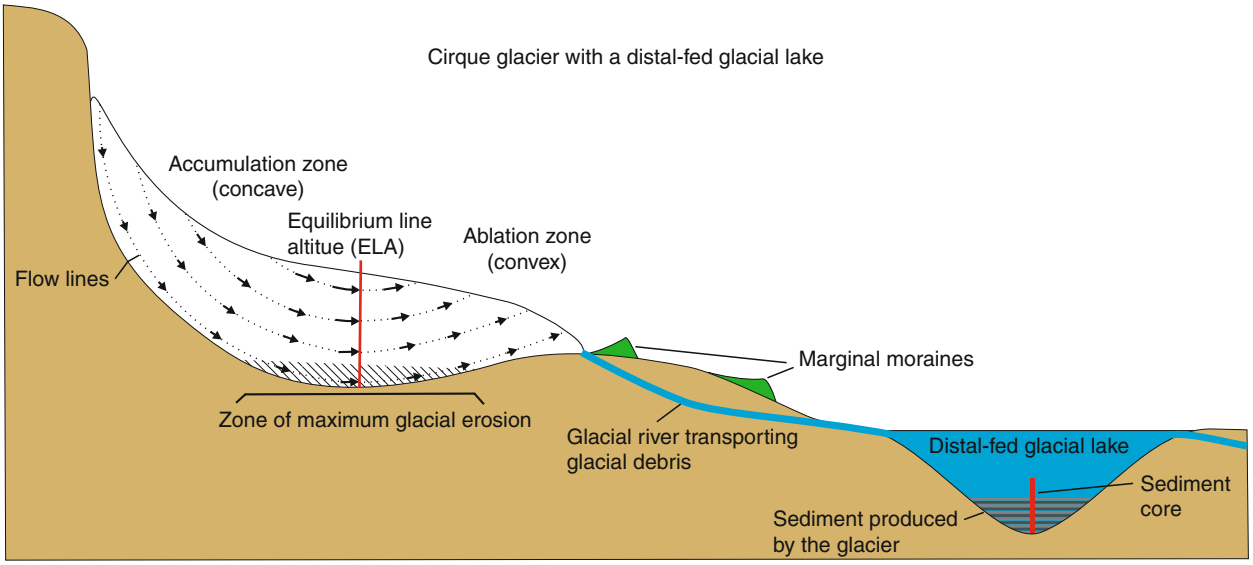
A way to overcome the problem of defining the upper limit of a former glacier is to use the maximum altitude of the glacier catchment. Louis (1955) suggested that the ELA may be calculated from the arithmetic mean of the altitude of the highest mountain and the terminal moraine. For the European Alps, Gross et al. (1976) demonstrated that this approach yields ELAs that are about 100 m too high. For modern glaciers in the northernmost mountain range of the Mongolian Altai, the inferred values are in agreement with snowlines on glaciers observed in the field and on aerial photographs (Lehmkuhl, 1998). The TSAM method gives, despite its crudeness, rapid estimates of former ELAs in remote areas. ELA estimates based on the TSAM method should be determined for each region separately because they may be due to significant variation due to variations in glacier type.

The accumulation area ratio to the total glacier area (AAR)

The ratio of the accumulation area to the total area (AAR) is based on the assumption that the steady-state AAR of former glaciers is typically 0.55–0.65 (Porter, 1975). An AAR of 0.6 ± 0.05 is generally considered to characterize steady-state conditions of valley/cirque glaciers. Ice caps and piedmont glaciers may, however, differ significantly from this ratio. Gross et al. (1976) inferred a mean AAR value of 0.67 for glaciers in the European Alps. The AAR of a glacier varies mainly as a function of its mass balance; ratios below 0.5 indicating negative mass balance; 0.5–0.8 corresponding to steady-state conditions, and values above 0.8 reflecting positive mass-balance regimes. For modern mid- and high-latitude glaciers, steady-state AARs typically lie in the range 0.5–0.8. The AAR approach requires contour maps of former glacier surfaces, and this method can therefore only be used where detailed topographic data/maps are available. Information about mass-balance gradients is not required for the AAR method. The largest source of inaccuracy related to the AAR method of determining the ELA on former glaciers is the reconstruction of the surface contours, especially if the glacier margins intersect valley-side topographic contours at small angles or coincide with them for some distance. A theoretical evaluation of the AAR approach, using changing slope angles and valley morphology on idealized glaciers, shows that glaciers advancing into flat areas underestimate the ELA depression, whereas glaciers moving into areas of increasing slope angle overestimate the climatic ELA difference. Consequently, topographical and morphological effects on calculated ELA depressions on glaciers must be carefully evaluated.

The balance ratio (BR) method

The balance ratio (BR) method is a refinement of the AAR approach. As demonstrated above, one shortcoming of the AAR method, and also the MEG approach, is that they do not fully account for variations in the hypsometry. To overcome this problem, a balance ratio (BR) method was developed by Furbish and Andrews (1984). This approach takes account of both glacier hypsometry and the shape of the mass-balance curve and is based on the fact that, for glaciers in equilibrium, the total annual accumulation above the ELA must balance the total annual ablation below the ELA. This can be expressed as the areas above and below the ELA multiplied by the average accumulation and ablation, respectively. The BR approach assumes that the accumulation and ablation gradients are approximately linear, that the ratio between the two is known, and that the hypsometry of the glacier is known. The BR method can thus only be used where detailed topographic maps are available and the surface contours of former glaciers can be reconstructed in detail (Benn and Gemmel, 1997). Because accumulation and ablation gradients are controlled by different climatic variables, the accumulation and ablation gradients generally have different values, with the ablation gradient somewhat steeper than the accumulation gradient. In a study of 22 glaciers in Alaska, Furbish and Andrews (1984) found that balance ratios clustered around 1.8, meaning that the ablation gradient is 1.8 times greater than the accumulation gradient.



Equilibrium-Line Altitude (ELA), Figure 3 Erosion beneath the glacier produces "rock-flour," which is deposited in downstream proglacial lakes. Quantification of these sediments and later correlation between periods with known glacier size form the fundamentals for doing continuous reconstructions of the ELA in the past.

Benn and Gemmel (1997) published a spreadsheet program that rapidly calculates glacier ELAs using the balance ratio method that allows hypsometric variations to be accounted for in ELA reconstructions. Later another spreadsheet was made available for calculation of the Area-Altitude Balance Ratio (AABR) (Osmaston, 2005). These spreadsheets are becoming increasingly used in palaeoglacier reconstruction for estimating ELA and subsequently deriving quantitative estimates of palaeoclimate. However, there are still only a few studies that have established, from contemporary environments, AABR/BR ratios. Rea (2009) provides an empirically derived dataset characterizing AABR ratios, which may be used for ELA estimation in palaeoglacier reconstructions and for palaeoclimate quantification based on data from World Glacier Monitoring Service, US Geological Survey, and Norwegian Water Directorate.

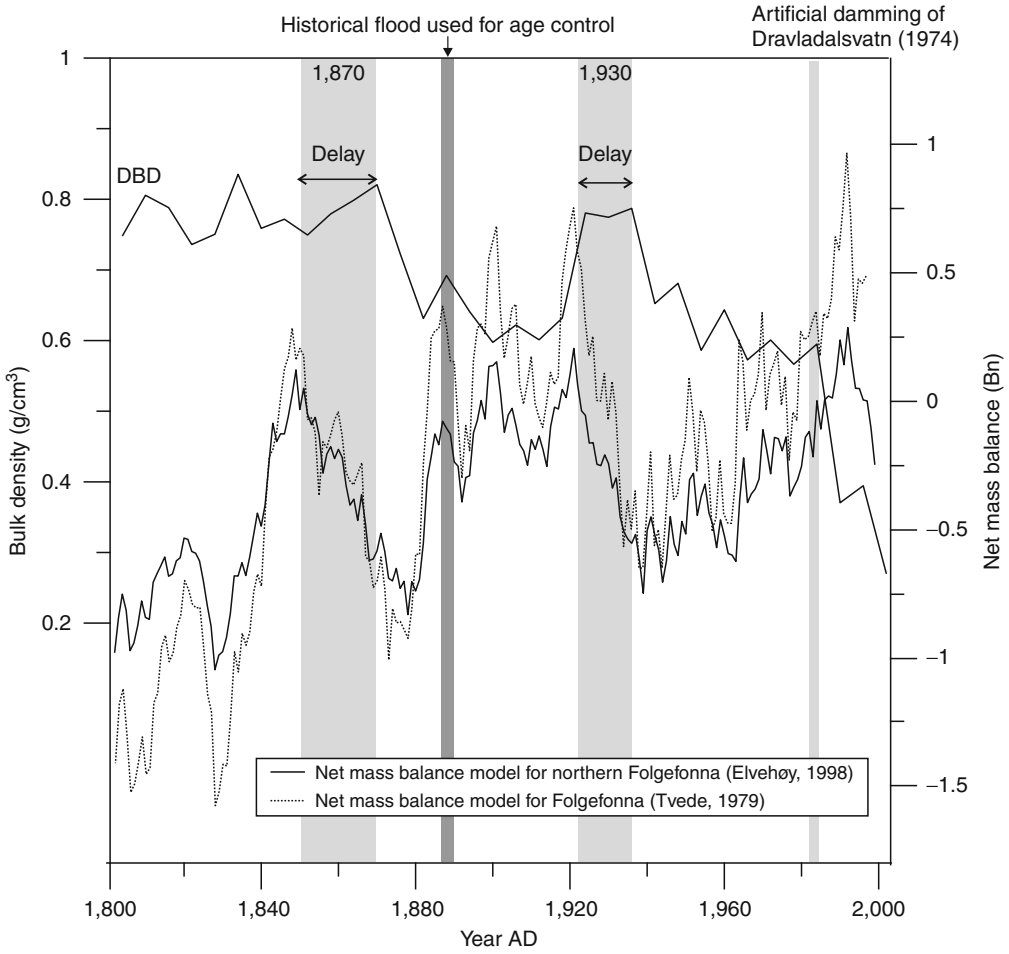
Cirque floor altitudes

Cirque floor levels or altitudes have been used as indicators of the elevation of former glacier snowlines for Pleistocene glaciers. The elevation of the cirque floor/basin does not, however, have a close relationship with the ELA of the glacier that formed it (see Benn and Lehmkuhl, 2000). Cirques develop cumulatively over many glacial cycles and they can therefore not be attributed to any particular glacial event. They may, however, give some insight into regional trends in glaciation levels and average climatic conditions over longer time scales.

Proglacial sites

Several approaches have been applied to record past variations in ELAs based on lacustrine and terrestrial proglacial sites (Figure 3). These approaches are based on quantification of ELA fluctuations based on analyses of sediments deposited in distal glacier-fed lakes. Several groups worldwide have worked with this approach; here we give some examples from Scandinavian glaciers. Dahl et al. (2003) presented a conceptual model of glacier-meltwater-induced sedimentation in which a variety of proxies are related to the occurrence and size variations (as a response to variations in the ELA) of a glacier in a catchment. In order to quantify glacier reconstructions, it is necessary to validate that the sediments is of glacial origin (not from any mass movement or sub aquatic process) (Bakke et al., 2005b). This can be done by different sediment analyses such as grain-size variations, dry bulk density (DBD), magnetic properties, and X-ray (and XRF). When sediment DBD and glacier size based on the analyses have been established, the altitudinal position of the moraine can be used to calibrate the ELA curve by a correlation between ELA and DBD (Figure 4). The moraines need to be independently "dated" by the use of lichenometry and/or historical sources/or by exposure dating. Periods with anomalies in the sediment parameters are removed from the ELA reconstruction (open squares in Figure 4). The approach has been tested against a net-balance model in a lake downstream from the Folgefonna glacier in Norway. Tvede (1979) established some equations for modeling of the glacier mass balance (Bw/Bs and Bn) of Folgefonna based on temperature and precipitation from the Bergen-Florida meteorological station (station. no. 5054/56). The equation was later reformulated (Elvehøy, 1998) and established also for the northern part of Folgefonna:

$$B_n = 444 + 2.16^{*}P - 54^{*}T_3 \quad (1)$$



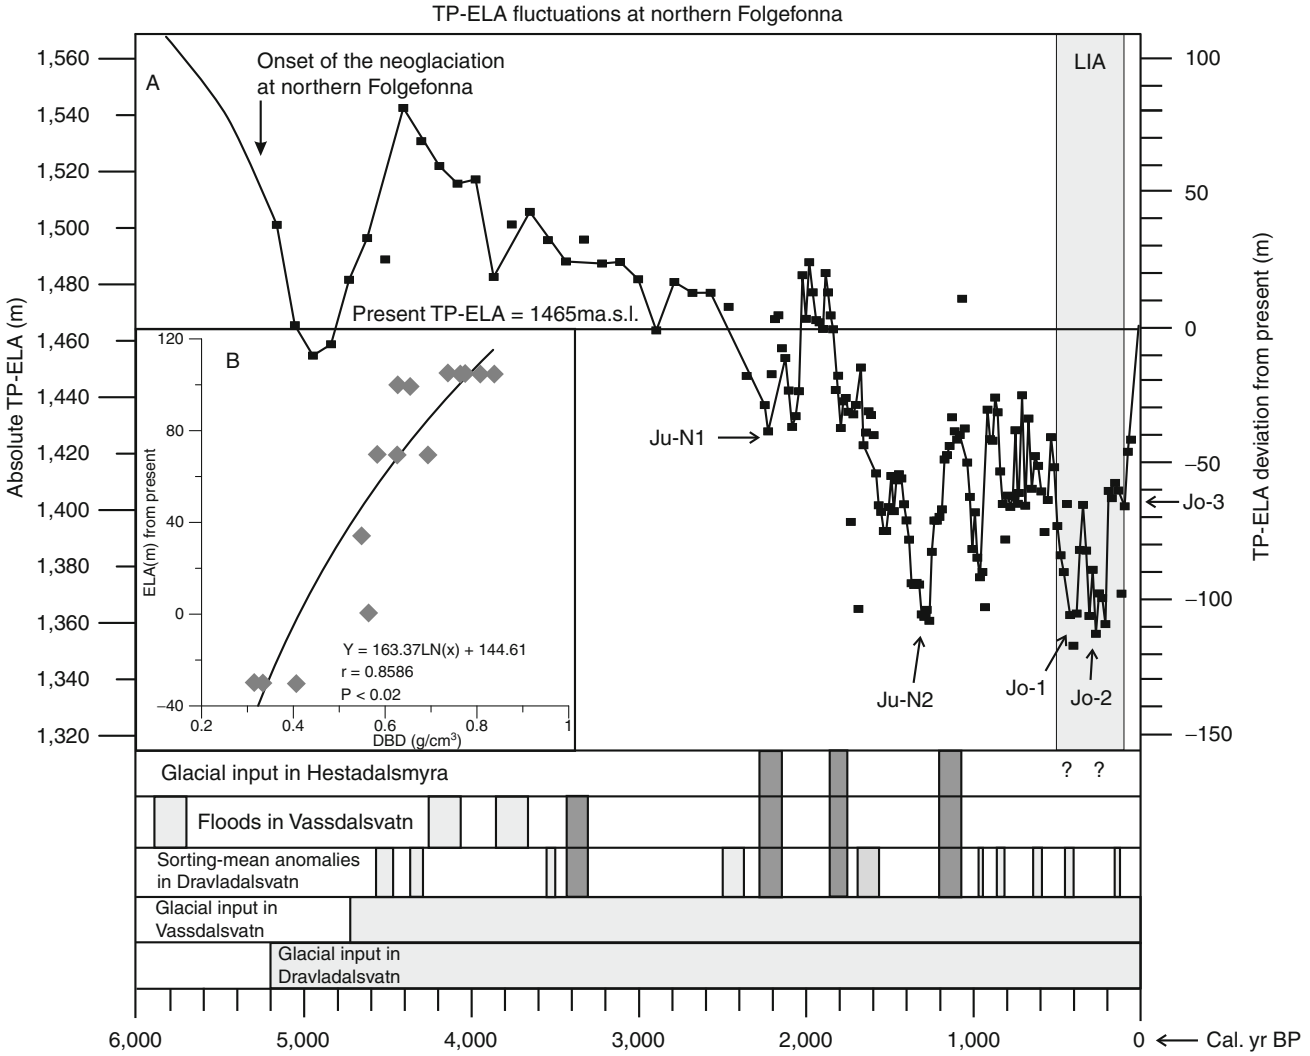
Equilibrium-Line Altitude (ELA), Figure 4 Dry bulk density (DBD) compared to two different glacier net mass-balance models for the Folgefonna and the northern Folgefonna glaciers. The dotted line shows a model developed by Tvede (1979) for the southern part of the Folgefonna glacier, whereas the black line was produced for northern Folgefonna in this study. Both models are compared with a glacier net mass-balance model and net-balance measurements from AD 1963 to 1997 (Elvehøy, 1998) at Folgefonna. The reconstruction is based on temperature and precipitation records from Bergen and Ullensvang (Birkeland, 1932). Thick gray-shaded areas indicate periods with moraine formation in front of the glacier (Bakke et al., 2005b).

where P is winter precipitation in Bergen (01.10–31.05) and T_3 is average summer temperature (01.06–31.08). The equation gives high predictability compared to the net mass balance from 1963 to 1997 ($r^2 = 0.84$). In the reconstruction, temperature and precipitation records from Bergen back to AD 1841 (data from Meteorological Institute) were put into the equation, whereas a temperature record from Ullensvang was used from AD 1800 to 1840 (Birkeland, 1932). As there is a lack of precipitation records for this time span, a linear regression model between the January, February, and March temperatures ($r = 0.6$) to reconstruct the winter precipitation was used. Both models reproduce the AD 1870 (late LIA) glacier advance and the AD 1930 glacier advances, which correspond to two independently dated terminal moraines. The low B_n values from AD 1800 to 1840 reflect the retreat of the glacier after the AD 1750 glacier event, and may explain the high DBD values during the time span (Figure 5). Based on the assumption that the age depth model is correct, another interesting feature is that there apparently exist lags in the bulk-density record with 10 years from a change in net balance to increased bulk-density values. This is suggested to reflect the frontal time lag time of the glacier to mass-balance perturbations.

ELA reconstructions – learning from the past

The use of proglacial lake sediments to reconstruct continuously ELA variations makes it possible to do high-resolution palaeoclimatic analyses. The quantification of sediment variability and better dating techniques make it possible to infer detailed information about the climatic factors affecting the ELA (accumulation and ablation).

In Scandinavia, this approach has been applied in many glaciated areas (Nesje and Dahl, 1991; Nesje et al., 1995;



Equilibrium-Line Altitude (ELA), Figure 5 (**a**) TP-ELA curve for northern Folgefonna based on a record of bulk-density record. The lower part of the figure is a summary of sources for validating the ELA record; the peat bog in Hestadalsmyra, floods in Lake Vassdalsvatn, sorting anomalies in Dravladalsvatn, glacial input in Vassdalsvatn, and record of glacial input to Dravladalsvatn. (**b**) Regression between periods with known ELA (calibrated against the moraine chronology) and bulk-density values. The regression model is used to transfer the bulk-density record to a continuous TP-ELA curve (Bakke et al., 2005b).

Dahl and Nesje, 1996; Nesje et al., 2000; Nesje et al., 2001; Seierstad et al., 2002; Bakke et al., 2005a; Bakke et al., 2005b). The overall evolution of maritime glaciers along the western coast of Norway shows a gradual decrease in ELA from 5,200 cal. yr BP until after the termination of the "Little Ice Age." This pattern fits well with the general insolation curve for 65°N that may indicate a close linkage between glacier growth and solar orbital forcing at high latitudes during the late Holocene. Wetter conditions combined with lower summer insolation made the climate favuorable for glacier growth in Scandinavia, especially at maritime sites along the North Atlantic coast of Norway (e.g., Nesje et al., 2001). The linkage to solar insolation also makes it clear that the retreat of maritime glaciers along the entire western Scandinavia over the last century is unprecedented in the entire Neoglacial period spanning the last 5,200 years. Hence, this observation puts the reported glacier retreat in the twentieth century (Oerlemans, 2005) into a long-time western North Atlantic perspective as an anomaly. However, some of the most maritime glaciers in Southern Norway with short response time to climate have shown expansion during the latest decade of the last millennium with a retreat toward the present. This is proven to be a response to larger winter precipitation due to positive winter NAO during some years in the early 1990s (Nesje et al., 2005).

Summary

The equilibrium-line altitude (ELA) marks the area or zone on a glacier where accumulation is balanced by ablation

over a 1-year period. The ELA is sensitive to several meteorological factors, such as variations in winter precipitation, summer temperature, and wind transport of dry snow. When the annual net mass balance is negative, the ELA rises, and when the annual net mass balance is positive, the ELA falls. Fluctuations in the ELA provide an important indicator of glacier response to climate change that allows reconstructions of palaeoclimate (accumulation-season precipitation, ablation-season temperature, and prevailing snow-bearing wind directions). Palaeoclimatic reconstructions based on former glacier extent commonly include estimates of equilibrium-line altitudes (ELAs) and depression of ELAs from present values. Several methods have been developed to estimate steady-state ELAs of former glaciers as a tool to reconstruct palaeoclimates in glaciated regions. A survey of literature related to ELA depressions during the last glacial maximum, Younger Dryas, and the "Little Ice Age" shows lowerings from modern values in the order of 1,000 ± 300 m, 500 ± 200 m, and 100 ± 50 m, respectively. High-resolution reconstructions of ELA give valuable palaeoclimatic information from the terrestrial realm allowing comparison with other high-resolution archives, e.g., ice core and marine sediment records.

EROSION OF HARD ROCK BED

D. P. Dobhal
Wadia Institute of Himalayan Geology, Dehradun, Uttarakhand, India

Definition

As the river passes over the hard rock bed, it scours rock. The continuous scouring of the rock produces a vertical drop in the river channel. It behaves like the waterfall. The energy of the falling water will continue to erode the bed of the river so that eventually a plunge pool will develop at the base of the waterfall. The plunge pool develops initially because the force of the falling water creates a slightly deeper pool in the bed of the river. As the rivers' bed load falls into the pool it swirls and scours the base of the pool causing it to deepen.

EROSION RATE

Subhajit Sinha
DBS College, Dehradun, Uttarakhand, India

Definition

Sedimentation is the process by which material is deposited from the water column to the bed. Conversely, erosion occurs when material is removed. A long-term (say more than 30 years) average annual erosion rate is the average amount of erosion that occurs from a watershed or study area. The sedimentation/erosion rate in waterways is naturally variable because of the variability in natural processes influencing it such as water-current/flow patterns, climate (rainfall, seasonality), geology, slope (or topography), etc. Human activity (e.g., dredging, impoundments, hydrodynamic alterations, land clearing, etc.) may also result in changes to sedimentation/erosion rates. Increased sedimentation/erosion rates can result in important changes to the form and function of waterways. For example, they may cause changed shoreline and mudflats

area, channel infilling, habitat/benthic community smothering or removal, community composition changes, increased turbidity levels, and the burial or re-suspension of nutrients, trace elements, toxicants, and organic matter. In general erosion rate from the active glaciers is very high.

ESTIMATION OF GLACIER VOLUME AND VOLUME CHANGE BY SCALING METHODS

David B. Bahr
Department of Physics and Computational Science, Regis University, Denver, CO, USA

Definition

Scaling relationship. A power-law exponential equation that relates two quantities such as volume and area.

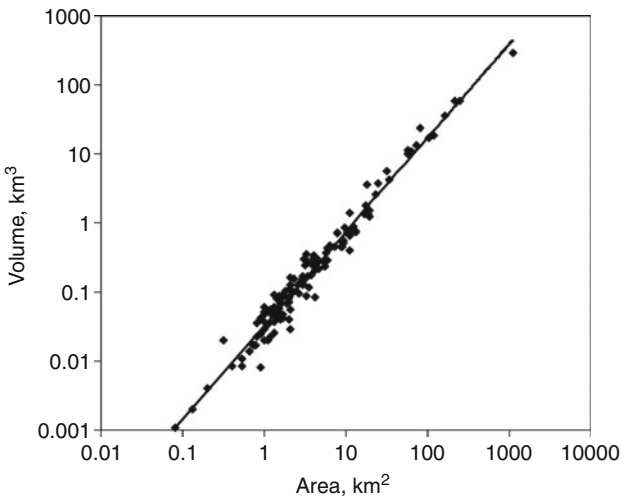
Estimating volume

Glacier volume V can be estimated from the glacier surface area A using the scaling relationship

$$V = kA^{\gamma} \quad (1)$$

where γ and k are derived from either data or theory (Figure 1). Typical values are $\gamma = 1.36$ and $k = 0.033$ km$^{3-2\gamma}$ for valley glaciers (Macheret et al., 1988; Chen and Ohmura, 1990; Bahr et al., 1997; Bahr, 1997). In many cases, measurements of the glacier volume would be preferable, but this has been done for relatively few glaciers (less than 200), and generally cannot be accomplished without considerable time or expense. The most common measurement technique uses ground-penetrating radar (see entry "*Ground Penetrating Radar Measurements Over Glaciers*"), but with crevasses and inaccessible terrain, hundreds of thousands of glaciers cannot be practically measured using this approach.

In contrast, a scaled estimate like Equation 1 uses a power law to relate an easily measured quantity like surface area to a difficult to measure property like volume. Other power-law scaling relationships involving glacier length, thickness, width, and various quantities have been derived from both theory and data. For example, surface velocity scales with thickness and therefore volume (Bahr, 1997). Many of these power laws can be used to estimate volume (Radic et al., 2008), but glacier area is one of the easiest quantities to measure, and abundant area data have made Equation 1 the most common volume-scaling relationship.

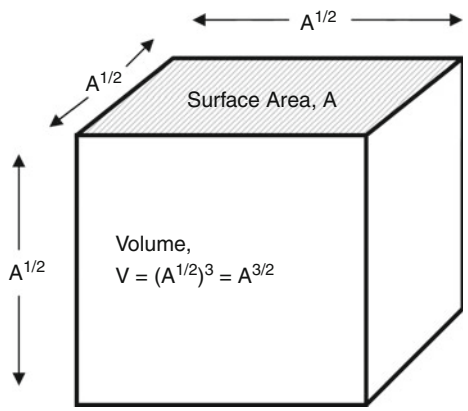


Estimation of Glacier Volume and Volume Change by Scaling Methods, Figure 1 On a log-log plot, glacier area and volume scale linearly. For this set of 144 temperate valley glaciers from around the world, $V = 0.033\ A^{1.36}$ with a squared correlation coefficient of $R^2 = 0.97$. Data are available on request.

Deriving volume–area scaling

The principle of volume–area scaling can be illustrated with a box (Figure 2). Given the surface area A of a square box, we can calculate the length, width, and depth as the square root of the area, $A^{1/2}$. The volume V of the box becomes the cube of the length or $V = A^{3/2}$. Therefore, for a box, the volume–area scaling exponent is 3/2. Similarly, the volume of a glacier is related to its area by a somewhat smaller exponent that reflects a glacier's more elongated shape caused by flowing ice. In this case, the volume–area scaling exponent can be derived directly from the equations of glacier flow.

Glacier flow is described by mass and momentum conservation along with a constitutive relationship that relates deviatoric stresses to strain rates, most commonly Glen's flow law or a similar modification (see entry "*Dynamics of Glaciers*"). Mass conservation (or mass balance) leads to the continuity equation (see entry "*Glacier Mass Balance*"). Momentum conservation leads to the force balance equations (see entry "*Dynamics of Glaciers*"). To derive scaling



Estimation of Glacier Volume and Volume Change by Scaling Methods, Figure 2 The volume of a box can be derived from its surface area, similar to a glacier.

relationships, each physical quantity in these equations can be rescaled by multiplying by a constant factor. This leads to the stretching symmetries of the differential equations (Bahr and Rundle, 1995).

For example, horizontal velocity v can be stretched or rescaled as $v_{\text{stretched}} = \lambda^a v$, where λ^a is a constant. Similarly, thickness h can be rescaled as $h_{\text{stretched}} = \lambda^b h$ where λ^b is another constant. Length x can be rescaled as $x_{\text{stretched}} = \lambda^c x$. Mass balance rate $\dot{b}$ can be rescaled as $\dot{b}_{\text{stretched}} = \lambda^d \dot{b}$, and so on with stretching constants applied to each variable. Substituting these stretched quantities into the original equations and factoring out λ gives a set of relationships between the exponents a, b, c, d. In other words, if the length of the glacier is stretched by a certain amount, then the thickness (and other quantities) will have to be stretched by another specified amount to maintain consistency within the equations.

These stretching relationships give nondimensional numbers for glaciers that are analogous to Reynolds, Froude, and other quantities from the linear-viscous Navier–Stokes equations. For example, the nondimensional number arising from the continuity equation is

$$\frac{\dot{b}\,x}{vh} = C \tag{2}$$

for some constant C. Equivalently by rewriting, $\dot{b}\,x \propto vh$, and we see that this nondimensional number relates two well-known quantities that describe the response time of glaciers (Jóhannesson et al., 1989).

By combining Equation 2 with other nondimensional numbers from force balance and the constitutive relationship, we can relate volume to surface area as in Equation 1 (Bahr et al., 1997; Bahr, 1997). The scaling exponent γ becomes a function of the flow law exponent n and the slope. For $n = 3$ and shallow slopes like ice caps, $\gamma = 1.25$. For $n = 3$ and steeper slopes, $\gamma = 1.375$. These values are in notable agreement with available data which suggest values of ~1.22 for ice caps (Meier and Bahr, 1996) and ~1.36 for glaciers (Bahr et al., 1997).

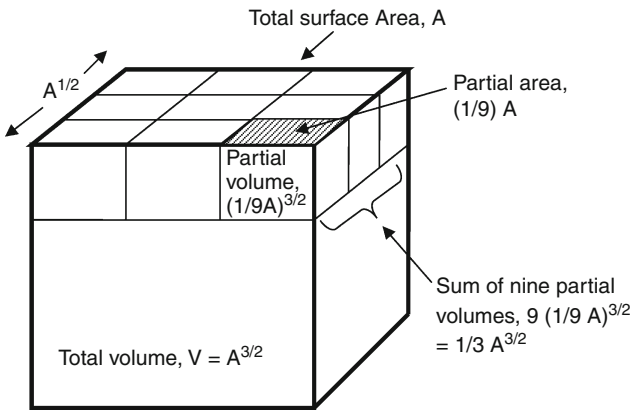
The scaling constant k is derived as a combination of the nondimensional numbers like C in Equation 2 (using the same combination of nondimensional numbers that produce the volume–area scaling relationship). Just like rivers which can have different Reynolds numbers depending on the amount of turbulence, every glacier can have a unique set of nondimensional numbers associated with its dynamics. However, unlike rivers, most glaciers have relatively similar flow regimes. So while rivers can have both high and low Reynolds numbers (indicating turbulent flow versus laminar flow), most glaciers will have similar nondimensional numbers and therefore similar scaling constants. Data suggests that the volume–area scaling constant has a well-defined normal distribution with a mean value of 0.034 $\text{km}^{3-2\gamma}$ and a standard deviation of 0.013 when volume and area are measured in kilometers (Bahr, 1997). A value of 0.12 $\text{m}^{3-2\gamma}$ has also been derived by assuming a total worldwide volume of ice and tuning the scaling relationship accordingly (Van de Wal and Wild, 2001).

Limitations of volume scaling

When applied to a single glacier, volume–area scaling should be treated as a reasonable but low-order approximation. Any single glacier is expected to fall along the power-law curve but may deviate slightly as illustrated in Figure 1. As discussed above for nondimensional numbers, the volume has a distribution of possible values with the mean falling on the volume–area curve. For linear regressions on a log-log plot, the standard deviations for large glaciers are more pronounced than deviations for small glaciers.

Volume–area scaling works most accurately when applied to large sets of glaciers. Errors that overestimate one glacier will be offset by errors that underestimate another glacier. For example, the total volume summed from many glaciers will be more accurate than the volume estimate of any single glacier (Bahr et al., 2009). The number of glaciers necessary for a sufficiently large set is a statistical question and depends in part on the quality of the data as well as sampling biases such as preferentially choosing larger glaciers over smaller glaciers. However, as seen in Figure 1, an order of magnitude of 100 glaciers appears sufficient and in many applications far fewer glaciers may be reasonable.

Although published examples exist, volume–area scaling cannot be applied to parts or subsections of a glacier. The stretching relationships and nondimensional numbers are derived from the equations for the entire glacier. As an example, consider a box again with the scaling relationship $V = A^{3/2}$ (Figure 1). If the square surface A of the box is subdivided by a grid into nine equally sized smaller squares (Figure 3), then each smaller part has a length that is one-third of the original and has an area that is one-ninth of the original. Using the scaling relationship, the volume



Estimation of Glacier Volume and Volume Change by Scaling Methods, Figure 3 Volume–area scaling cannot be applied to subsections of a glacier. As illustrated with a box, subdividing the surface into nine parts and then applying scaling will give a fraction of the correct total volume.

of each smaller part will be 1/27 the original. If we add up all nine subsections, the total volume will be only one-third of the correct volume. Although the scaling exponent is different for glaciers, using subsections of a glacier would result in similar underestimates of the volume. Only linear scaling relationships with an exponent of 1.0 can be subdivided in this manner.

Estimating volume changes

The derivation of stretching symmetries does not assume steady-state conditions, and volume–area scaling can be used to analyze changing volume with time. A number of numerical simulations have tested the accuracy and demonstrated the application of scaling to changes in volume in both steady-state and non-steady-state conditions (Pfeffer et al., 1998; Church et al., 2001; Van de Wal and Wild, 2001; Radic et al., 2008). In a straightforward approach, a derivative of Equation 1 gives

$$\partial V = k\gamma A^{\gamma-1}\partial A \tag{3}$$

In other words, a change in the volume can be estimated from the original area as well as the subsequent change in the area. However, Equation 3 is only exact for the infinitesimal changes for which the derivative is calculated. As the change in area grows large, Equation 3 will become a poor estimate, and an integration of small changes will be necessary.

Alternatively, finite changes in area can be used. From Equation 1,

$$V + \Delta V = k(A + \Delta A)^{\gamma} \tag{4}$$

where ΔV is a finite change in volume caused by a finite change in area ΔA. Dividing by the volume gives

$$(1 + p_v) = (1 + p_A)^{\gamma} \tag{5}$$

where $p_v = \Delta V/V$ and $p_A = \Delta A/A$ are the fractional changes in volume and area (Bahr et al., 2009). Equation 5 will work well for glaciers affected by climate change, most of which have experienced large fractional changes in area. Conveniently, the scaling constant k is not necessary when estimating fractional changes in volume from Equation 5. This eliminates a potential source of measurement error.

The change in area necessary for a glacier to reach equilibrium with the current climate (where the glacier is neither gaining nor losing mass) can be estimated from its accumulation-area ratio, *AAR*. Using the relationship between *AAR* and glacier surface areas,

$$p_A = AAR/AAR_0 \tag{6}$$

where AAR_0 is the glacier's accumulation-area ratio when in equilibrium (Bahr et al., 2009). Data show that the worldwide average AAR_0 is 0.57 ± 0.01. Consequently, a volume change to AAR scaling relationship is derived by combining Equations 5 and 6, and the fractional change in volume p_v is easily estimated from the glacier's current accumulation-area ratio. The total change in glacier volume is just $p_v V$. By summing $p_v V$ over all glaciers, estimates of glacier meltwater contributions to sea-level rise are possible.

Summary

While difficult to measure directly, glacier volume can be more easily approximated by measuring surface area and applying a power-law scaling relationship. The volume–area scaling relationship has been predicted and well established from field data, theory, and numerical modeling. As a glacier changes size, the consequent changes in glacier volume also can be estimated and predicted by derivations from the same volume–area relationship. Summing such changes over all the world's glaciers gives a convenient measure of global changes in sea level.

What is an estuary?

An estuary is a semi-enclosed coastal body of water (Figure 1). The downstream limit is where seawater is measurably diluted by fresh river water. Its upper boundary extends as far as tidal effects are felt. Often, the interpretation of the estuary's limits will depend on the phenomena of interest. For example, some may use a narrow interpretation such as the brackish zone near the mouth of a river. Others may use biological markers that could well extend up into the zone where the water is always fresh but where the tidal signal is still important for flora in shallow zones. If regional processes are of interest, then the definition can cover areas as large as the Arctic Ocean (Macdonald, 2000) since most of the saltwater within it is indeed diluted by the many rivers entering it. Therefore, the working definition of an estuary depends, to a certain extent, on the phenomenon of interest. The important element of an estuary is that there is a mix (to a greater or lesser extent) of sea- and land-based processes.

Estuary classification

Estuaries may be classified according to their geographical location (e.g., Arctic; Sub-Arctic; Continental; etc.); their overall aspect (Archipelago; Delta; Bay; Sound; Fjord; Lake; Gulf; etc.); their size; their shape (e.g., narrow; open; funnel); their depth; their direction of flow (northerly, etc.); their source of freshwater: glacier (fjord) or river (ria); their geological origin (sea level rise; sediment deposition; etc.); their tidal amplitude (macrotidal; mesotidal, or microtidal); the fresh/saltwater mix profile (salt wedge, partially mixed, well mixed, or frozen); the longitudinal salinity gradient (positive or negative); as polluted or pristine; as healthy, recovering or sick; as productive or dead; as urban or natural; and, of course, as ice-covered or not.

River and sea dynamics

All these characterizations are useful and necessary to help describe and understand particular phenomena of interest. Another viewpoint that can help understand estuaries is to view them as battle zones of competing forces and processes. From the watershed, the river enters an estuary and must fully succeed in transporting into it, its load of water, sediment, suspended particulates, dissolved gases, nutrients, fish, mammals, plants, and pollutants. At the downstream end, the sea enters the estuary and must accept the river's load but not, however, without imposing its own characteristics. The sea's saltwater is heavier than freshwater, its temperature is normally very different than the river's, its point of fusion is suppressed (typically $-1.9°C$ for fully saline water); and as the brackish water travels upstream, it does so with the erosive force of its waves, currents and most importantly, its tides. Seawater comes with its own chemistry, fish, plants, mammals, nutrients, and purity or pollutants. The river and the sea battle for physical, chemical, and biological dominance; the river wins mostly in the upstream reaches while the sea wins mostly in downstream flats. In the middle is a unique habitat where

the plants, fish, and birds present there can adapt to rapidly changing salinity, water levels, waves, and currents.

The two bodies of water (fresh and saline) are normally totally out of sync with each other and therefore the fight between river and sea is somewhat cyclical. The timing and intensity of the river's transport is dictated by processes dependent on the river's characteristics and on its watershed size, relief, shape, aspect, content, anthropogenic activity, climate, season and weather. Seawater is governed by longer term weather patterns, changes in ocean currents and salt content; the wave intensity is due to large weather systems, storm surges, and tides that are dictated by the earth's rotation and the relative position of heavenly bodies (i.e., moon and sun) having nothing to do with land-based dynamics.

Atmospheric dynamics

The third actor on the battle field could be described as the atmosphere whose characteristics include humidity; precipitation (rain, snow); wind (speed and direction); airborne particles (inert, organic, living spores, and pollutants); incoming radiation (short and long wave); insects, and birds. The estuary has no choice but to adapt itself to these inputs.

Anthropogenic influence

The fourth influence is comprised of human interactions with the estuaries and includes shore protection; channel dredging; harbor construction; river training; wetland infilling; thermal additions (e.g., thermal plumes from power plants); fishing and overfishing; exotic species invasions; oxygen depletion (by pollution and excess nutrients); and oil, nuclear, and toxic spills, ice management, and ice-breaking activities.

The spatial nature of the estuary and ice

The spatial extent is sculpted by the relative strengths of river's discharge, the atmosphere's wind, the anthropogenic activities, and the sea's tide. On the flip side, the estuary's spatial character will highly influence the nature of the interactions, providing a relative advantage to one over the other and will therefore dictate how the four actors interact. The estuary physical space is defined by its geographical location; size; width; length; shape; orientation; bathymetry; the presence or absence of islands; the extent of its shelf; sediment size; vegetative cover, and the presence of ice in all its many forms.

The ice cover as a barrier between water and atmosphere

The presence of an ice cover dramatically changes the nature of the battlefield and may go so far as to absolutely change the character of an estuary (if only seasonally). An ice cover normally reduces mixing (leading to stabilization and stratification of the water column) because it provides a barrier between the wind and water diminishing the strength of the sea waves, longshore currents, and Ekman flows. The cover arrests light penetration affecting plant growth and fish dynamics. It limits heat and mass transfer (modifying evaporation rates and protecting tidal flat animals from freezing). It cuts off airborne particles drastically reducing sediment transport, limiting reoxygenation and other gaseous exchanges. The cover is a physical barrier forcing sea mammals to come up through ice holes to breathe and preventing ships from navigating. It offers a platform providing support for bears to fish upon; to support people and animals to traverse; to enable caribou to find salt and to enable wolves to attack animals upon.

The ice cover as a barrier between fresh- and saltwater

The ice cover can also be a pathway or a barrier between fresh- and saltwater that can damp tidal amplitudes (e.g., the presence of sea ice formed over the greater Canadian Archipelago reduces James Bay tidal amplitudes from 1.5 m in summer to 1.0 m in winter at the inlet to La Grande River). The ice sheet can provide conditions allowing large freshwater penetration under the ice into the sea in Russian Arctic estuaries and those of Eastern Hudson's Bay. At the edge of the cover, a ridge can be built up into a deep (>20 m) ridge. Virtually all of the Mackenzie's winter flow (0.3 m tide) is stored locally behind this barrier in a unique vertically and longitudinally stratified system known as a "winter" estuary (Macdonald, 2000). It is then released in sync with the spring freshet providing a dramatic freshwater pulse to the Beaufort Sea. In the case of the mesotidal Churchill Estuary (3.3–4.2 m tide), the ridge's role only delays the outpouring of the freshwater into the Western Hudson's Bay by a few days but ice is still the dominant feature of the estuary that highly influences physical and biological processes: "Until late May, the rubble zone partially impounded river discharge, influencing the surface salinity, stratification, flushing time, and distribution and abundance of nutrients in the estuary. The river discharge, in turn, advanced and enhanced sea ice ablation in the estuary by delivering sensible heat. Weak stratification, the supply of riverine nitrogen and silicate, and a relatively long flushing time (6 days) in the period preceding melt may have briefly favored phytoplankton production in the estuary when conditions were still poor in the surrounding coastal environment. However, in late May, the peak flow and breakdown of the ice-rubble zone around the estuary brought abrupt changes, including increased stratification and turbidity, reduced marine and freshwater nutrient supply, a shorter flushing time, and the release of the freshwater pool into the interior ocean. These conditions suppressed phytoplankton productivity while enhancing the inventory of particulate organic matter delivered by the river. The physical and biological changes observed in this study highlight the variability and instability of small frozen estuaries during winter/spring transition, which implies sensitivity to climate change" (Kuzyk et al., 2008).

Ice impact on the physical boundaries

An ice cover and the presence of grounded ice on tidal flats reduce the spatial boundaries of an estuary. In macrotidal estuaries (e.g., Bay of Fundy, Canada (16 m tide)), estuary ice can reach very significant thickness on the tidal flats. In a matter of days, the 5-m-thick stranded ice accumulated on the Petitcodiac Estuary's tidal flats forms "ice walls" that change the channel's trapezoidal shape (with side walls 1 V to 3.5 H) into a rectangular shape (Desplanque and Bray, 1986). As such, the tidal prism and associated flow rates are substantially reduced. In the 5.9-km long mesotidal Portneuf Estuary, Canada, no tidal walls were noted but nevertheless, the midwinter fast ice cover (0.5 m thick), through the combined effects of change in bathymetry and increased wetted perimeter, attenuates the neap tidal range (1.9 m) and spring tidal range (4.0 m) by 17% and 37%, respectively, near the upstream end of the estuary. The arrival of low water is also delayed by about 1.5 h. At the mouth, the cover attenuates the peak ebb tide flow (200 m^3/s) and flood tide flow (500 m^3/s) by approximately 18% and 13% (the river's winter discharge is 20 m^3/s). In general, the ice cover attenuates peak velocities by 12% to 20%, although at certain times and locations, its presence could increase velocities. The ice cover also retards and diminishes the salt wedge intrusion (Morse et al., 2006).

Ice as a barrier between water forces and sediment transport

Bottom fast ice can protect permafrost and can help shape the estuary's beach profile. Ice on tidal flats can be present as a smooth cover or multilayered pieces of drift ice that are frozen together. This ice can rest on the beach, float, or be frozen into the bottom. It provides a barrier between currents, waves, and the shore and can thereby protect the shore from coastal erosion. However, through freezing contact, it can also pick up significant amounts of sediment and organic material and can be an important agent of tidal flat formation. Some ice pieces grow into huge blocks laden with sediment and weigh several tons. They can be lifted on a flood tide and moved. Since they can potentially be both neutrally and negatively buoyant, they represent a significant risk to boats, fishing nets, and marine infrastructure (such as tidal power installations).

Ice as storage

The fast ice preserves water (primarily fresh) until breakup. Depending on the severity of the climate and the tidal range, a substantial amount of water is stored as ice. This implies that the freshwater output from the estuary is significantly reduced in winter. As freshwater goes into storage, brine is released leading to salinization and the creation of a locally "negative" estuary (Macdonald, 2000). The eventual melting of the ice is normally in sync with the spring freshet and thus the freshwater yield (volume of water divided by spatial area) from the estuary to the sea can be significantly increased. This has many implications for primary productivity, for ocean currents and for atmospheric–ocean interactions.

The ice ridge–ice flaw system

Another feature of some ice-covered estuaries is the existence of an open flaw lead (polynya) separating the ice ridge and the mobile sea ice pack. In some cases, the flaw exists in absence of the ridge. The lead can generate a great amount of ice and therefore a great amount of brine resulting in significant vertical mixing. The interplay between the lead, the rubble ridge and the ice cover is fascinating and is documented by Macdonald et al., (1999).

Global coverage of estuaries subjected to ice processes

Many estuaries of the world form an ice cover. The frequency and duration depend primarily on the local climate (particularly the number of degree-days) and the water temperature of the local sea. In some cases, a cover forms each winter (Canada, USA, Alaska, Northern Europe and Russia where it lasts for 9 months), whereas in lower latitudes ice on estuaries is present infrequently (e.g., Columbia Estuary, OR, USA; Chesapeake Bay, VA, USA or the Garonne Estuary at Bordeaux, France). In the following paragraphs, some chosen estuaries from different geographic locations will be discussed.

Continental macrotidal estuaries

Ice cover formation in estuaries depends primarily on the tidal amplitude, the estuary's spatial layout and the wind speed and direction. After presenting an estuarine ice terminology, Desplanque and Bray (1986) provide a detailed discussion of ice formation in a macrotidal estuary in eastern Canada: In the upstream zone of the estuary, a classic river-type of ice cover forms. In the second zone (delineated at the upstream end by high water at spring tide and at the downstream end by high water at neap tide), a series of layers of drift ice stacking up on the tidal flats forms ice walls. The third zone is delineated at the downstream end by the low water associated with spring tides. It is characterized by vast intertidal mud flats whereon drift ice may become temporarily stranded and frozen to the sediment. The fourth zone is always covered with water having a salinity of 10–25‰. This vast zone produces most of the ice (slush, pan, cake) that is transported up the estuary as drift ice. Zone 5 is too deep to cool to the freezing point and therefore produces no ice.

Nelson and Whitney (1996) describe the macrotidal Cook Inlet, Alaska. It "is unique in that it has a very high suspended sediment load, high tides (10 m), a moderate snow fall and an air freezing index of 1,400°C days per year. These conditions combine to cause low visibility, extreme tidal currents (8 kts) and unique modes of ice generation within the inlet. The major mode of formation of floating ice is identified as slush ice formation. The slush then coalesces in the turbulent waters to form various ice features. Ice features with depths greater than 2 m that formed in less

than 7 days are described. Ice buildup on shore based structures results in significant downward and upward vertical forces as well as potential horizontal forces."

Continental mesotidal estuaries

One of the most striking descriptions of an ice cover formation is given by Meese et al., 1987 for an inner estuary having a 3 m tide near Newington, NH known as Great Bay. The authors note that freshwater inflow is very modest (only about 2% of tidal flow) and that the salinity is typically 23‰. "The first stage of the freezing process was characterized by growth of frazil crystals that began forming on the surface of the water on 17 December 1983, giving it a greasy appearance. These crystals, up to 2 cm in diameter, coalesced to form the initial ice sheet. Two days later, wave action caused this sheet to break up into circular-shaped masses (pancakes) that developed raised rims due to collisions with other masses. Frazil continued to grow between the pancakes until, on 22 December, a continuous sheet of ice had formed. By 28 December the ice had thickened to 12 cm and the sheet extended to the edge of the cove. Beneath the frazil ice a structural transition was observed that was characterized by a change in the crystalline texture of the ice that led ultimately to the formation of relatively large columnar-shaped crystals exhibiting brine lamella ice plate substructure, the trademark of typical congelation sea ice. Locally, snow ice was found, formed by the flooding of a snow-covered ice surface by seawater. This results in the formation of slush which subsequently freezes to form the top layer of the ice sheet. The crystals in this layer are generally fine-grained and have a random orientation. Mixing of snow with rain or melt water followed by freezing produces a similar result." The authors go on to note that the snow-ice layer can contain a high degree of salinity when the sheet is flooded by estuarine water or may have a very low salinity when the sheet is flooded by rain. The frazil ice layer had a low salinity. The columnar ice layer's salinity depended on its age. The older it was the more time it had to reject brine and the fresher it was.

Morse et al. (2006) describe the ice cover in midwinter in a mesotidal estuary and its subsequent breakup. In this case, the cover was similar to a river's with the exception of a very large number of longitudinal fissures outlining the principal channel (thalweg); the precarious nature of the ice; the thinning of the ice cover from the banks toward the deeper portions; and a number of local ice effects (e.g., slush balls) related to a tidally dynamic environment. Breakup is also described and is shown to occur as a specific sequence over a few spring tide semidiurnal cycles. On the first ebb tide, ice from the main channel is removed over a certain distance (~1–2 km). On the next ebb tide, ice from the adjacent tidal flats is removed as is the next upstream section of ice cover in the channel portion. After the third ebb tide, thick ice pieces got stranded along the main channel bottom at low tide creating a series of weirs that the water cascaded over. On the following ebb tide, virtually all the ice was gone.

The Saint Lawrence estuary

Ice formation and breakup on the St. Lawrence is also of great interest because of its length and socio-economic-environmental importance. Ice on the Estuary is surveyed about three times a week and is available online from Environment Canada. The St. Lawrence is a huge system and therefore ice processes vary greatly. Upstream of Montreal are vast expanses of water commonly referred to as lakes where, until they are frozen over, large quantities of floating sheets are generated. These are broken up through the rapids near Montreal wherein frazil ice and anchor ice can also be added to the mix. From Montreal to Sorel, although the River is affected by the tides, the diurnal amplitude signal is absent and therefore, this reach acts just like any river wherein shore ice forms near the banks and the drift ice increases in thickness and concentration as it moves down the River. The Sorel to Trois-Rivières reach is so vast that it is referred to locally as a lake. It has a very small (10–20 cm tide) and is very shallow (3 m) except through the middle of it where a 12 m navigation channel is maintained. As such, the shallow portions quickly form a cover (held in place by artificial islands and booms) and the drift ice continues down the navigation channel. Because of the very small river slope, this reach is particularly susceptible to forming jams under adverse wind conditions. The Trois-Rivières (30 cm tide) to Québec (6 m tide) reach has high concentrations of drift ice moving down the river, frazil ice is formed in the water column causing blockages of local water intakes and blocks of ice are stranded on the tidal flats. Near Québec, ice on the flats can build into walls and ice elements on tidal flats have strong interaction with sediment processes. Downstream of Québec, there is primarily drift ice consisting of very large floes. Late in the winter season, during cold years and under unfavorable wind conditions, ice thickness and concentrations can reach significant levels and ships must be escorted by ice breakers (Smith et al., 2006).

Canadian arctic estuaries

The ice features of the Churchill (Hudson's Bay) mesotidal Arctic estuary are beautifully described by Kuzyk et al., 2008 (some elements are presented above). Prior to the major flow diversion to the Nelson River in the mid-1970s, the inner Churchill estuary ice was primarily composed of freshwater having an increased salt content as one travels downstream. Pratte (1975) gives an insight into the ice formation at the Port of Churchill, noting that "operations are forced to stop for ice formed upstream in the rapids, which comes down at ebb tide, jamming against the ships at the dock . . . breaking mooring lines."

Ice features of the microtidal Mackenzie estuary are fully described by Macdonald in a large number of papers (e.g., Macdonald et al., 1999). One particular ice-growth hypothesis for the Mackenzie is the formation of frazil ice in the overlying freshwater layer because of the colder

saltwater layer below. An associated article incorporating local ecological knowledge is presented by Carmack and Macdonald (2008). It is also compared to the neighboring Husky lake estuary of a very different nature (Macdonald, 2000). In all cases, the main winter features of the McKenzie are a smooth thin ice cover in the river portion of the estuary bounded by a significant ice ridge outside the mouth, a flaw lead on the other side and mobile pack ice further out. The nature of Beaufort nearshore ice and some explanations for the ice ridge are provided by Timco (2008) and the role of tidal jacking in the Canadian Arctic is discussed by Stander et al. (1988) for inlets north of Baffin Island.

Some biological processes are described by Emmerton et al., 2008. During river passage through the Mackenzie estuary, particulate matter, dissolved organic carbon and inorganic nutrients showed sedimentation, dilution and biological uptake patterns common to other arctic and non-arctic estuaries. Alternatively, inorganic content of particles increased offshore and dissolved organic N and P increased substantially over the shelf, reaching concentrations among the highest reported for the Arctic Ocean. These observations are consistent with the presence of a remnant ice-constrained ("stamukhi") lake from the freshet period and a slow flushing river plume constrained by sea-ice in close proximity to shore.

Making the link with biological processes, "snow and sea ice cover melt and/or break-up controls the timing of the phytoplankton bloom but primary producers (ice algae and phytoplankton) on the outer shelf are essentially nutrient limited. The total annual primary production (22.7 to 27.7 g-C m^{-2}) is thus controlled by nutrient "preconditioning" in the previous fall and winter and by the depth of wind mixing that is controlled in part by the supply of freshwater at the end of spring (ice melt or runoff)" (Lavoie et al., 2009).

According to Barnes (1999), ice causes the most important disturbance to polar benthic communities. "This occurs in four main forms: the ice-foot, ice scour, anchor ice and fast ice, each of which influences benthos in a very different temporal and spatial manner. The four described forms of ice disturbance are all seasonal, but combined, influence communities throughout the year. The magnitude of ice mediated disturbance is often catastrophic and as a result both dominates benthic community structure and makes recolonization and development rates critical."

The role of water on the ice cover in reducing the albedo and promoting spring melt due to surface melting prior to breakup and the imposition of the massive freshet water. The importance of overlying spring water on the nearby Simpson Lagoon, Alaska, is discussed by Matthews and Stringer (1984).

Russian arctic estuaries

Because of their large freshwater discharge rates, Russian rivers dominate the Arctic Ocean. An overview or these estuaries is given by Dolgopolova and Mikhailova (2008). They note that a "distinguishing feature of freeze-up of Siberian rivers is the beginning of ice formation at the supercooled anchor ice then lifting up to the water surface." Furthermore, "hanging dams are usually formed at the northern rivers . . . meeting the firm estuary ice cover" that normally reaches 2 m thick. Of particular interest is the role of ice jams upstream in drastically diminishing the flow in the estuary that can lead to stagnation there: "its color becomes reddish that results in suffocation of fish." Also of interest is the formation of an intermediate "cold layer of brackish water, which is kept after ice formation" in nontidal estuaries. In fact, one of the interesting elements of this paper is that the estuaries are presented as a function not only of estuary mouth type but, more importantly, as a function of tidal range that increases from East to West in the Russian Arctic Ocean.

Eicken et al. (2005) present a very important paper on the Lena and Yana "open" estuaries of the Laptev Sea. What makes the paper so interesting is the direct comparison of these estuaries with the Mackenzie. They show that Russian estuaries are "winter" estuaries (having a unique saline stratification due to the presence of ice) but that they do not have the very important ice rubble ridge to confine freshwater. "Freshening of under-ice waters during winter and north-/northeastward spreading of the river plume with under-ice spreading rates of 1.0–2.7 cm s^{-1}" (about ten times faster than the spreading in the Mackenzie). For the years studied, the Laptev brackish water plume extended to a depth of 10 m. Stable-isotope data show that the landfast shelf ice is composed of about 62% of river water, locking up 24% of the total annual Lena and Yana discharge. Inside the mouth (delta), the ice samples contained virtually no salt. In the nearshore, salinity of the cores increased as a function of distance from the mouth and as such there is a gradual 10% (0.2 m) decrease in fast ice cover thickness.

Arkhipov et al. (1997) present the results of a two-dimensional laterally averaged model developed to describe the hydrodynamic and thermohaline processes in the Ob and Tas Rivers estuary. Koziy et al. (1998) developed a one-of-a-kind 3-D model for the assessment of contamination in coastal seas and inland water bodies. It includes a high resolution numerical hydrodynamic submodel, a dynamic-thermodynamic ice submodel, and submodels for suspended sediment and pollution transport. Presented are simulations for the assessment of the consequences of the possible release of radionuclides from scuttled nuclear reactors in the Novaya Zemlya fjords and the East Novaya Zemlya Trough of the Kara Sea.

Northern European estuaries

According to Carstensen (2008), "ice events may naturally occur on the German coasts. Ice at the Baltic Sea coast exists mainly as drifting ice. In coastal regions a continuous ice cover over a wide area forms only in very severe winters also due to the salinity of the water. These ice covers are then

generally broken up when storms cause water level fluctuations and the resulting ice floes are subsequently carried out to the sea or onshore depending on the currents (induced by wind or tides) and/or the wind. Ice events such as ridging (ca. 0.5 m high) or hummocking can force ice to pile up to several meters in height. Such ice events can greatly damage coastal protection structures and in the worse case make them unfit for use." Furthermore, "when spray water or defrosting water freezes on pile constructions or groynes above the water surface level, ice is accumulated, building formations several times the diameter of the structure. Due to these accreted formations, rising water levels may exert buoyant forces on these structures therewith pulling them up and diminishing there stability against collapse and usability." Water quality parameters in northern Germany estuaries are described by Grisard (1994).

Ice floes are widely known to abrade surfaces of structures constructed in seawater areas where ice floes move actively in the Gulf of Bothnia, Sweden.

Although people use to skate most winters on Norwegian fjords, over last 2 decades, there has been virtually no ice. This, of course, is a significant cultural loss and the fjords are changing because they are now open to much stronger winter storms. Much further north, the interplay of icebergs and bergy bits with currents and sediment processes for Kongsfjorden, northwest Spitsbergen are described in detail in Dowdeswell and Forsberg (1992).

Conclusion

Estuary ice has many interesting features (smooth cover, hummocks, ridges, stamukha, blocks, ice feet, hanging dams, ice weirs, ice walls, slush balls, frazil ice, anchor ice, landfast ice, bottomfast ice, cakes, pans, floes, brash, nilas, huge lengths of thick ice in Arctic Estuaries known as "massives," slush ice, spray ice, grease ice, bellycatters, etc.). Many of these are related to the stratification and salinity of the water; tidal fluctuations (particularly over tidal flats); wind and waves; and the associated currents. Spray, drifting ice and neutrally buoyant ice can all damage structures and vessels; bottom fast ice can protect shores but can rip also them apart; ice walls and stranded ice can reduce flow rates and currents and protect organisms from freezing; ice covers can impede commercial navigation, change mammal behavior, block out heat, cold and sun; separating water from wind (significantly reducing the fetch required for erosional processes), ice covers can cause unique and very stable salinity vertical and longitudinal stratification known as "winter estuaries"; ice covers can impede or encourage freshwater plumes in the nearshore; ice pressure ridges can form a barrier separating the estuary from the sea that can retard freshwater's voyage by days, weeks, or months; ice can dominate biological processes, can dictate ocean currents, and can jam up inside the mouth causing significant flooding that can damage infrastructure but can also revitalize ecological communities.

When present, an ice cover has a tendency to provide great stability to the estuary, however, covers can disappear very rapidly thereby dramatically changing the nature of the estuary with all the associated impacts on local biota and far-field ocean currents. Depending on the geographical location, the estuary could be very vulnerable to climate change. In isolated cases, the impact is only local but should a group of estuaries change regime, there could be "a strong impact on the thermohaline circulation and sea-ice regimes over the shelves and in the Arctic Basin" (Eicken et al., 2005).

One can only conclude that estuaries are terribly fascinating because of their spatial diversity and the intricacy of the interplay between cryological, hydrodynamic, atmospheric, oceanographic, astronomical, sedimentary, biological, anthropological, and climatic processes.

F

FAST ICE

D. P. Dobhal
Wadia Institute of Himalayan Geology, Dehradun, India

Definition

Fast ice is defined as the sea ice that has frozen along coasts ("fastened" to them), along the shoals, or to the sea floor over shallow parts of the continental shelf, and extends out from land into the sea. In the Antarctic area, fast ice may also extend between grounded icebergs. Unlike drift ice, it does not move with currents and wind.

FINGER RAFTING

Dominic Vella[1], John Wettlaufer[2]

[2]Yale University, New Haven, CT, USA

Synonyms

Thrust structures

Definition

The formation of interlocking fingers when two "*ice floes*" alternately over- and under-ride one another during "*rafting*."

Generation: Finger rafting is caused by two ice floes being forced together under the influence of atmospheric and oceanic stresses (Weeks and Anderson, 1958). It is understood that finger rafting is initiated by the presence of small overlapping regions. Such a region leads to vertical displacements of the two floes that are exactly out of phase with one another so that further forcing causes them to "cut" the fingers out of each other (Vella and Wettlaufer, 2007).

Occurrence: Finger rafting is generally observed in young, thin sea ice with thickness up to approximately 15 cm. The interaction of thicker ice floes leads to simple "*rafting*" for intermediate thicknesses or pressure ridging for thickness above around 1 m (Vella and Wettlaufer, 2008). Laboratory models using thin ($\approx 100\,\mu$m) floating wax sheets have demonstrated that finger rafting is not unique to ice but is observed in brittle floating sheets (Vella and Wettlaufer, 2007).

Properties: The width, w, of the fingers created by the rafting of equally thick ice elastic sheets is (Vella and Wettlaufer, 2007):

$$w = 3.32\left(\frac{B}{\rho g}\right)^{1/4},$$

where B is the bending stiffness of the sheet (dependent on thickness and elastic modulus), ρ is the density of the liquid, and g is the acceleration due to gravity.

FIRN

Rachel W. Obbard, Ian Baker, Rachel W. Lomonaco
Thayer School of Engineering, Dartmouth College, Hanover, NH, USA

Definition

Crystal – A solid material whose constituent atoms, molecules, or ions are arranged in an orderly repeating pattern such that regularly spaced atomic planes are found in three dimensions.
Firn – Compacted snow that has survived at least one melt season in a temperate glacier, or, in a Polar Region, compacted snow that underlies fresh snow, if any, and has undergone some metamorphism.
Firn-ice transition – The change from a packed granular material containing interconnected pores to a polycrystalline solid containing individual bubbles.
Grain – A small single piece of a substance. In firn, the term is used to refer to a single connected piece of ice, regardless of its atomic arrangement; hence, it could include one or more actual crystals. In polycrystalline ice, the terms crystal and grain are used interchangeably (Snow Grains).
Pore close-off depth – The depth at which only individual bubbles are found, rather than interconnected pores.
Snowpack – An area of naturally accumulated snow.

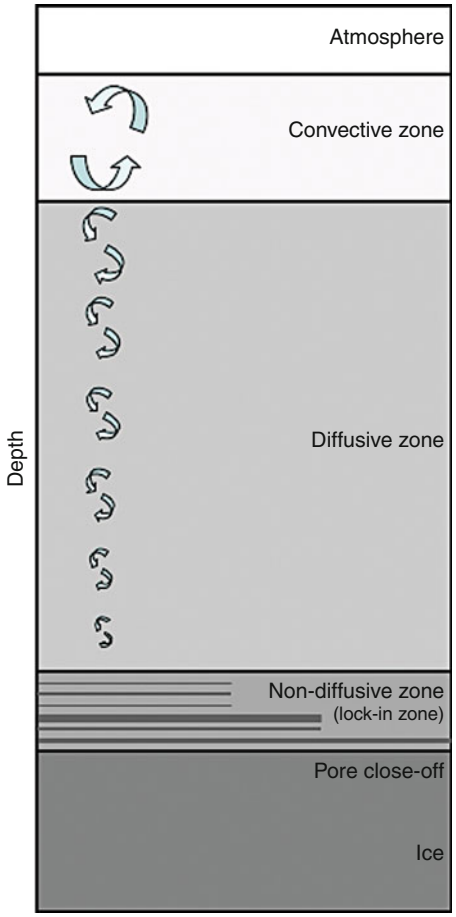
Introduction

When fallen snow accumulates and the snowpack persists past the depositional season, it undergoes metamorphism and becomes firn.

In temperate glaciers (Temperate Glaciers), firn is defined as snow that has survived at least one melt season. In Polar Regions, where there is no melt season per se, firn is found under the snowpack, or, in areas of low accumulation, such as the Antarctic Plateau, even at the surface. It differs from fresh snow however, in that it has undergone sintering and metamorphism, described.

At the other end of the firn column, which can be several tens of meters to more than 100 m thick, the depth at which pores are no longer interconnected defines the beginning of glacial ice. The depth of pore close-off, and the firn-ice transition, depends on accumulation rate and temperature.

Glaciologists and climatologists use ice cores to study past climate, which can be understood by analyzing the structure and chemistry of the ice, and in particular the contents of gas inclusions (Chemical and Microbe Records in Snow and Ice). Firn is of interest because atmospheric air penetrates it to several tens of meters of depth, permitting chemical exchange and resulting in differences of up to 7,000 years in the age of meteoric ice and the gas it contains (Bender et al., 2006).



Firn, Figure 1 Schematic of the interstitial air column in firn with labeled mixing zones. Arrows indicate the magnitude of mixing where large convection occurs near the surface and a net downward diffusion occurs in the lower portions of the firn column.

Firn has three zones that can be distinguished by the extent of gas transport taking place there (Figure 1). In the uppermost "convective zone," gas is freely exchanged with the local troposphere through convection. This exchange is the reason that the gas entrained in glacial ice is younger than the ice itself. Below this is the "diffusive zone" in which diffusion within the firn itself takes place, but there is no exchange of gases with the overlying atmosphere. In this zone, the gas becomes increasingly enriched with the nitrogen isotope ^{15}N, and other heavy gas isotopes, due to barometric pressure (Sowers et al., 1992) (Isotopic Characteristics of Ice, Snow, and Glaciers). The thickness of the diffusive zone can vary dramatically, depending on local snow accumulation rates, and the age of trapped gases becomes especially hard to determine in regions such as the Antarctic Plateau where accumulations rates are low and diffusion takes place for many thousands of years (Bender et al., 2006). Below

the diffusive zone is a "non-diffusive zone" in which local cap layers have formed that trap gases and limit diffusion.

Because firn occupies the region between freshly fallen snow and glacial ice, it is a region of great change. The morphology of firn, that is its grain size, porosity, and pore connectivity, plays an important role in convection and diffusion and is key to interpreting the climate record contained in ice cores.

Metamorphism and the development of firn

Snow falls as individual crystals and aggregates of crystals (Snow Grains) and is packed by the force of gravity and the accumulation of more snow. Where the individual crystals contact one another, they sinter, and in time, the geometry of these bonded areas changes. This process, which is called metamorphism, is driven by temperature gradients and results in a reduction in surface free energy. It leads to changes in density, pore shape and size, crystal size, diffusion, chemistry, and impurity distribution. The rate of metamorphism, and grain growth, is related to the local snowfall accumulation rate and surface temperature (Spencer et al., 2006).

Metamorphism can take place as either a wet or dry process. Wet metamorphism takes place where all three phases (solid, liquid, and gas) of water are present, in temperate glaciers (Glacier) for example, whereas dry metamorphism requires only two phases (ice and water vapor), such as is found in Polar Regions.

After deposition (snowfall), there is a period of rapid deformation as the more delicate snowflake structures are destroyed. This "destructive metamorphism" is due to mechanical processes and chemical potential, the preferential sublimation of highly curved surfaces. During this process, angles become more rounded and individual grains approach a more spherical shape (Colbeck, 1983).

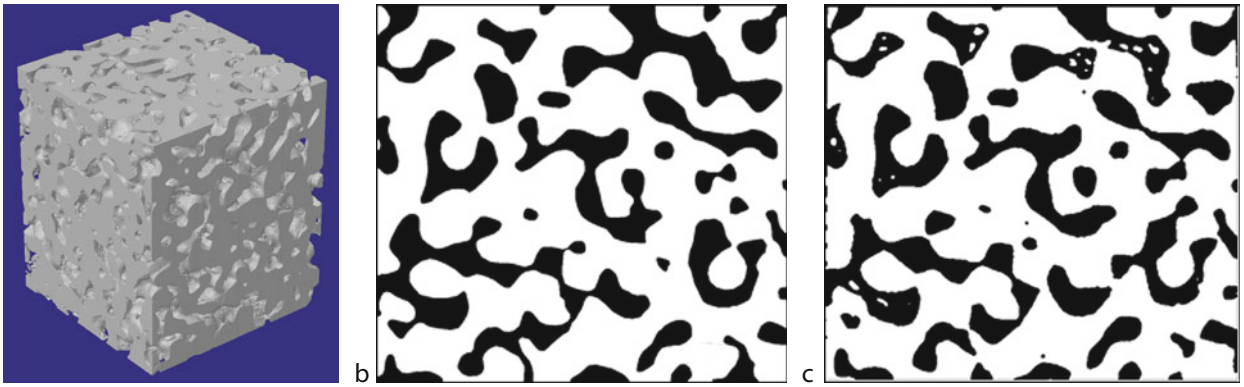
The thermal gradient in the snowpack, a function of changing tropospheric temperatures, geothermal heat (Geothermal Heat), and the insulating properties of the snow, affects the structural changes found in the firn. Low mean temperature and small temperature gradients permit particle coarsening and lead to equilibrium structures characterized by relatively small, rounded grains that are well bonded. Large temperature gradients (i.e., >10°C m^{-1}) produce kinetic structures characterized by relatively large faceted structures (Colbeck, 1983). Seasonal variations in climate result in layering, with kinetic structures produced in summer and equilibrium structures produced in winter. This stratigraphy of structure (and density) is preserved during densification (Stratigraphy of Snowpacks) and can be used to identify annual layers (Bender et al., 1997) (Layering of Snow).

Sintering describes a process during which particles are bonded to one another to reduce overall surface free energy. Sintering does not require the presence of liquid water (Domine et al., 2003). Material will migrate and become redistributed in order to minimize surface curvature (and thus length). Under stress (Overburden Pressure), it may also compress vertically and expand laterally, producing an anisotropic microstructure. In its initial stage, adjacent grains bond to produce a neck, or circle of contact. The neck grows until individual particles are no longer distinguishable and pores connected by a network of channels are produced. Finally, the pore spaces become isolated and spherical (Swinkels and Ashby, 1980). There are six primary mechanisms for mass transport and sintering. Surface, lattice, and vapor diffusion, all from surface sources, transport mass between particle surfaces. Grain boundary diffusion from a grain boundary source, lattice diffusion from a dislocation source and lattice diffusion from a grain boundary source densify the matrix (Swinkels and Ashby, 1980). The relative effect of each of the six mechanisms depends on the driving forces present.

There are three main driving forces: temperature gradient, chemical potential gradient, and overburden pressure. Temperature gradients result in the redistribution of mass from warmer surfaces to colder ones, a process that begins with sublimation. When the saturation vapor pressure at a given temperature is greater than the vapor pressure over an ice particle, sublimation from the solid phase to the vapor phase occurs to eliminate the imbalance. Warmer particles have higher saturation vapor pressure and are more likely to sublimate. When the bottom of an ice column is warmer than the surface, there exists a temperature gradient that produces mass transport from the bottom upward. Lower, warmer particles tend to sublimate and the vapor produced condenses on the downward-facing surfaces of higher, colder particles. Atmospheric air that circulates into the snowpack and firn results in vapor pressure imbalances that produce a continual supply of vapor. As the air travels downward, it is warmed and takes up material from the surrounding solid. As it rises, it cools and deposits vapor locally on the bottoms of particles.

Chemical potential gradients lead to grain growth by surface and vapor diffusion that is governed by equilibrium thermodynamics (Colbeck, 1983). Specifically, vapor pressure is lower over concave surfaces and large particles, and higher over convex surfaces and small particles. This leads to local variations in vapor pressure that seek equilibrium. Molecules migrate from regions of higher vapor pressure to regions of lower vapor pressure, or from small particles and sharp edges to large particles and broad junctions between particles (Colbeck, 1983). The overall effect is coarsening of firn texture.

Overburden pressure produces a vertical stress field that increases with depth. This induces strain that leads to densification. Grains merge and displaced material moves along the grain boundary or through the crystal lattice to new bonding sites. Chemical potential gradients also govern this diffusion. Molecules on convex surfaces have higher surface free energy, arising from relatively fewer shared bonds. The amount of overburden pressure



Firn, Figure 2 (**a**) Reconstructed MicroCT image of firn sample (from 27 m, Summit, Greenland) 8 mm^2 on the base, with (**b**) binarized scanning electron microscope image of a horizontal cross section later made from the sample, compared to (**c**) a binarized MicroCT image of the same cross section of the original sample.

is determined by accumulation rate and is most influential at great depths.

Firn morphology and microstructure

The microstructure of polycrystalline ice is described by its texture (crystal size and shape) and fabric. As discussed in the preceding section, firn coarsens with depth, time, and temperature due to mechanisms that tend to minimize free energy.

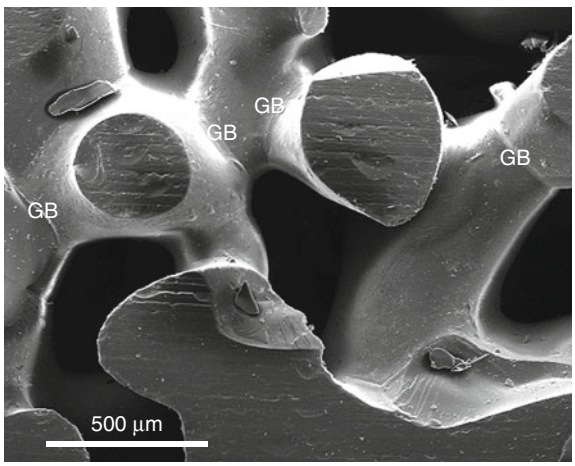
Traditionally, the structure of firn has been studied using optical microscopy. The sample is permeated with a hydrocarbon such as dimethyl phthalate (melting point 2°C, density 1.19 g cm^{-3}), and then the ice matrix is allowed to sublimate away. This leaves a negative impression of the interconnected pore structure, which can be sectioned and studied using optical microscopy (Albert and Shultz, 2002). This has the disadvantage that very small or isolated pores may not be preserved with the infiltrate. More recently, X-ray micro computed tomography (MicroCT) has been used to nondestructively image pore space in three dimensions, and scanning electron microscopy of sectioned samples used to verify the MicroCT results (Figure 2) and examine grain boundaries in firn in more detail (Figure 3).

Overburden pressure in glacier ice is often sufficient to induce slip within the crystal lattice, and this leads to preferred crystal orientation. The development of preferred orientation has not been observed in firn.

Air movement in firn

Isotopic ratios preserved in interstitial air present in firn and air bubbles are important to determine past atmospheric compositions. Thus, the cycling of air through firn needs to be understood before the atmospheric record preserved in bubbles can be interpreted.

In the convective zone, (as deep as 20 m) rapid air movement takes place. Here, air interacts with the atmosphere by ventilation and natural convection. Ventilation, also known as wind pumping, is the process by which atmospheric pressure changes cause interstitial air movement in firn and snow. Barometric changes, turbulent surface winds, and surface topography produce pressure changes that drive movement (Colbeck, 1989; Albert, 1996, 2002).



Firn, Figure 3 Scanning electron microscope image of firn (from 10 m, Summit, Greenland). Note the interconnected pores and the grain boundaries (GB) separating the sintered crystals.

In the diffusive zone, air mixes by atomic and molecular diffusion due to thermal and chemical gradients (Bender et al., 1997; Schwander et al., 1997). Gravitational fractionation leads to an enrichment of heavy isotopes with depth because of their superior settling ability based on mass (Craig et al., 1988; Sowers et al., 1992; Schwander et al., 1997).

As depth increases, firn porosity decreases and air mixing becomes more restricted (Schwander et al., 1997; Bender et al., 1997). Seasonal layering can also affect the rate of air movement through firn (Albert, 1996) and may produce impermeable layers in the non-diffusive zone. These prevent air from equilibrating with that in the diffusive zone (Sowers et al., 1992; Schwander et al., 1997). While air may mix locally, within the summer layer for example, impermeable winter layers impede its vertical diffusion (Fain et al., 2008).

Firn measurements

Borehole logging is used to measure firn properties in situ. These include temperature, density, and vertical strain. Unlike snow, which must be sampled at depth by digging a large snow pit and sampling from the sides, firn has enough cohesion (Cohesion) to permit the extraction of intact cores that are used to measure density, porosity and permeability, grain size, and anisotropy.

Because firn is compressible, seasonal layers thin with depth. It is also porous and subject to the migration of chemical species deposited with the snow (Chemical Composition of Snow, Ice, and Glaciers). Both of these aspects can complicate age-depth calculations. Where annual layers cannot be distinguished optically or from the geochemical record, a density profile produced from a borehole log of vertical strain or measurements of mass, length, and diameter of core sections can reveal seasonal layering.

Summary

A transitional state between fallen snow and meteoric ice, firn is a complex material where vast morphological and chemical changes are taking place.

Fiord

Definition

Fjords are long, narrow, and over-deepened features with steep sides and are carved into bedrock by the glacial activity and flooded by melting water (Figure 1).

Fjords, Figure 1 Fjord as seen in Milford Sound, New Zealand. Photo courtesy Dr. Luke Copland.

Fjords are erosional landforms that represent the movement of a glacier within a confined channel along the valley bottom. The movement of a glacier and formation of fjords is entirely controlled by topography. They are common in the polar regions, but can also be found in subpolar and temperate regions (Table 1). Fjords have existed for millions of years and they range from a few kilometers to several tens of kilometers wide and several kilometers long. Because of their location and relationship with the sea level on one side and tectonically active high mountains on the other side, they are an important feature. They also possess unique characteristics of oceanic processes and ice-ocean interface (Straneo et al., 2010), and therefore, they are appropriately termed as one of the complex and dynamic landsystems that provide information about glacial, fluvial, and oceanographic features.

Most fjords are a Palimpsest feature which makes them an extremely important feature, because they can provide information about the successive glaciations through floor sediments. However, these sediments need to be carefully analyzed, since they may have been buried by younger glacimarine sediments. Fjords act as natural sediment traps and typically have high sediment accumulation rates, providing the potential for high-resolution palaeoclimatic and palaeoenvironmental studies on decadal to centennial timescales and presenting a unique opportunity to study land–ocean interactions. Cowan et al. (2010) used the fjord sediment to identify two prominent glacial erosion surfaces associated with Last Glacial Maximum advance and Little Ice Age advance. Fjords comprise several rock basins, but many of them are deepest at the beginning and become gradually shallower toward the sea. This could be related to the erosive power of glaciers, which becomes lesser and lesser toward the end of the feature.

Sediment deposition in fjords can be related to retreating glaciers by depositional zones moving in the upward direction and hiatuses in retreat by push moraines or morainal banks. Powell and Molnia (1989) has shown various depositional system models associated with retreating glaciers, and he (Powell, 2003) has discussed such models in various types of environment from polar to temperate. Sediment deposition can also be related to advancing glaciers in the form of increasing till thickness from head of a fjord toward the sea limit.

Fjords also provide critical information about marine limits and relate to with the isostaic uplift of deglaciated outer coasts.

FOLIATION

Gulab Singh
Centre of Studies in Resources Engineering, Indian Institute of Technology Bombay, Mumbai, India

Synonyms

Type of layering in glacier

Definition

Foliation is a planner or layered structure that developed in glacier ice during flow.

Origin

The foliation is subjected to stress and strain effects with the glacier sliding down slope and consequently folia (Raina and Srivastva, 2008). Foliation is usually formed by the deformation of preexisting inhomogeneities in the ice. The major inhomogeneities are sedimentary bands, faults, and shear zones and exhibit fold pattern (Paterson, 1994; Raina and Srivastva, 2008).

Type of foliation

Generally two types of foliation, namely, transverse and longitudinal with respect to the direction of ice flow can be observed.

Transverse Foliation: Transverse foliation perpendicular to the linear movement of the ice. These foliation plains of ice often exhibit a highly folded nature.

Longitudinal Foliation: These foliation planes are parallel to the linear movement of the ice.

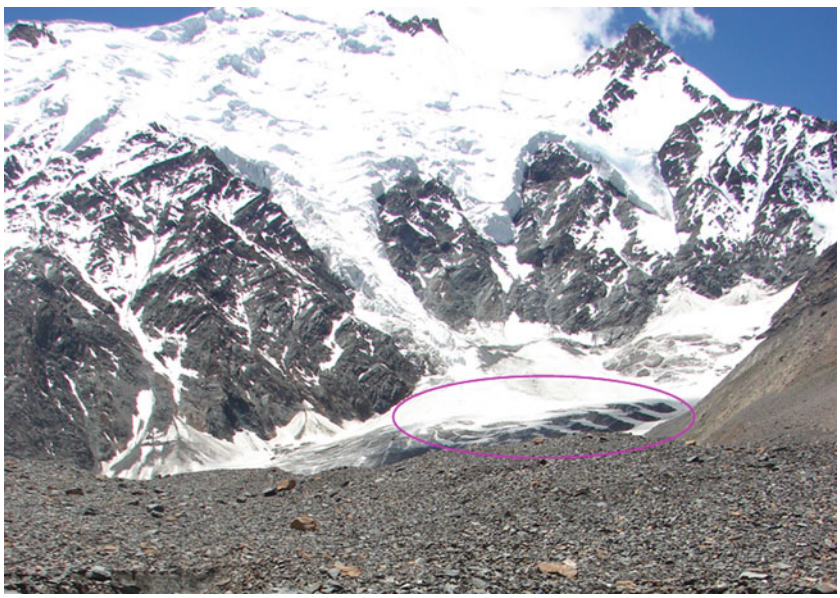
FORBES BAND

Gulab Singh
Centre of Studies in Resources Engineering, Indian Institute of Technology Bombay, Powai, Mumbai, India

Definition and origin

Alternating convex bands of light and dark ice on a glacier usually found down the glacier from steep narrow icefalls and considered to be the result of different velocity and ablation rates in summer and winter. Forbes band is also known as band ogives. Forbes band are generally formed first at the foot of icefalls. Because forbes band are always formed in icefalls as series of undulation in the surface, the amplitude of these series of undulation decreases toward the terminus (snout) of the glacier. Figure 1 shows an example of the light and dark band in the surface of Panchi Nala Glacier (Bhaga Catchment in Indian Himalaya, Himachal Pradesh). The combined width of one light and one dark band corresponds to the distance the ice moves in a year. It can form on surging glaciers also. It's useful in velocity calculations and identifies basal features. Forbes bands are one of the most enigmatic indicators of glacier flow. Stratification is preserved in these bands.



Forbes Band, Figure 1 Panchi Nala Glacier (Photo: CSRE, IIT Bombay Team).

Uses:

1. Forbes bands can be used for stratification.
2. Used to determine velocities or surge intervals.
3. These band can be used to predict crevasse formation by identifying crevasse scars.

FORMATION AND DEFORMATION OF BASAL ICE

Simon J. Cook
Centre for Glaciology, Institute of Geography and Earth Sciences, Aberystwyth University, Ceredigion, UK

Definition

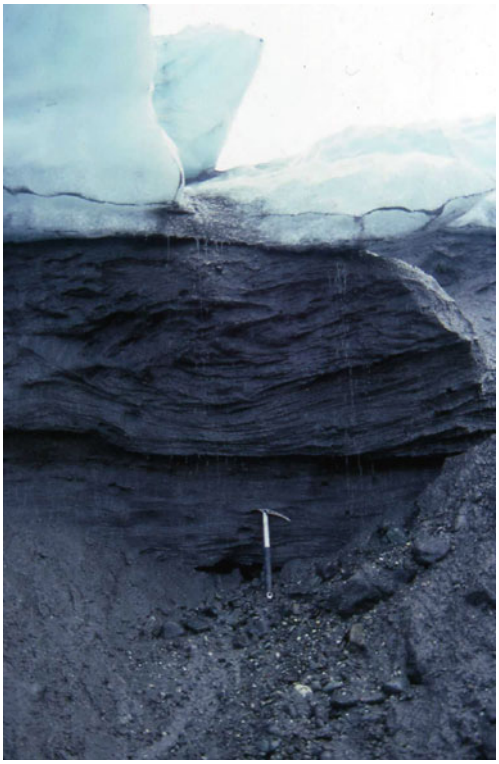
Basal ice. Ice at the glacier base which has acquired distinctive physical and/or chemical characteristics that differ from those of meteorically derived englacial ice due to its formation and/or metamorphosis by processes operating at or near to the glacier bed.

Introduction

Many glaciers exhibit a layer of basal ice which is conditioned primarily by processes acting at or near to the bed. Where it exists, the basal ice layer can be on the order of a few millimeters to tens of meters in thickness, and is typically more debris rich than the overlying englacial ice (Figure 1), although may not necessarily contain any debris. Basal ice may be absent where basal thermal conditions do not allow the net buildup of ice at the glacier base, or where basal ice is formed but destroyed by subsequent melting (e.g., by glacier sliding or by subglacial water flow), or simply where the requisite conditions to permit the operation of basal ice formation processes are not met. Ice and sediment may accrete to the glacier base through a number of different processes, and may then be altered by processes of melting, refreezing, and deformation. Basal ice thus inherits physical and/or chemical characteristics that are distinct from the overlying englacial ice. Basal ice exerts an important influence on glacier motion, sediment transport and deposition, and geomorphology as a result of these unique characteristics (e.g., Knight, 1997).

Tectonic incorporation of debris into ice

One of the oldest theories for basal debris entrainment is the shearing of subglacial debris into a glacier to create debris bands (e.g., Chamberlin, 1895). This process involves the thrusting of sediment from the bed along shear zones penetrating upward into the ice. Weertman (1961) criticized this model suggesting that it could not account for the varied appearance or the millimeter-scale spacing of debris bands, nor was there sufficient evidence that "scraping" of debris along shear planes from a subglacial position could actually occur. More recent studies suggest, however, that shearing and thrusting can be important for basal ice development, especially where there is intense longitudinal compression at the margin to allow differential movement between ice either side of a thrust plane. The requisite conditions for thrusting may occur in polythermal glaciers where warm-based ice from the interior flows against cold-based ice at the margin, or during glacier surges (e.g., Hambrey et al., 1999). Folding of sediment into the basal zone has also been observed to be important for basal ice development.



Formation and Deformation of Basal Ice, Figure 1 Debris-rich "stratified" facies basal ice (*dark*) overlain by clean, bubble-rich firnified englacial ice, Matanuska Glacier, Alaska (Photograph by Richard Waller).

Accretion of new ice to the glacier base

Regelation around bedrock obstacles

Weertman (1957) described a process of pressure melting and refreezing around bedrock obstacles important in *Glacier Sliding* (qv). Ice flow against a bedrock obstacle generates high pressure on the stoss side of the obstacle causing the ice to melt. Meltwater flows around the obstacle along the ice–rock interface to the low-pressure area in the lee of the obstacle where it refreezes, with the potential to entrain sediment particles. Latent heat released during ice formation is conducted back through the bedrock obstacle

to promote continued melting on the stoss-side face. This process, often termed "Weertman regelation," can operate around bedrock obstacles smaller than 1 m in amplitude, but the resultant basal ice layer is typically limited to just a few centimeters in thickness because regelation layers may be destroyed by subsequent phases of regelation. Basal ice produced in this manner tends to exhibit alternating millimeter-scale layers of sediment and ice.

Regelation into subglacial sediments

Vertical regelation allows ice to intrude into substrates composed of unconsolidated sediments (e.g., Iverson and Semmens, 1995). In this case, ice melts above individual grains and refreezes below them at speeds proportional to the downward pressure gradient across the particles. Ice can penetrate downward into the substrate until the point where basal melting equals the rate of regelation, producing debris-bearing basal ice up to 1 m in thickness.

The "heat pump" effect

Robin (1976) described basal ice accretion through a "heat pump" effect which results as a consequence of regelation around bedrock obstacles. Upstream of the obstacle water that exists in the vein network between ice crystals is squeezed out of the ice along a pressure gradient toward low-pressure subglacial water films that exist in the overlying ice. Unless there remains some free water in the ice that can release latent heat when the pressure is released, the ice will remain at a colder pressure melting point until the ice mass can warm again by thermal conduction and heating due to internal friction. This process may produce a cold patch several meters in diameter in which subglacial water freezes to the glacier sole. This process may be sufficient to chill a basal layer of up to 2 m by 1°C, and is suggested by Robin to account for the bubble-free nature of the glacier sole where air is expelled with the squeezed water. Additionally, Knight (1997) described how the debris-poor "clotted facies," which contains predominantly silt-sized debris at 3-grain ice crystal intersections, could be formed by the squeezing of water and sediment away from the bedrock in the manner described by Robin (1976).

Basal adfreezing

The term "basal adfreezing" typically refers to the model of basal ice formation proposed by Weertman (1961) associated with cyclic shifts in basal thermal regime. Meltwater may exist beneath a glacier where heat supplied to the glacier sole by geothermal sources and by sliding friction exceeds heat loss by conduction through the ice thickness. As meltwater flows to the glacier margin, the thickness of the overlying ice decreases, thus the temperature gradient between the air and the glacier base steepens allowing meltwater to freeze. Where meltwater flows through subglacial sediments, freezing will also incorporate sediment to form debris-rich basal ice. Basal ice may be partially or completely destroyed in the summer as warmer air intrudes to the glacier base through crevasses and fractures in the thin marginal ice. Debris bands or laminations may develop as a result of freeze-on of new ice beneath any preexisting basal ice.

Glaciohydraulic supercooling

Glaciohydraulic Supercooling (qv) is a process that allows subglacial water to exist in a liquid state at a temperature below the ambient pressure melting point, and subsequently for this *Supercooled Water* (qv) to freeze to the glacier base to produce basal ice (see Cook et al., 2006 for a review). Supercooling of subglacial water occurs where the pressure melting point of water ascending the adverse slope of an overdeepened subglacial basin rises faster than it can be warmed by viscous dissipation. For the water to remain in thermal equilibrium with the overlying temperate ice, some of this water must freeze to release latent heat, resulting in the production of *Frazil* (qv) (porous aggregates of lozenge-shaped crystals) and *Anchor Ice* (qv) (ice platelets anchored to the glacier or substrate). Sediment-laden water percolates through anchor and frazil ice until pore spaces freeze shut, and subsequent debris – ice segregation produces debris-laden "stratified facies" basal ice. Glaciohydraulic supercooling has been suggested to explain anomalously thick basal ice (i.e., greater than 1 m) which is characteristically debris rich (>25% debris by volume) and often layered (hence "stratified").

Freeze-on of porewater

Christoffersen and Tulaczyk (2003) described a process of basal freeze-on beneath ice streams analogous to the process of frost-heave in permafrost environments. In fine-grained subglacial till water is unable to freeze due to interfacial tension effects and insufficient space for crystal growth. In polar ice streams, basal temperatures may be reduced by ice thinning, or by fast downward advection of cold surface ice. Reduced basal temperatures are accompanied by a decrease in water pressure at the ice–water interface producing a hydraulic gradient that drives the supercooled porewater to the freezing front where it freezes to produce basal ice which may comprise solid debris with only interstitial ice, massive ice comprising stacked debris laminae, laminated ice, or clear ice with only dispersed debris aggregates.

Accretion of preexisting ice

Apron entrainment

Ice Apron (qv) entrainment involves the attachment to the glacier sole of ice that already exists in front of the glacier. Shaw (1977) recognized the importance of apron entrainment for debris-rich basal ice formation at arid polar glaciers where basal adfreezing, which is dependent on meltwater generation, cannot operate to produce basal ice. This involves the glacier advancing and overriding pro-glacial accumulations of snow, superimposed ice, and ice-cored debris. Sharp et al. (1994) recognized the process of apron entrainment at the surge-type Variegated

Glacier where they found that "basal diffused" facies was physically indistinguishable from englacial ice, and hence likely formed from fallen ice blocks that had been tectonically incorporated into the basal ice during the surge.

Subglacial ice entrainment

Tison and Lorrain (1987) explained how ice coatings form in subglacial cavities and are entrained into basal ice. Ice coatings form where water enters a subglacial cavity and freezes due to the penetration of cold air into the cavity (e.g., overnight). Debris layers are formed where debris is carried in by water or falls from the cavity ceiling and is covered by freezing of water on top. In some cases, the downward movement of the glacier as it enters the cavity drags the ice coatings along, detaching them from the bedrock and causing them to fold. At the down-glacier margin of the cavity, the folded ice coatings and debris layers are pinched between the sole and the bedrock and become recumbent allowing the repetition of debris layers within the basal ice sequence.

Deformation of basal ice

Although deformation processes do not create new basal ice, they are important in controlling basal ice thickness, the evolution of basal ice character, and can be important for basal sediment entrainment. Glacier ice can be regarded as a metamorphic rock deforming at temperatures very close to, or below the pressure melting point, and this deformation is enhanced close to the glacier bed where basal ice is subject to intense simple shear.

Numerous deformation structures have been identified within basal ice layers. Sharp et al. (1994) identified recumbent folding, thrust faulting, and nappe overriding in the basal ice of Variegated Glacier. Basal ice deformation at this glacier was enhanced by intense longitudinal compression associated with the down-glacier propagation of a surge front. Sharp et al. listed three tectonic processes that occurred during the surge that accounted for the geometry of the basal ice layer: (1) apron overriding which explained the inclusion of flattened blocks of ice that had fallen from the glacier surface and had been overridden and incorporated into the basal ice; (2) intrusion of ductile basal ice into the core of large frontal anticlines which became overturned to produce up-glacier-dipping debris bands that outcropped on the glacier surface after the anticlines had been unroofed by ablation; (3) upward ramping of imbricate thrust faults from the basal décollement through the overturned limbs of growing anticlines.

Deformation in the basal zone promotes the mixing and intercalation of different basal ice facies to produce different sub-facies. Waller et al. (2000) described how deformation could explain the generation of different sub-facies within the debris-rich "stratified facies" basal ice at the Russell Glacier. After initial entrainment, intense shear stress at the glacier base caused frozen sediment within the basal ice to fracture along lines of weakness and to disaggregate under imposed stresses. They observed recumbent folds in the stratified facies basal ice comprising a core of "solid sub-facies" (high sediment content with interstitial ice) surrounded by a folded layer of "discontinuous sub-facies" ice (ice with typically lower debris content interstratified with solid sub-facies). Waller et al. (2000) suggested, therefore, that discontinuous sub-facies ice was tectonically attenuated from the solid sub-facies. This work was an extension of previous work which suggested that after initial debris entrainment by adfreezing or regelation, continued ice movement would tend to attenuate ice-sediment layers and cause sediment to migrate upward through the basal ice profile. Hence a debris band would evolve into a thinner debris band, then into a debris aggregate, and finally into individual particles.

Summary

Basal ice may be formed and deformed by a range of processes, the operation of which varies over time and space dependent upon local environmental conditions. Thus, there is usually complexity in basal ice sequences at point locations, and across entire glacier margins. Study of basal ice characteristics can be used to infer *Subglacial Processes* (qv) and conditions, which in turn play a major role in controlling ice dynamical behavior. The fact that new mechanisms of basal ice formation continue to be identified from analysis of basal ice cores and sections (e.g., Christoffersen and Tulaczyk, 2003) suggests that there is much yet to learn about the controls on ice mass behavior, and how such controls may vary over time and space.

FRAZIL

Gulab Singh
Centre of Studies in Resources Engineering, Indian Institute of Technology Bombay, Powai, Mumbai, India

Synonyms

Lolly ice or slushy ice (Disorganized, slushy ice crystals in the water column)

Definition

"Frazil" is the name given to ice crystals in suspension in water and form in very cold water. The first stage of freezing gives an oily or opaque appearance to the surface of the water. The frazil ice is also called "lolly ice" or "slush."

Formation

It sporadically forms in open, turbulent, supercooled water. When the water surface begins to lose heat at a very quick rate, the water becomes supercooled. Turbulence, caused by strong winds or flow from a river, mixes the supercooled water throughout its entire depth. The supercooled water allows the formation of small ice crystals (frazil ice), and the crystals get taken to the bottom of the water body. Frazil ice is the first stage in the formation of sea ice. Through a crystallization process, the crystals quickly increase in number, and because of its supercooled surrounding, the crystals continue to grow. This process of crystallization is known as nucleation.

The accumulation of frazil ice in rivers frequently causes flooding and damage to various water objects, such as trash racks. And since frazil ice is found below the surface of water, it makes it very difficult for humans to detect its formation. Damage could be reduced by promoting designated flood regions with mechanical structures. There are several ways to control frazil ice buildup. They include suppression, mechanical control, thermal control, vibration, prior thought, and damage mitigation.

FREEZING BOTTOM (ICE SHELF)

Gulab Singh
Centre of Studies in Resources Engineering, Indian Institute of Technology Bombay, Powai, Mumbai, India

Synonyms

Freezing of water to the bottom of Floating glacier tongues and of ice shelves

Definition

Freezing bottom of floating glacier tongues and of ice shelves is controlled by the temperature of the water in which they float. Water (ocean) supercooling leads to ice shelf bottom freezing (i.e., freezing bottom is a process to freeze of sea water from below Floating glacier tongues and ice shelves).

An *ice shelf* is a thick, floating platform of ice on the sea but attached to the land or to a grounded ice sheet. Ice shelf forms where a glacier or ice sheet flows down to a coastline and onto the ocean surface. The boundary between the floating ice shelf and the grounded (resting on bedrock) ice that feeds it is called the grounding line or grounding zone (Paterson, 1994). Ice shelves are in hydrostatic equilibrium with the water in which they float, so their melting would not contribute directly to a sea level rise (Knight, 1999).

Ice shelves are found much in Antarctica, Greenland, and Canada. They are nourished by flow from the ice sheets and by snow accumulation. The world's largest ice shelves are the Ross Ice Shelf and the Filchner-Ronne Ice Shelf in Antarctica (Paterson, 1994).

Origin

Ice shelves can also occur by the freezing of the water from the ocean below onto the base of the shelf (Paterson, 1994). The freezing of freshwater can be identified to the base of shelf ice, where meltwater become trapped between the base of the ice shelf and more saline deeper water. Cold meltwater produced at the base of shelf ice close to the grounding line. Because of the pressure dependence of the freezing point, the rising limb of the cell can cause ice platelets to form and accrete to the bottom of the shelf. Thermo-haline circulation cell beneath an ice shelf is causing the form of marine ice at the shelf bottom. Melting (near to the grounding zone) produced low salinity and low density water that rises and flows outward along the shelf bottom and with decreasing depth the pressure-dependent freezing point rises, and supercooled water releases ice platelets that accumulate at the ice shelf bottom (Knight, 1999).

FREEZING MELTWATER

Gulab Singh, F. S. Birajdar
Centre of Studies in Resources Engineering, Indian Institute of Technology Bombay, Mumbai, Maharashtra, India

Synonyms

Glacial meltwater

Definition

Melt water is the water released by the melting of snow or ice, including ice sheets and ice shelfs over oceans. Meltwater is often found in the ablation zone of glaciers, where the rate of snow cover is reducing. Meltwater can be produced during volcanic eruptions, in a similar way in which the more dangerous wave/currents are formed. When meltwater pools (rather than flowing) on the ground surface or ice surface, it forms melt ponds. As the weather gets colder, meltwater often re-freezes, known as freezing meltwater. Meltwater can pool or melt under the ice's surface. These pools of water, known as sub-glacial lakes, can form due to geothermal heat and friction.

FREEZING AND THAWING INDEX

Jiang Fengqing, Zhang Yanwei
Xinjiang Institute of Ecology and Geography/ Chinese Academy of Sciences, Urumqi, Xinjiang, China

Definition

Freezing and melting index is defined as the cumulative degree-days within a certain time interval (Cheng et al., 2003).

The freezing index is given by the summation of the degree-days for a freezing season with daily mean temperature below zero (Cheng et al., 2003).

Freezing and thawing index

A number of concepts and methods are available for the computation of the freezing and thawing indices. Thorough review of these methods can be found in literatures (e.g., Frauenfeld et al., 2007). Cheng et al. (2003) proposed a method to calculate the freezing and thawing indices of the surface of a railway base based on the annual mean maximum and minimum air temperatures. In general, the freezing and thawing indices can be calculated using daily air temperature observations. However, the monthly air temperature can be used to estimate these indices in some places where almost no data are available for analysis, especially in high-latitude areas and the alpines (Zhang et al., 1997). The freezing and thawing index are defined as the cumulative number of degree days for a given time period. Areas where the thawing index is much lower than the freezing index may be covered by permafrost, while areas with smaller thawing indices and larger freezing indices may have underlying continuous permafrost (Frauenfeld et al., 2007).

The freezing index can be computed as (Frauenfeld et al., 2007; Jiang et al., 2008):

$$\mathrm{FI} = \int_{t_0}^{t_1} |T| \mathrm{d}t, \quad T < 0^\circ\mathrm{C}$$
$$= \sum_{i=1}^{N_F} |Ti| \qquad Ti < 0^\circ\mathrm{C}$$

where the first equation is for theoretical computation and FI is the freezing index with unit in °C. The second one of the aforementioned equations is empirical, which simply defines the freezing index as the cumulation of absolute values of temperature below 0°C in freezing season. In the aforementioned equation, $i = 1, 2, 3, \ldots$; T_i is the daily mean temperature.

Similar to the definition of freezing index, the thawing index is given by the summation of the degree-days with daily mean temperature above 0°C for a thawing season.

Generally, the thawing index can be determined as (Frauenfeld et al., 2007; Jiang et al., 2008):

$$\mathrm{TI} = \int_{t_0}^{t_2} T \mathrm{d}t, \quad Ti > 0^\circ\mathrm{C}$$
$$= \sum_{i=1}^{N_F} Ti \qquad Ti > 0^\circ\mathrm{C}$$

where the first equation is for theoretical computation and FI is the thawing index with unit in °C. The second one of the aforementioned equations is empirical, which simply defines the thawing index as the cumulation of temperature above 0°C in thawing season. In the aforementioned equation, $i = 1, 2, 3, \ldots$; T_i is the daily mean temperature.

FREQUENCY ANALYSIS OF SNOW STORMS

Stanley A. Changnon
University of Illinois, Urbana, IL, USA

Definition

Snowstorm data based on events when 15 cm or more occurred in 1 or 2 days were the basis for developing heavy snowfall frequency information for the United States. Data on such snowstorms were available for 204 locations (first-order weather stations) with historical snowfall records for the 1948–2001 period. This was sufficiently long to accurately determine recurrence interval values for return periods of 5 and 10 years.

Introduction

Information essential to designing and planning for heavy snowfall events is data on snowfall amounts expected for various frequencies of occurrence. Structures impacted by snow loads need design information for heavy amounts apt to occur. Planning for snow removal and management of snow-impacted activities requires knowledge of how often and how much snow is apt to occur. Snowfall amounts do not always equate to snow loads, which are dependent on the amount of water in the snow.

Analysis

Analysis of original weather records from weather stations with long-term daily snowfall records revealed that many of the cases when 15 cm or more fell in 2 days were situations when the total snow had fallen in less than 24 h. Nearly 85% of all 2-day events were cases of the total snow falling in 24 h or less. Events of 15 cm or more in 1 or 2 days were defined as snowstorms. The values of snowfall for these snowstorms were the data used in this frequency assessment. The station values were sorted and ranked from high to low to allow fitting to statistical distributions.

Various statistical distributions were tested for applicability in fitting the extreme snowstorm values of each station following established approaches for analyzing extremes of precipitation. A partial duration series was developed for each station using the 54 largest values in the 54-year period of data. Distributions considered included log normal, Frechet, and log-Pearson. Log-log and semi-log fitting procedures were also investigated. The assessment of these various fitting methods for the snowstorm data at the 204 station across the United States showed that the log-log method provided the best fit for recurrence intervals of 2 years or longer. Hence, a log-log analysis was used for the final derivation of the frequency relations.

Examination of the distributions for the 204 stations revealed that stations with lower snowstorm amounts had steeper trend than did those of the stations with heavier snowfalls. The 5- and 10-year recurrence interval values were determined from the linear best fit for each station.

Regional variations

Frequency values determined for selected stations in the eastern half of the United States are listed in Table 1. The record highest values exceed 40 cm at most locations. Comparison of the station values reveals sizable differences between stations and varying locations in the United States. The 5-year values vary from 7 cm at Dallas to 44 cm at Buffalo. Other interesting differences include the 5-year values at Boston and New York, which are similar, but their 10-year values are more different.

The national pattern of snowfall values expected to be equaled or exceeded at a point at least once every 5 years, as based on the 204 stations, shows a general latitudinal distribution from lowest to highest across the central United States. Values are less than 2 cm along the Gulf Coast and range from 25 to 35 cm along the Canadian border. The Great Lakes exert an influence by increasing snowfalls in storms around all the lakes. For example, the 5-year amounts around Lake Michigan show 2 to 5 cm more on the lake's west side and 5 to 10 cm more from storms on the east side. The Appalachian Mountains enhance values from North Carolina north through Virginia, Pennsylvania, and New York. Five-year values in central Maine are 40 cm, and at similar latitudes in North Dakota, the values are 25–28 cm. The mountain and lake effects interact to produce 5-year values of 45 cm or more in upstate New York. In the west, there are notably high values from the central Rockies north into Montana, ranging from 27 to 40 cm. Isolated very high values occur at Flagstaff (57 cm), Mt. Shasta in California (80 cm), in the central Cascades in California (90 cm), and at Stampede Pass in Washington (70 cm).

The national pattern of 10-year values is similar to the 5-year pattern. These include a latitudinal distribution in

the central United States; high values in the western and eastern mountain ranges; and high values around the Great Lakes. The 10-year values in the South are 5–7 cm, approximately double the magnitudes of the 5-year values, and farther north, the 10-year values are 45–55 cm. In the Appalachian Mountains the 10-year values were 12% (north with 40 cm) to 25% (south with 29 cm) higher than the 5-year values. In the western mountains the 10-year values were 33–45 cm, differences that ranged from 10 to 18% higher than the 5-year values. In general, the 10- and 5-year differences were least in the higher snowfall regions of the United States (Table 1).

Summary

The point magnitude of snowfall from storms with 5- and 10-year recurrence intervals is lowest along the Gulf Coast and highest in the mountains of the western United States. The magnitude of the 10-year values is 25–30% greater than the magnitude of the 5-year values. Most locations in the United States have had record snowstorms that produced more than 40 cm.

FRESH WATER STORAGE

Pratima Pandey
Centre of Studies in Resources Engineering, Indian Institute of Technology Bombay, Mumbai, Maharashtra, India

Definition

Freshwater is naturally occurring water on the earth. The source of almost all freshwater is precipitation (rain and snow). Snow and glaciers are considered as a huge storehouse of freshwater. The release of fresh water from the glaciers provides valuable natural resources in the form of rivers, lakes, springs, and streams. Freshwater can be defined as water with less than 500 parts per million (ppm) of dissolved salts.

FRICTIONAL MELTING

Pratima Pandey
Centre of Studies in Resources Engineering, Indian Institute of Technology Bombay, Mumbai, Maharashtra, India

Definition

When glacier moves over a terrain, friction occurs at the sides and bottom of the ice mass. This friction caused melting of glacier ice. This type of melting is called frictional melting. Frictional melting is the result of the conversion of mechanical deformation to heat under adiabatic conditions of slip. The pathway to friction melting is controlled by the mechanical properties of a rock's constituent minerals.

FROST

Alan W. Rempel
Department of Geological Sciences, University of Oregon, Eugene, OR, USA

Synonyms

Hoar; Ice deposition (opposite of sublimation); Icing (as in: *aircraft icing* – the term "icing" is also sometimes used to refer to ice formation on a surface from supercooled liquid)

Definition

Frost is the ice deposited from water vapor.

Introduction

Frost formation is caused by the decrease in saturation vapor pressure with reduced temperature, which leads to the removal of water from chilled air by the heterogeneous nucleation of ice on available surfaces. Frost typically occurs at and near the ground surface following radiative heat losses on winter nights in temperate and colder climates. "Frost" also forms the beginning of a number of open compound words (e.g., frost action, frost creep, frost heave, etc.) that refer to phenomena that involve ice that is present near the ground surface, but that are otherwise not at all related to ice deposition from the air. Several of these phenomena are discussed in the following sections.

Frost action

Frost action refers to the weathering, or damage, of near-surface natural materials and anthropogenic structures by the build-up of ice. The degree of damage often correlates with repeated freeze–thaw transitions between liquid water and solid ice. Because liquid water has a higher density than solid ice, when a fixed mass of liquid water is frozen its volume increases. In a closed system that is at fixed volume, freezing can cause large increases in pressure and

these have been suggested as the source of frost action. Though plausible under special circumstances, this cause of frost action may be rare in nature if closed-system freezing is not common. Research that traces its roots to experiments by Taber (1929, 1930), and includes several recent notable developments (e.g., Walder and Hallet, 1985; Hallet et al., 1991; Murton et al., 2006), demonstrates that frost action is more typically associated with increases in ice mass that accompany a migration of liquid water towards colder temperatures where freezing occurs. Because (a) the pathways for this liquid migration are more permeable at temperatures close to the melting point, (b) higher temperature gradients promote more rapid liquid flow, and (c) more water is available for transport towards colder regions when thawing occurs nearby, the correlation of frost damage with freeze–thaw cycles is also predicted by the modern explanation of frost action that is supported by the aforementioned controlled experiments. The physical mechanisms that lead to the observed increases in ice mass are closely related to the phenomena of frost heave, which is discussed below; the density difference between liquid water and ice is incidental to this behavior.

Frost and permafrost

Permafrost is the term given to soil that is at or below the ice melting temperature for 2 or more years. Permafrost is often insulated from atmospheric conditions by an "active layer" of soil that undergoes seasonal temperature excursions above the melting point. Frost is typically more transient than permafrost since it forms by deposition at the ground surface where it is susceptible to changes in atmospheric temperature and vapor content. Vapor transport through permafrost soil can occur under conditions that allow frost to form at depth and remain stable for much longer time spans. Locations where this is important include the Dry Valleys of Antarctica (e.g., Sugden et al., 1995; Ng et al., 2005) and the surface of Mars (e.g., Schorghoffer, 2007).

Frost blister

Frost blisters are seasonal frost mounds (see below).

Frost boils

Frost boils form low elevation mounds in regions that have much less vegetative cover than their surroundings. The reduced thermal insulation causes a component of frost heave to push material outwards from the boil center.

Frost churning

Frost churning refers to the movement of soil that accompanies frost heave and frost action over long time periods.

Frost cracking

Frost cracks form in ice-bound sediments that are subjected to significant and rapid cooling. The patterns of cracking are similar to contraction cracks that form from other causes, common examples of which include mud cracks and columnar basalt. Over long time periods, frost cracking can lead to frost wedging (see below).

Frost creep

The motion of sediments down a slope caused by frost action is known as frost creep. Since frost heave acts parallel to temperature gradients, sediment is lifted normal to the slope of the ground surface during freezing. Upon melting, the sediment settles downwards under gravity. Over many freeze-thaw cycles, frost creep can cause significant down-slope movement (for a review, see Matsuoka [2001]).

Frost heave

Frost heave refers to the upwards displacement of the ground surface that is caused by the formation of ice within frost susceptible sediments. The fact that ice is less dense than liquid water has been suggested as the most obvious explanation for the resulting ground deformation. However, the volume of a fixed mass of ice is only about 10% greater than the same mass of liquid water, and the void fraction (porosity) of soils is typically less than 50%. If the expansion of water upon freezing was responsible, the displacement of the ground surface would be limited to roughly 5% of the depth to the freezing front. In fact, as Taber (1929, 1930) noted in his pioneering work, observed heave often exceeds this by an order of magnitude or more. Taber's experiments conclusively showed that the mass of ice in frost-heaved sediments is greater than the mass of liquid water originally present in the pore space. Additional moisture is transported from warmer regions towards the ground surface, where it freezes in layers known as *ice lenses* that form parallel to isotherms and grow to produce the observed heave.

The presence of ice lenses in frozen sediments has long been recognized; Beskow (1935) gives an extensive survey of the early literature as it relates to the construction of roads and railroads. As heat is extracted from the ground surface, growth of the lowest lens is supplied by liquid water that flows through unfrozen sediments at greater depths and along microscopic liquid films that separate the ice from the sediment grains near the solidification front. This growth continues until a new lens forms lower down in the sediment column and stems the flow.

O'Neill and Miller's (1985) "rigid ice" theory of frost heave has been the basis for many subsequent models that have been successful at predicting observed heaving behavior. We now understand that the pathways for liquid transport in partially frozen soils are in equilibrium at temperatures below the normal melting temperature both because of intermolecular interactions between the ice and sediment across thin liquid films, and because of the energy associated with highly curved ice–liquid interfaces. The equilibrium coexistence of a liquid with its solid below the melting temperature is referred to as premelting (for a recent review, see Dash et al. [2006]).

Premelting is common to the phase behavior of other solids, so it should not be surprising that "frost heave" phenomena have also been observed during solidification experiments with benzene and nitrobenzene (Taber, 1930), helium (Mizusaki and Hiroi, 1995), and argon (Zhu et al., 2000). For each of these other materials the density of the solid is greater than that of its liquid. The intermolecular interactions that cause the solid to be wetted by premelted films are responsible for producing the net force that enables heave to take place and liquid to be drawn towards colder temperatures (Dash, 1989; Rempel et al., 2004; Worster and Wettlaufer, 2006). The conditions of lens initiation and growth can be predicted by continuum treatments that examine the balance of heat, mass, and momentum as freezing progresses.

In their most basic form the models descended from O'Neill and Miller's (1985) treatment only account for relative motion between sediment particles that are separated by a lens.

Recent investigations of freezing in colloidal suspensions have demonstrated that patterns of ice growth, including lensing behavior, also emerge from models that treat the Brownian diffusion of colloid particles and describe the equilibrium melting temperature as a function of their local concentration (Peppin et al., 2006, 2007, 2008). Experiments and theory demonstrate that the concentration and temperature profiles resemble those seen during the solidification of alloys. Growth of a planar ice lens can be disrupted by a morphological instability that produces dendritic growth – with new lenses potentially forming as side-branches to the primary dendrites.

Frost mound

A frost mound is a hill with a core of ice that has formed in the active layer above permafrost. Many frost mounds are seasonal features, but there are also perennial examples, known as pingos. The ice in frost mounds can result from the lens formation that causes frost heave, but elevated artesian water pressures are also sometimes implicated.

Frost susceptibility

The frost susceptibility of a sediment gauges its tendency to host the ice-lens growth that causes frost heave. It is difficult to nucleate ice lenses in coarse-grained sediments such as gravels, and only very restricted liquid pathways are present below the melting temperature when pore sizes are large; such sediments have low frost susceptibility. It is difficult to transport water to supply lens growth in very fine-grained sediments such as clays, so lenses nucleated within these sediments grow slowly; these sediments have an intermediate frost susceptibility. Moderately fine-grained sediments such as silts can both host the nucleation of ice lenses and facilitate relatively rapid liquid transport to supply lens growth; these sediments have high frost susceptibility.

Frost weathering

Synonym for frost action – see above.

Frost wedging

Frost wedges are ice deposits that develop over many seasons in the contraction cracks formed by frost cracking. Ice-infiltrated sediments that have sufficient cohesion to resist inter-particle deformation can fail by cracking as a result of thermal contraction. Wind-blown material and meteoric water subsequently infiltrate cracks to form vertically oriented ice deposits. Over many seasons, cracking in the same location can cause frost wedges to grow many decimeters across.

Summary

Though frost itself forms from vapor deposition, many of the periglacial processes and associated landforms that incorporate frost within their names are more commonly associated with ice formed by freezing of liquid water. Thin films of premelted water that remain unfrozen at the interfaces between ice and sediment particles at subzero temperatures enable significant water redistribution. This behavior leads to frost action, frost creep, frost heave, and the formation of numerous geomorphic features.

Hydrology in frozen porous media

Definition

Frozen soil hydrology. The study of water behavior in soil below the freezing point of liquid water.

Permafrost. Ground with a temperature below 0.0°C for at least two consecutive years.

Segregated ice. Discrete layers or lenses of ice in freezing mineral or organic soils, as a result of the migration (and subsequent freezing) of pore water.

Massive ice. A comprehensive term used to describe large masses of ground ice, including ice wedges, pingo ice, buried ice, and large ice lenses.

Pingo. An eskimo term for a perennial frost mound consisting of a core of massive ice with soil and vegetation cover; the size can range from a few meters to tens of meters, in both diameter and height; can be found in continuous and discontinuous permafrost zones.

Talik. A layer or body of unfrozen ground occurring in a permafrost area due to a local anomaly in thermal, hydrological, hydrogeological, or hydrochemical conditions.

Injection ice. Also called intrusion ice, is formed when liquid water under hydraulic pressure forms an ice core and pushes the soil surface up. The ice is a form of massive ice and can be found in a pingo core.

Regelation. Motion of an object through ice by melting and freezing that is caused by pressure differences; this process allows a glacier to slide past small obstacles on its bed.

Ice wedge. A epigenetic ice wedge is a solid ice mass that can be up to 4 m (13 ft) wide near the ground surface, and extends as much as 10 m (33 ft) down. A syngenetic ice wedge is a solid ice mass that can be up to 2 m (7 ft) wide near the ground surface, and extends as much as 30 m (99 ft) down, due to sedimentation on the surface. These features form when the ground temperature decreases during the winter, which leads to contraction of the ground and cracking of the ice wedge; these cracks fill with snowmelt and freeze; the ice wedge expands again in summer, thereby pushing the soil on both sides of the ice wedge upward.

Patterned ground

Sorted patterned ground:

Sorted circles. A patterned ground form that is equidimensional in several directions, with a dominantly circular outline, and a sorted appearance commonly due to a border of stones surrounding a central area of finer material.

Sorted nets. A type of patterned ground with cells that are equidimensional in several directions, neither dominantly circular nor polygonal, with a sorted appearance commonly due to borders of stones surrounding central areas of finer material.

Sorted polygon. A patterned ground form that is equidimensional in several directions, with a dominantly polygonal outline, and a sorted appearance commonly due to a border of stones surrounding a central area of finer material.

Sorted step. A patterned ground feature with a step-like form and a downslope border of stones embanking an area of relatively fine-grained bare ground upslope.

Sorted stripe. A patterned ground with a striped and sorted appearance, due to parallel strips of stones and intervening strips of finer material, oriented down the steepest available slope.

Non-sorted patterned ground:

Non-sorted circles. Sometimes referred to as *frost boils* are approximately 1–3 m in diameter and generally have little vegetation on them due to excessive soil expansion from ice accumulation during winter. Non-sorted circles are, however, typically surrounded by dense vegetation, which acts as an insulator against winter cooling, leading to preferential formation of ice within the circles.

Non-sorted stripes. These features are similar to non-sorted circles, but elongated downslope due to gravity.

Non-sorted polygons. Polygonal shaped features often formed by desiccation cracking of the surface, with vegetation establishment in the cracks. These features are often accentuated on hill slopes where they are also called turf hummocks.

Ice-wedge polygons. A polygon outlined by ice wedges underlying its boundaries.

Introduction

Frozen soil hydrology is a cold climate phenomenon. Approximately 50% of the northern hemisphere experiences frozen soil conditions. Freezing has a profound effect on hydrology in general, but in particular on soils where ice crystals form in soil pores and change the characteristics of the porous medium. These changes can be beneficial and detrimental. Agriculture benefits from freezing and thawing processes, because it increases the porosity of soils, which helps grow crops. Freezing and thawing processes drive cryoturbation, which is an important process for carbon storage in the arctic tundra. Detrimental effects of frozen soils include degradation of infrastructure and foundations, flooding, and hazardous road conditions.

Properties of water in frozen conditions

The properties of water are unique compared to properties of all other matter known to science. Without this unique behavior of water, life would not be possible in cold climates. Phase change from the liquid phase to the solid phase releases a significant amount of heat and the volume of a kilogram of water increases from 1 L to approximately 1.1 L, thus reducing the density of water in the solid form. These two properties (phase change and reduction in density) make ice float on water and prevent lakes in the arctic from freezing to the bottom. The large buffer for heat consumption also prevents permafrost from degrading during the summer months. The negative effects of expansion are bursting water pipes if not protected from cold weather.

Soil water-ice characteristics and frost heave

In soils, the expansion of water upon freezing causes frost heave. There are two components of frost heave, primary and secondary frost heave. Primary frost heave is expansion of liquid water in the soil pores. Secondary frost heave is caused by liquid water movement in the soil while it is freezing and expanding. Many people have recognized this process and have worked on understanding its mechanisms (Henry, 2000).

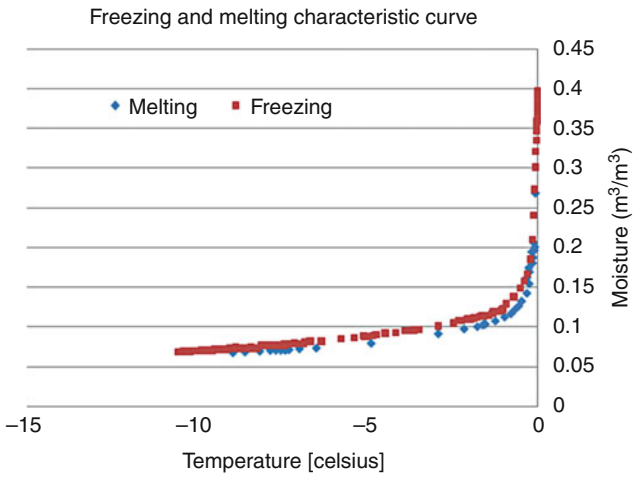
Liquid water in porous media freezes at the point where the soil temperature drops below the freezing temperature of liquid water. This freezing temperature is not constant, but rather a function of the soil texture, liquid water content, ice pressure, and contaminant concentration under freezing condition. The liquid pressure inside a porous media experiences forces that result in an increase in the pressure as the porous media dries. The same principle works for a freezing soil, that is, as the soil becomes more frozen, the liquid experiences a greater pressure (Dash et al., 2006; Koopmans and Miller, 1966; Spaans and Baker, 1996). An example of the relation between temperature and liquid water content of a freezing soil is illustrated in Figure 1 for a clayey silt loam.

The freezing characteristics curve (Figure 1) can be described with the use of the van Genuchten equation and the Clapeyron equation. The van Genuchten equation was developed for non-freezing soil moisture characteristic relations and proposed by van Genuchten (1980) as

$$S_l = \left(\frac{1}{|\alpha\psi_m|^n + 1}\right)^m \tag{1}$$

where $m = 1 - \left(\frac{1}{n}\right)$.

Where S_l is the pore saturation (%), ψ_m is the matric pressure head (m), and α, n, and m are empirical parameters. For a clayey silt loam soil, values for $\alpha = 0.1$ and



Frozen Soil Hydrology, Figure 1 Soil freezing characteristics measured in Northern Alaska (Data procured by Dr. Ronald P. Daanen using NSF grants of Prof. Vladimir Romanovsky, Permafrost Laboratory, University of Alaska Fairbanks, Grant Numbers ARC 0632400 and ARC 0856864).

$n = 1.6$. These values describe the pores size and structure of a particular soil.

The general Clapeyron equation is used to relate the matric pressure head with the temperature for the freezing characteristic curve, assuming an ice pressure head of zero. This thermodynamic relation is the basis of phase change and can be described as

$$\psi_m = \left(\frac{L_f}{273.15 \times g}\right) T + \psi_i \tag{2}$$

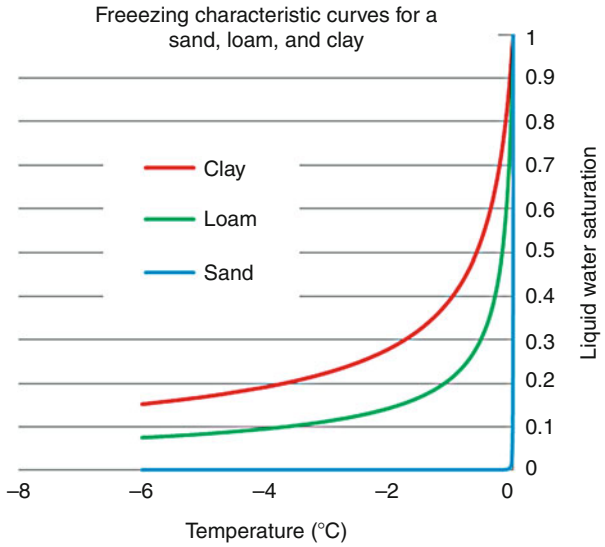
where L_f is the latent heat of fusion (334 kJ/kg), g is the acceleration due to gravity, ψ_m and ψ_i are the matric and ice pressure heads, and the constant 273.15 is the reference freezing point of liquid water at atmospheric pressure.

Examples of these combined equations in sand, loam, and clay are illustrated in Figure 2.

Frost susceptibility of a soil

Frost heave is caused by a supply of liquid water in the soil to feed growing ice lenses that are established in a thermal gradient and capable of displacing the soil in the perpendicular direction to the gradient. The liquid water content below the freezing temperatures of the porous medium and the hydraulic conductivity of frozen soils quantifies the frost susceptibility of a soil. We can describe the liquid water hydraulic conductivity by van Genuchten's (1980) relationship as

$$K = K_S S_e^{0.5} \left(1 - \left(1 - \left(S_e^{(1/m)}\right)\right)^m\right)^2 \tag{3}$$



Frozen Soil Hydrology, Figure 2 Examples of freezing characteristic curves for sand, loam, and clay using the combination of van Genuchten equation and Clapeyron equation.

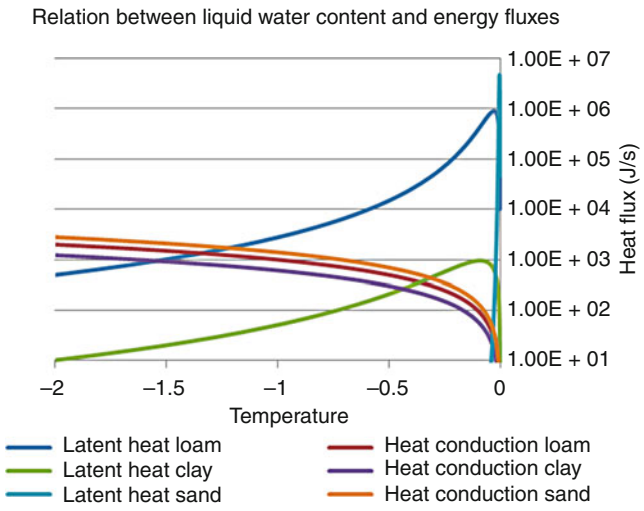
where, the effective saturation (S_e) is related to the soil temperature through the general Clapeyron equation and the freezing characteristic function. The value for K_s (saturated hydraulic conductivity) is dependent on the temperature of the super cooled liquid.

Usually, silty and loamy soil types are susceptible to frost heave. Frost susceptibility can easily be visualized by using Equations 1–3 and varying the soil temperature and temperature gradient to determine heat and water fluxes, while keeping the ice pressure zero. The induced liquid water flow and the induced heat conduction can be expressed as an energy flux. Phase change from liquid to ice is used to express the liquid water flow in an energy flux condition as illustrated in Figure 3.

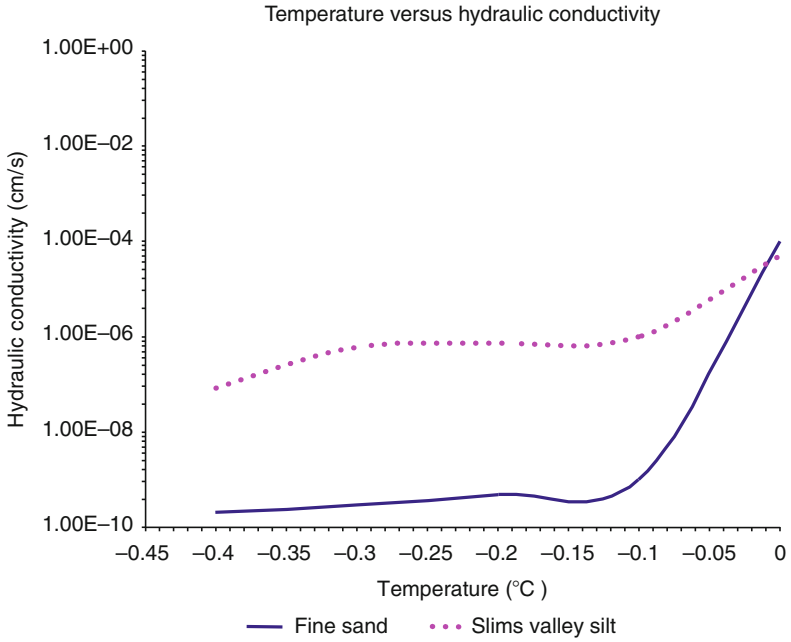
From Figure 3 it becomes clear that frozen soil processes are highly nonlinear and difficult to solve numerically. Ice pressure was kept constant in the curves of Figure 3, but it has a major influence on the liquid water content, liquid water movement, and heat flux from latent heat during freezing. A value for the ice pressure is hard to obtain but attempts have been made to incorporate it in the mathematical equations governing frost heave (Rempel, 2007). Secondary frost heave described here is the main force behind degradation of foundations, road beds, and plant roots.

Hydraulic conductivity of frozen soil

The understanding and quantification of the hydraulic conductivity of frozen soil has gained interest due to the need of improved prediction methods and control of frost heave (Nixon, 1991), development of an understanding of transport and control of contaminants (especially



Frozen Soil Hydrology, Figure 3 Frost susceptibility expressed as energy fluxes. The maximum frost heave occurs when heat conduction and latent heat consumption are equal. This point occurs at a different level of heat flow for different soils, loam has the most favorable properties for frost heave with a maximum at a temperature of −1.3°C.

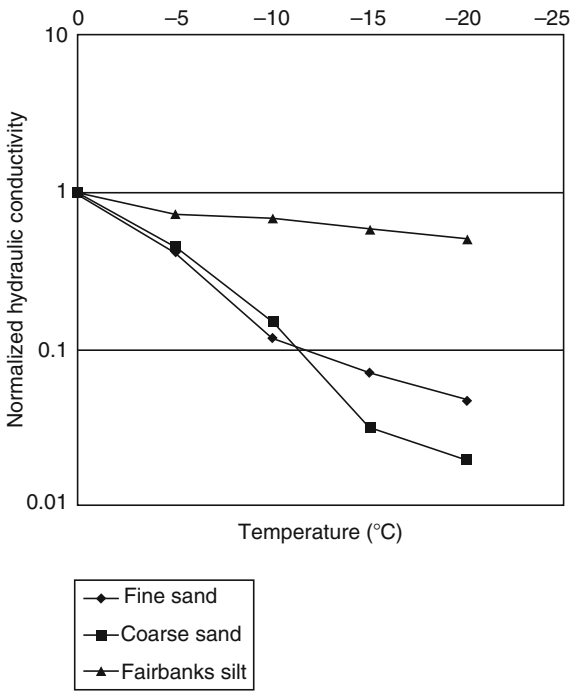


Frozen Soil Hydrology, Figure 4 Variation of hydraulic conductivity with temperature (adapted from Burt and Williams, 1976).

hydrocarbons from surface spillage) in permafrost underlain areas (Biggar et al., 1998), design of containment and remediation of hazardous liquid waste contaminants using frozen soil barriers (Vick, 1994), and remediation of dense nonaqueous phase liquids from soils in cold regions using permeability modification (D'Cunha et al., 2009). The hydraulic conductivity of the soil is directly proportional to the intrinsic permeability, which is usually a constant for any permeable material with a given porosity characteristics (see e.g., Fitts, 2002 or Andersland and Ladanyi, 2004). A change in soil ice content will change the intrinsic permeability of the soil and thus impact the overall hydraulic conductivity of the freezing soil.

The existence of liquid water in freezing or frozen soils allows migration of water under a hydraulic gradient. Experimental investigation by Burt and Williams (1976) indicated that ice formation was faster in high permeability zones (large grained soils) than the low permeability zones (fine grained soils) in a soil. Thus, at below freezing temperatures, large grained soils demonstrated lower hydraulic conductivity than fine grained soils (Figure 4).

D'Cunha et al. (2009) demonstrated through experimental investigation that the rate of change of hydraulic conductivity as a function of decreasing temperature was lower in fine grained soils compared to coarse grained soils (Figure 5). Such understanding has implications in engineering designs in cold regions.



Frozen Soil Hydrology, Figure 5 Rate of change of hydraulic conductivity of three soils as a function of temperature.

Frost features and engineering

Thermokarsts, slides and flows, and aufeis are among the frost processes that are of special concern in engineering (Eranti and Lee, 2000). Thermokarsts are caused by thawing of ice-rich permafrost due to change in the ground thermal regime caused by disturbance in vegetation cover, for example, those that are caused by fire, heavy traffic, or alteration of the ground drainage due to construction. Thermokarsts cause erosion, sinkholes, and beaded

streams that impact structures and landscape. Flows and landslides are also caused due to change in soil thermal regime along slopes underlain with permafrost. Groundwater emerges to the surface due to blocked path (caused by vertical migration of freezing front into soils) in the winter and freezes on the surface causing aufeis conditions. All these features have extensive effect on roads and other structures in cold regions.

Frozen ground usually provides very strong support to short-term loads. However, creep occurs in frozen ground due to long-term loading especially in warm ice-rich frozen ground. Thaw settlement occurs due to such loading over time. The active layer (freezing and thawing regime of the soil) poses the major problems to engineering. Only clean coarse-grained minerals and ice-free bedrocks are not affected by frost action (Eranti and Lee, 2000). According to Eranti and Lee (2000), if the soil contains a few percent of grains that are smaller than 0.02 mm, then the soil is frost susceptible and hence prone to heave. Frost susceptible soils pose significant problems in engineering that includes frost heave, thaw weakening, and thaw settlement.

Impact of freezing soil on landscape

A process related to water migration in frozen soil is the formation of *segregated ice* and *massive ice* in the ground. *Ice wedge polygons* are an example of *massive ice* and responsible for the formation of polygonal patterned ground. *Pingos* are ice mounds formed in drained lake beds. The water from the *talik* underneath the lake slowly freezes and pressurizes to form a large ice core, which lifts the lake bottom up to form the mound. *Injection ice* or intrusion ice is associated with massive ice in pingo formation core, but can also occur along streams at the bottom of hill sides where water in the active layer can pressurize during fall. The top of the active layer along the hill slope freezes in the fall to form shallow confined aquifer, thus pressurizing water beneath the frozen layer. The pressurized water is injected out at the bottom of the hill where ice forms.

Preferential ice formation under rocks and stones caused by thermal conductivity differences drives a sorting process. During freezing of a mixture of soil and rocks, the rocks migrate slowly upward and get pushed out of the ground. Local macro scale thermal differences in the surface then drive a three-dimensional sorting similar to the theory for *non-sorted circles* (Daanen et al., 2008) which form *sorted circles* (Kessler and Werner, 2003), *sorted nets*, and *sorted polygons*.

Another form of sorting also known as *regelation* happens when objects are completely submerged in the ice, for example at the bottom of a glacier where ice moves around rocks and sediments as the glacier slides down the slope (Rempel, 2008). This movement happens under the influence of a temperature or pressure gradient from one to the other side of the object. On the cold end of the object the ice forms, but on the warm end the ice melts. Water migrates through a pre-melt thin film of water from the melting side to the freezing side, and heat flows the opposite way.

On a landscape level, frozen ground affects soil hydrology significantly. Flooding during spring snowmelt is often caused directly by frozen ground. Soil pores are blocked with ice, which reduces infiltration into the soil and increases the amount of water available for runoff. In agricultural regions, the excess water lingers in local depressions where it saturates the root zone and damages the crops in spring due to oxygen deprivation. Frozen ground in these depression-focused groundwater recharge areas thaws preferentially in narrow pockets. After these pockets form, they drain the depression in just a few hours.

Impact of frozen soil on bio- and ecosystems

Biological processes are hindered, but also benefit from frozen soil hydrological processes. For many microorganisms, it is not the temperature that limits their survival or respiration rate, but rather the abundance of liquid water. As we know from the previous sections, liquid water is present at temperatures below freezing, albeit in very thin layers surrounding soil particles. The organisms that survive in these small pores can also be active. An example is soil respiration during winter months in cold regions (Grogan and Jonasson, 2006; Schimel et al., 2006; Zimov et al., 1996). An added effect of the frozen ground is that tension cracks form, which are filled with air. These cracks are conduits for oxygen flow into the ground during the frozen season. Oxygen can reach depths that are usually oxygen depleted due to saturation of the soil profile during the warm season. Besides oxygen, there is also enrichment of nutrients in the thin liquid layers in the frozen soil. This enrichment is caused by solute exclusion from the pore and segregated ice as the water freezes (Konrad and Mccammon, 1990).

Perennial species of plants have to survive the winter months with enough roots to anchor themselves and stay upright so there is a chance to develop new roots in spring. Repeated freeze and thaw cycles create ice lenses within the root zone of plants, which has a negative effect on winter varieties of cereals (Shaw and Blackett, 1966). Besides crops, there is also a negative effect on ecosystems in northern regions. *Permafrost* (frozen ground for at least two consecutive years) limits drainage and controls summer root temperatures, which strongly limits plants from colonizing northern latitudes. In addition, ice lens formation and cryoturbation causes soil movement which has a strong negative effect on the vegetation. A clear example of this phenomenon is ice lens formation, which limits vegetation succession in *non-sorted circles* (Daanen et al., 2007; Daanen et al., 2008).

Summary

Frozen soil hydrology is a cold climate phenomenon. Approximately 50% of the northern hemisphere experiences frozen soil conditions. In soils, the expansion of water upon freezing causes frost heave. Most of this heave is caused by liquid water movement in the soil while it is freezing and expanding. Liquid water in porous media

freezes at the point where the soil temperature drops below the freezing temperature of liquid water. This freezing temperature is not constant, but rather a function of the liquid water and ice pressure. The liquid water content below the melting temperature of a porous medium and the hydraulic conductivity of frozen soils quantifies the frost susceptibility of a soil. Rate of change of hydraulic conductivity in frozen soils are lower in fine grained materials as opposed to coarse grained materials. Frost susceptibility leads to ice lens formation and frost heave, which limits vegetation succession in *non-sorted circles*. Preferential ice formation under rocks and stones caused by thermal conductivity differences drives a sorting process, which leads to sorted patterned ground. Regelation is another sorting process where impurities in ice can move, due to melting and freezing. On a landscape, level frozen ground affects soil hydrology dramatic. Flooding during spring snowmelt is often caused by frozen ground. Soil pores are blocked with ice which reduces infiltration into the soil and increases the amount of water available for runoff. Biological processes are hindered, but also benefit from frozen soil hydrological processes. Liquid water with increase nutrient concentrations in thin films and added oxygen through cracks in the frozen ground can sustain microorganisms during the cold season.

FROZEN TOE (OUTER ZONE OF GLACIER SNOUT)

Pratima Pandey
Centre of Studies in Resources Engineering, Indian Institute of Technology, Bombay, Powai, Mumbai, Maharashtra, India

The frozen toe is a leading edge of a glacier formed due to the glaciotectonism or the thrust which takes place beneath a glacier. It is the frozen outer zone of the snout and has a shape of a boot (shoes) or toe.

G

GELISOLS

Divya Dudeja
Department of Geology, DBS (PG) College, Dehradun, Uttarakhand, India

Gelisol comes from the Latin word "gelare" meaning "to freeze". These are soils of very cold climates that contain permafrost within about 100 cm of the soil surface and/or have gelic materials. Gelic materials are mineral or organic soil materials that have evidence of cryoturbation (frost churning), ice segregation in the active layer, or the upper part of the permafrost. Low soil temperatures cause soil-forming processes such as decomposition of organic materials to proceed very slowly. As a result, most gelisols store large quantities of organic carbon which accumulates in the upper layer and yield black or dark brown color to gelisol layers. Despite the influence of glaciation in most areas where gelisols occur, chemically they are not highly fertile because nutrients, especially calcium and potassium, are very easily leached above the permafrost. The vegetation supported is mostly lichens, mosses, sedges, shrubs, black spruce, and white spruce. Engineering use of gelisols is also limited due to permafrost as large structures are adversely affected by frost heaving and thaw weakening. Gelisols are found chiefly in Siberia, Alaska, and Canada. Smaller areas are found in the Andes (mainly near the intersection between Chile, Bolivia, and Argentina), Tibet, northern Scandinavia, and the ice-free parts of Greenland and Antarctica.

GEOCHEMISTRY OF SNOW AND ICE

Tandong Yao, Yongqin Liu, Huabiao Zhao, Wusheng Yu
Laboratory of Tibetan Environment Changes and Land Surface Processes (TEL), Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Haidian District, Beijing, China

Definition and introduction

The geochemistry of snow and ice is a very broad subject. This chapter includes only the chemistry associated with major ions (Na^+, NH_4^+, K^+, Mg^{2+}, Ca^{2+}, NO_3^-, SO_4^{2-}, and Cl^-) because of limitations of space and the current state of knowledge. As generally known, atmospheric aerosols are scavenged by snow, and dry deposition and/or other forms of wet deposition, such as rain and mist, may add solute to snow cover. The snow on a glacier incorporates impurities and eventually transforms into ice by compaction and recrystallization with time. In this way, airborne constituents can be faithfully recorded by the chemical compositions of glacier ice in suitable locations. Postdepositional effects, such as ablation, sublimation, and snow drifting, may impact on the geochemistry of ice cores. However, ice cores recovered from polar ice sheets and mid- to low-latitude glaciers and ice caps provide numerous proxy records representing past climatic and atmospheric environmental parameters over a wide range of time scales.

Vijay P. Singh, Pratap Singh & Umesh K. Haritashya (eds.), *Encyclopedia of Snow, Ice and Glaciers*, DOI 10.1007/978-90-481-2642-2,

Polar ice sheets

Polar ice sheets contain a wealth of environmental history because of their geographical position and prevailing meteorological conditions. Information retrieved from polar ice sheets has hemispheric or global significance due to their remoteness from local aerosol sources (Delmas, 1992), and holds important historical clues for a better understanding of modern global climatic and environmental changes (Wolff, 1990; Legrand and Mayewski, 1997; Meeker et al., 1997; Wagenbach et al., 1998; Banta et al., 2008; Burkhart et al., 2009).

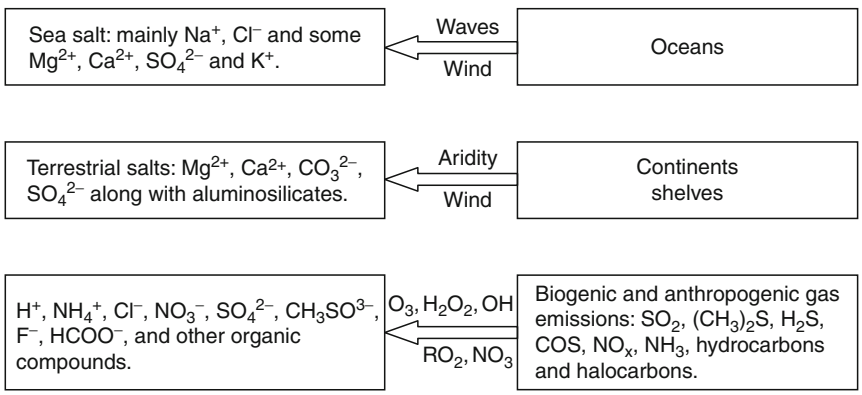
Studies of impurities in polar snow allow the determination of relationships in chemical concentrations between snow and the atmosphere. These then permit interpretation of ice core records based on changes in sources and transport processes. In the past, researchers generally assumed that snow concentrations change proportionally with the atmospheric concentrations from which they derive (Wolff, 1990). However, some solutes do not always follow this generalization because of the post-depositional effects, such as diffusion from the gas phase to the ice crystalline lattice and redistribution in firn after snow deposition (Mayewski and Legrand, 1990; Staffelbach et al., 1991; De Angelis and Legrand, 1995; Wolff et al., 1998). Therefore, caution must be applied when attempting to use chemical compositions in snow and ice as proxies for past atmospheric concentrations.

Impurities within polar snow have a variety of sources including both natural and anthropogenic emissions (Figure 1). Winds from oceanic and continental surfaces introduce primary aerosols directly into the atmosphere, or as secondary aerosols through chemical reactions with trace gasses (Legrand and Mayewski, 1997). Concentrations of soluble species in snow show significant spatial and seasonal variabilities over the Greenland and Antarctic ice sheets (Kreutz and Mayewski, 1999; Bertler et al., 2005; Burkhart et al., 2009). Therefore all species present in snow and ice must be studied in order to better understand and reconstruct the original associations among the various constituents.

Natural aerosols

Natural aerosols dominate in the polar ice sheets due to the long distances from human habitation. Sea salt (e.g., Na^+, Cl^-) deposition in polar snow is very high in coastal areas but decreases rapidly inland as a function of elevation, distance from the sea, and snow accumulation (Mulvaney and Wolff, 1994; Yang et al., 1996; Goktas et al., 2002; Suzuki et al., 2002; Bertler et al., 2005). Sodium exhibits well-delineated maximum concentrations during winter and glacial periods in both central Greenland and Antarctic ice cores as a consequence of more enhanced advection of marine air masses during winter over ice sheets (Herron, 1982; Legrand and Delmas, 1984), and/or due to the existence of highly saline brines and fragile frost flowers on newly formed sea ice in winter, both very effective sources of sea salt (Rankin et al., 2002; Wolff et al., 2003). Temporal correlations of sea salt concentrations in Antarctica (Kreutz et al., 2000) and Greenland (Meeker and Mayewski, 2002) suggest that oceans contribute a strong influence on the transport to these sites. High sea salt fluxes indicated in the Dome C and Dome Fuji ice cores during the LGM (Last Glacial Maximum) correspond to significantly increased production of winter sea ice on both the Indian and Atlantic sides of Antarctica (Wolff et al., 2003). The significantly increased concentrations of sea salt species in Antarctica (Röthlisberger et al., 2002) and Greenland (Mayewski et al., 1997) during the LGM suggest the influence of both enhanced atmospheric transport and local sea ice extent. Cl^- shows less seasonal variation than does Na^+ in the snowpack owing to additional input or loss of HCl, which could smooth the initial seasonal cycle (Legrand and Delmas, 1988; De Angelis et al., 1997).

Calcium, which derives from marine as well as the terrestrial sources, exhibits little variation in Antarctica, whereas distinct spring maxima appear in Greenland snow (Legrand and Mayewski, 1997). Assuming that Na^+ comes solely from sea salt, the respective contributions of sea salt (ss) and non-sea salt (nss) to the other species can be calculated based on standard seawater ion



Geochemistry of Snow and Ice, Figure 1 Various soluble impurities likely to be trapped in polar snow layers and their corresponding origins and sources. (Adapted from Legrand and Mayewski (1997) (copyright AGU).)

ratios. In this way, nssCa^{2+} (De Angelis et al., 1997; Wolff et al., 2006, 2007), and nssMg^{2+} (Legrand et al., 1988; De Angelis et al., 1997), can be used as good indicators of the continental input in polar snow and ice from areas of exposed bedrock in Antarctica (Kreutz, 2007), South America (De Angelis et al., 1992; Fischer et al., 2007), and Asia (Whitlow et al., 1992; Meeker and Mayewski, 2002). However, the terrestrial dust usually contributes little to modern polar snow (Legrand and Mayewski, 1997). Similar to the sea salt species, nssCa^{2+} concentrations show dramatic increases in Antarctic and Greenland ice cores from glacial periods (Fuhrer et al., 1993; Mayewski et al., 1996; Petit et al., 1999; Röthlisberger et al., 2002; Werner et al., 2002), which may be caused by changes in climate and vegetation over source areas during those times (Kreutz, 2007).

Natural SO_4^{2-} derives from multiple sources: marine (Legrand, 1995), evaporites (Legrand, 1997), and volcanic eruptions (Hammer, 1977), and is often used to reconstruct marine bioactivity and volcanic events. Volcanic eruptions emit large quantities of SO_2 into the atmosphere. Sulfate aerosols formed from the atmospheric oxidation of SO_2 and gas-to-particle conversions can be transported to, and deposited on, polar ice sheets. These processes often augment the SO_4^{2-} concentrations in polar ice for 1 or 2 years after large volcanic eruptions (Kreutz, 2007). Thus, SO_4^{2-} records in ice cores provide a powerful tool for investigating the impact of individual eruptions on climate and the atmospheric environment (Zielinski et al., 1994; Robock, 2000). Furthermore, the SO_4^{2-} layers of peak concentrations corresponding with well-known volcanic events can be used as marker horizons in ice core dating (Udisti et al., 2000). In addition to SO_4^{2-}, volcanic aerosols can also contribute other species including Cl^- and F^- to the overall solutes (Herron, 1982; De Angelis et al., 1997).

Various natural sources of NO_x (nitrogen oxides, mainly atmospheric precursors of NO_3^-) include soil exhalation, biomass burning, lightning, cosmic rays, stratospheric oxidation of N_2O, and ionospheric dissociation of N_2, and can contribute to the NO_3^- budget in polar precipitation (Legrand and Kirchner, 1990). Although a large amount of snow and ice core NO_3^- data exists, the major sources of NOx influencing the Polar Regions still cannot be identified, because of the reactive NOx cycling between the snow and the surface boundary layer (Mayewski and Legrand, 1990; Wolff et al., 1998; Ginot et al., 2001; Röthlisberger et al., 2002; Wolff et al., 2002). The nonuniform spatial variability of NO_3^- concentrations across polar ice sheets (Burkhart et al., 2004, 2009; Bertler et al., 2005) results from postdepositional alterations by temperature, accumulation, and other factors (Burkhart et al., 2004; Grannas et al., 2007; Wolff et al., 2007). Consequently, one needs to consider spatial variables to properly account for trends and variability in the NO_3^- record from polar ice cores.

NH_4^+ concentrations are usually one order of magnitude lower in Antarctica than in Greenland ice. In view of the geographical locations of the two ice sheets, such a discrepancy supports the idea that continental emissions such as plants, soils, bacterial decomposition, burning of biological materials, and animal activities dominate the atmospheric ammonia content (Legrand and Mayewski, 1997). NH_4^+ concentrations in aerosols and snow from coastal Antarctica vary considerably and most likely relate to the presence of large penguin populations near the site during the austral summer (Legrand et al., 1998). In contrast, high mean NH_4^+ concentrations with strong summer maxima in Greenland snow layers probably relate to NH_3 biospheric emissions from the northern continents (Legrand et al., 1992; Fuhrer and Legrand, 1997). In Greenland, the temporal profile of NH_4^+ concentrations has been used to reconstruct the history of forest fires in the high-latitude Northern Hemisphere (Savarino and Legrand, 1998). On multidecadal to glacial–interglacial timescales, NH_4^+ concentrations in Greenland mainly relate to continental biogenic emissions from soils; and no evidence has been found for a significant marine contribution (Kreutz, 2007). Furthermore, NH_4^+ in central Greenland shows no overall anthropogenic increase, but a doubling of springtime concentrations during the second half of the twentieth century, which may be caused by influence of Eurasian sources and enhanced long-range transport associated with high SO_2 and NO_x emissions (Fuhrer et al., 1996).

Anthropogenic aerosols

Emissions of SO_2 and NO_x from industrial activities and fossil fuel combustion provide significant sources for SO_4^{2-} and NO_3^- found in Greenland (Goto-Azuma and Koerner, 2001). The chemical profiles of ice cores covering the last 200 years provide a wealth of information on the impact of human activities on atmospheric compositions. The nssSO_4^{2-} concentrations in Greenland ice cores reveal an increase at the end of the nineteenth century (Mayewski et al., 1990; Fischer et al., 1998). The south Greenland nssSO_4^{2-} trend resembles that of North American SO_2 emissions (Mayewski et al., 1986, 1990), while the more pronounced nssSO_4^{2-} increase after 1940 in central Greenland might result from a stronger influence of Eurasian sources (Fischer et al., 1998). Greenland ice core samples from after 1980 also show a decreasing trend of nssSO_4^{2-}, which likely reflects the reduction of SO_2 emissions in industrialized countries. Concurrent increases of NO_3^- concentrations since around 1950 in several ice cores in Greenland exclude postdepositional effects, suggesting that the growing NOx emissions in the northern hemisphere originate mainly from fossil fuel burning (Mayewski et al., 1990; Fischer et al., 1998; Goto-Azuma and Koerner, 2001). At the present time, no convincing evidence exists for an anthropogenic impact on SO_4^{2-} and NO_3^- concentrations in Antarctica (Kreutz, 2007). In addition to SO_4^{2-} and NO_3^-, increases in Cl^- could be related to direct anthropogenic HCl emissions from coal burning and waste incineration (Legrand et al., 2002).

Generally, polar ice cores contain one of the better archives for chemical information regarding the composition of the atmosphere in the past. These cores have been widely used to investigate the past changes of global atmospheric circulation, climate in possible source areas, and environmental impacts of human activities. However, the processes that transfer pollutants between the atmosphere and snow under modern conditions provide the best foundation for interpreting ice core records.

Mid- and low-latitude glaciers and ice caps

Analyses of ice from polar ice sheets depict an unprecedented picture of past climatic and environmental changes for the scientific community. However, weather patterns and climate changes in Polar Regions differ from those in mid- and low-latitude regions. Environmental changes cause great concern at mid- and low-latitude regions of our Earth simply because these areas support about 85% of the global population. Thus, understanding potential environmental change in these nonpolar regions takes on prime importance, and can best be accomplished using information retrieved from alpine glaciers. Furthermore, mid- and low-latitude glaciers allow more reliable assessment of anthropogenic contributions that exceed the natural environmental variability because of their proximity to populated areas.

Because of their moderate temperatures, only a few mid- and low-latitude glaciers preserve accurate records of environmental changes over an extended time. For greatest preservation, these sites must have the following characteristics: high elevation, relatively simple ice-flow dynamics, flat- to low-angle bedrock topography, limited redistribution of snow, minimal snowmelt during the summer season, and a large ice thickness for maximum record length (Cecil et al., 2000). Quite a few ice cores have been recovered from mid- and low-latitude regions, such as the Andes (Thompson et al., 1995; Vuille et al., 2008), Rocky Mountains (Naftz et al., 1996, 2002), Alps (Döscher et al., 1996; Schwikowski et al., 1999a), and Central Asia (Yao et al., 1997; Kreutz et al., 2001). Because of the extensive scientific achievements having been made in snow/glacier chemistry from alpine glaciers, this chapter cannot cover all of the research work. Therefore, this section reviews studies of major ions from a small selection of these glaciers in the Alps and the Tibetan Plateau region to illustrate the more extensive work.

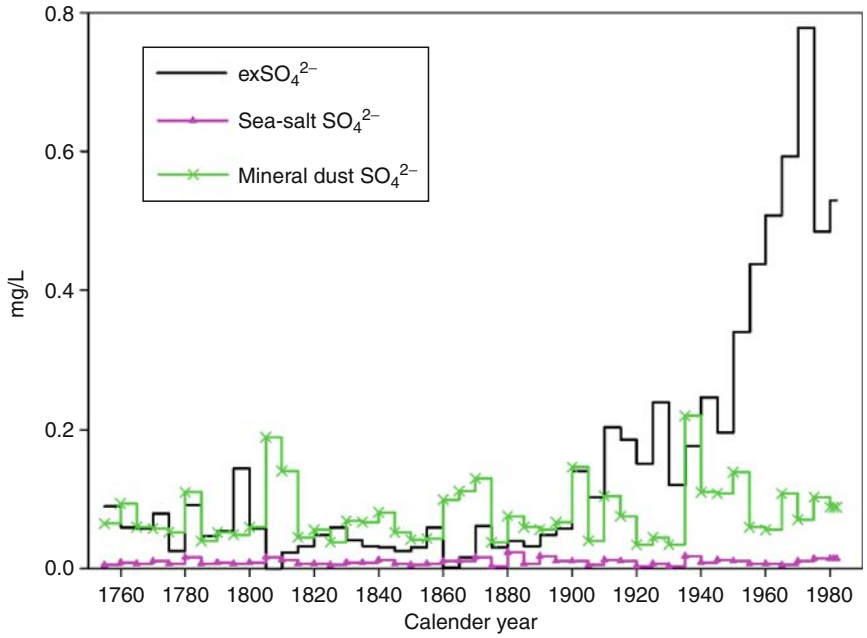
Glaciers in the Alps

Surrounded by densely populated and heavily industrialized countries, the Alps exemplify a suitable area for investigating the direct impacts of man-made compounds in the atmosphere (Maggi et al., 2006). Postdepositional processes can significantly remove, redistribute, and alter the chemical information about environmental change that arrives with the snowflakes falling on the surface of mid- and low-latitude glaciers (Schotterer et al., 2004). For example, a drastic disturbance of the concentration record of certain ionic species in a 13-m long firn section of an ice core from Grenzgletscher has been attributed to inflow of surface meltwater along a crevasse system in the glacier (Eichler et al., 2001). Although the seasonal pattern for NH_4^+, F^-, Cl^-, and NO_3^- was more or less well preserved, concentrations of K^+, Na^+, Mg^{2+}, Ca^{2+}, and SO_4^{2-} were significantly reduced (Eichler et al., 2001). Despite various postdepositional effects, ten different sites remain suitable for paleo-chemical investigations in four high-altitude areas in the Alps (Funk, 1994).

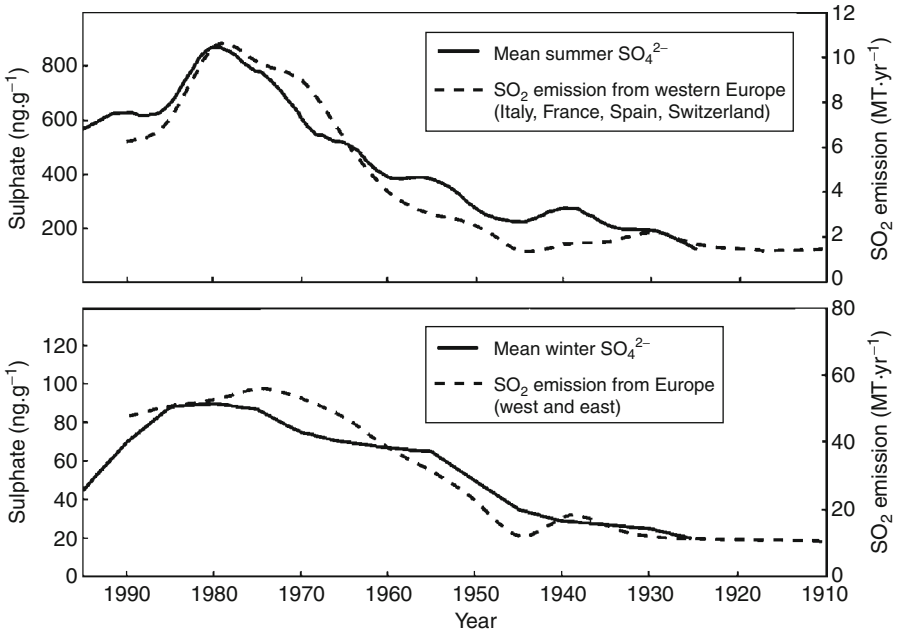
Very little postdepositional alteration of chemical solutes occurs at the high-accumulation alpine sites, such as in the Col du Dôme glacier (Mont Blanc Massif). Consequently, the ionic species show a sharply pronounced seasonal pattern, with concentrations low in winter and high in summer (Maupetit et al., 1995; Preunkert et al., 2000; Maggi et al., 2006), which can be used as reference horizons in ice core dating (Eichler et al., 2000; Largiuni et al., 2003). Many studies have demonstrated that the seasonal patterns of major ions in snow and ice from high-altitude glaciers generally correlate with each other, commonly attributed to the behavior of the planetary boundary layer. During winter, stable, low-altitude thermal inversions limit the vertical exchange between the boundary layer and the free troposphere, thus limiting the transport of ground-emitted pollutants to high-elevation locations In summer, convection circulates polluted air vertically, even up to the highest summits in the Alps (Schwikowski et al., 1999b; Largiuni et al., 2003; Maggi et al., 2006). The seasonal pattern of NH_4^+ concentrations in the Alpine glaciers can also be exacerbated by the increased emissions of NH_3 during summer (Maupetit et al., 1995; Kuhn et al., 1998).

Published records include concentrations of various chemical species obtained from the different Alpine ice cores. These records clearly demonstrate the effects of anthropogenic emissions on the chemical compositions of snow. The following discusses only SO_4^{2-}, NO_3^-, and NH_4^+.

The total SO_4^{2-} profile shows a constant level between 1756 and 1870, followed by an increasing trend, reaching maximum values between 1970 and 1985, followed by declining concentrations (Schwikowski et al., 1999b; Preunkert et al., 2001). The Na^+ and Ca^{2+} values provide sea salt and mineral dust tracers, respectively, for calculating the $exSO_4^{2-}$ (SO_4^{2-} concentration after correction for the sea salt and the terrestrial contribution). Because the natural SO_4^{2-} from sea salt and mineral dust had no trend during this period, the increasing trend in total SO_4^{2-} was attributed to anthropogenic SO_2 emissions (Schwikowski et al., 1999b; Schwikowski, 2004) (Figure 2). In order to identify potential source areas of anthropogenic SO_4^{2-} in high Alpine ice cores, the long-term changes of $exSO_4^{2-}$ concentrations in summer and in winter were compared with past SO_2 anthropogenic emission estimates from several combinations of countries in Europe. Preunkert et al. (2001) concludes that countries having an impact on the high-elevation Alpine sites for the Mont Blanc area



Geochemistry of Snow and Ice, Figure 2 Record of 5-year averages of $exSO_4^{2-}$ (SO_4^{2-} concentration after correction for the sea salt and terrestrial contributions) in Colle Gnifetti (Monte Rosa area) ice core, along with the corresponding records of sea salt and mineral dust derived SO_4^{2-}. (Adapted from Schwikowski et al., 1999b (copyright Munksgaard).)



Geochemistry of Snow and Ice, Figure 3 Comparison of Col du Dôme SO_4^{2-} profiles with the European SO_2 emission history. (Adapted from Preunkert et al., 2001 (copyright AGU).)

in summer include regions located within 700–1,000 km of the Alps, with emissions from France, Spain, Italy, and Switzerland having the major influence. In the winter record, $exSO_4^{2-}$ concentrations reflect limited contamination of the free troposphere, with contributions from all of Europe and possibly from the USA (Figure 3).

The nitrate record from an ice core at Colle Gnifetti (in the Monte Rosa area) shows that between the two time

periods of 1850–1880 and 1965–1981, the mean NO_3^- concentration more than doubled (Döscher et al., 1995). Nitrate concentrations remain constant in the ice core record prior to 1930, but after 1930 they increase sharply to 1965 (Döscher et al., 1995). Similar to the SO_4^{2-} example above, Preunkert et al. (2003) also examined the winter and summer trends of NO_3^- record from a Col du Dôme ice core separately. From 1960 to 1980, the summer nitrate changes follow rather closely with the estimates of growing NO emissions from the neighboring European industrialized countries (Italy, France, Switzerland, and Spain) within about 1,000 km (Preunkert et al., 2003). Data from 1980 to 2001 show a minor increase in summer NO_3^- levels, inconsistent with NO emission estimates, which show a decrease after 1993 (Preunkert et al., 2003). The reason for the discrepancy remains unknown. Data indicate that NO_3^- concentrations in rain have not changed much at most monitoring sites in the Alps in the last 15–20 years (Rogora et al., 2006). A weaker increase in winter than in summer seen in the NO_3^- record from 1930 to 1990 in the same ice core may correspond to less contamination of the wide European mid-troposphere (Preunkert et al., 2003).

NH_4^+ forms in the atmosphere via neutralization of NH_3, neutralizing up to 70% of the original acidity in precipitation (Buijsman et al., 1987). As pointed out in previous work on Alpine glaciers (Maupetit et al., 1995; Schwikowski et al., 1999a; Preunkert et al., 2000), NH_4^+ concentrations in high-elevation ice cores show the most pronounced seasonal pattern among all the major ions, with concentrations about one order of magnitude higher in summer than in winter. Within the Alpine regions, high NH_4^+ concentrations generally accompany high concentrations of SO_4^{2-} and NO_3^- (Maggi et al., 2006), because ammonia is always involved in the conversion of SO_2 and NO_x into the aerosol phase (Schwikowski, 2004). A 200-year-long record of NH_4^+ concentrations from the Colle Gnifetti ice core shows an increase in concentrations by a factor of 3 between 1870 and 1980 (Döscher et al., 1996), indicating that NH_3 emissions in Europe substantially increased in the twentieth century.

Sea salt transported together with mineral dust, mainly from the Saharan area, makes up the major source of Cl^- in the Southern Alps. However, an average 16% of the Cl^- deposition in the period 1937–1994 could be related to HCl emissions from anthropogenic sources (Eichler et al., 2000). The sharp increase of nssCl^- in the late 1960s record has been attributed to HCl emissions from waste incineration in some areas of Europe (Eichler et al., 2000; Legrand et al., 2002). Also, Saharan dust plumes can sporadically reach the Alps (De Angelis and Gaudichet, 1991) and disturb the snow chemistry by entraining additional species, such as Ca_2^+, Na^+, Mg^{2+}, and Cl^-, in the Alpine glaciers (Legrand et al., 2002; Maggi et al., 2006).

Cold glaciers from high-altitude regions in the Alps have provided very valuable natural archives for reconstructing variations in the atmospheric components over the last decades and centuries. In addition to the natural variability of the ice core records, several chemical species reveal an unambiguous anthropogenic contribution to mid-troposphere pollution during the second half of the twentieth century (Maggi et al., 2006). On a positive note, Alpine glaciers also reliably demonstrate the progress achieved in environmental protection (Schwikowski, 2004). Many of the pollutants in Alpine ice clearly show decreasing levels since around 1970, resulting directly from various air quality measures.

Glaciers on the Tibetan Plateau and surrounding regions

The Tibetan Plateau and surrounding regions contain over 46,000 glaciers, amounting to a total glacial area of about 59,400 km^2 (Yao et al., 2007) – the highest concentration of glaciers outside of polar regions. Some of these glaciers are suitable for the recovery of ice cores that extend back thousands of years and allow for the development of detailed, high-resolution records of climatic and environmental change in the region. These records provide important insights, considering the critical role of High Asia in regional and global atmospheric circulation, and the importance of the Asian monsoons in providing life-sustaining rains to more than half the world's population (Wake et al., 2001). Research on spatial and temporal changes in snow and ice core records over this broad area contributes greatly to the study of global change.

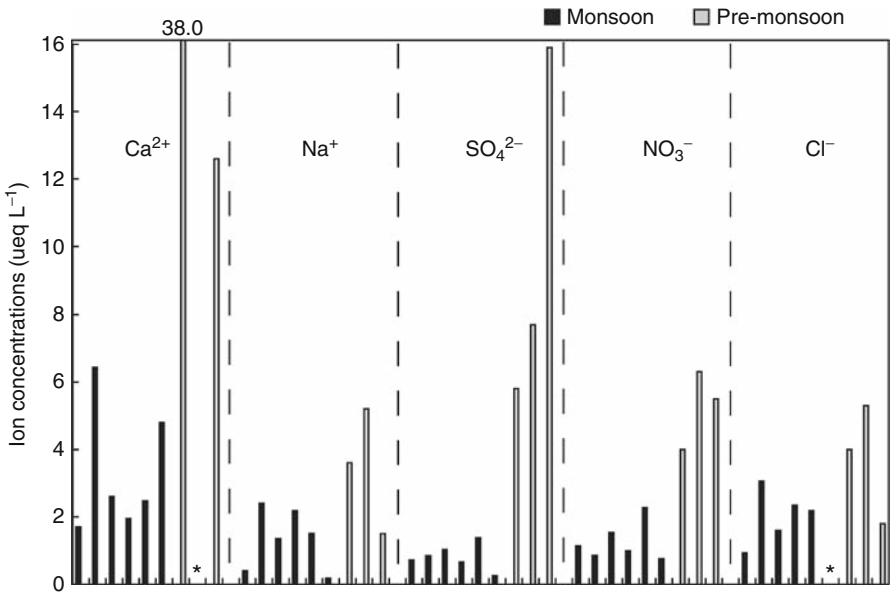
The influx of dust from the arid and semiarid regions in central Asia primarily controls the spatial distribution of snow chemistry in the region (Wake et al., 1993). These glaciers adjacent to vast arid regions display very high concentrations of dust-related major ions such as Ca^{2+}, Mg^{2+}, K^+, and Na^+. Glaciers more distant from major dust source regions show intermediate levels of major ions, while glaciers on the southern slopes of the Himalaya are relatively free from the influence of desert dust (Wake, 2007). By contrast, fluxes of sea salt species in the glaciers over the Tibetan Plateau show strong spatial gradients, with decreasing concentrations as the distance increases between the glaciers and the Indian Ocean (Wake et al., 1990, 1993; Xiao et al., 2002). Wake et al. (2004) analyzed the gradients of glaciochemical parameters across the crest of the Himalaya based on data from six glaciers in the eastern and central Himalaya: three on the southern slopes and three on the northern slopes. The results show dust-related major ions (Ca^{2+}, Mg^{2+}, and Na^+) to be two to three orders of magnitude greater for northern slope sites compared to the southern slope sites, and appear strongly influenced by dust derived from the arid regions in central Asia (Wake et al., 2004). However, the major and trace elements record from a new Mt. Everest ice core indicates that the dominant winter dusts come from the Arabian Peninsula, Thar Desert, and northern Sahara (Kaspari et al., in press).

The seasonal patterns of major ion concentrations and fluxes exist in the Himalayan glaciers as a result of interactions between the Indian summer monsoon and the

continental air mass (Kang et al., 2000, 2004; Balerna et al., 2003). Kang et al. (2004) summarized the ion concentrations in fresh snow in the vicinity of Mt. Everest from recent research (Figure 4). The seasonal differences in ion concentrations occur both during the monsoon and pre-monsoon seasons. For example, pre-monsoon Ca^{2+} concentrations exceed the monsoon values by an order of magnitude (Kang et al., 2004). While in north central Asia, dust deposition predominantly influences the soluble chemistry of snow and ice, with high ion concentrations coinciding with Asian dust storm events (Wake et al., 1992; Li et al., 1995; Yao et al., 1995; Kreutz et al., 2001). Consequently, the Ca^{2+} record from the Guliya ice cap, which lies adjacent to the dust sources, provides a good proxy for atmospheric dust loading in the region (Yao et al., 2004).

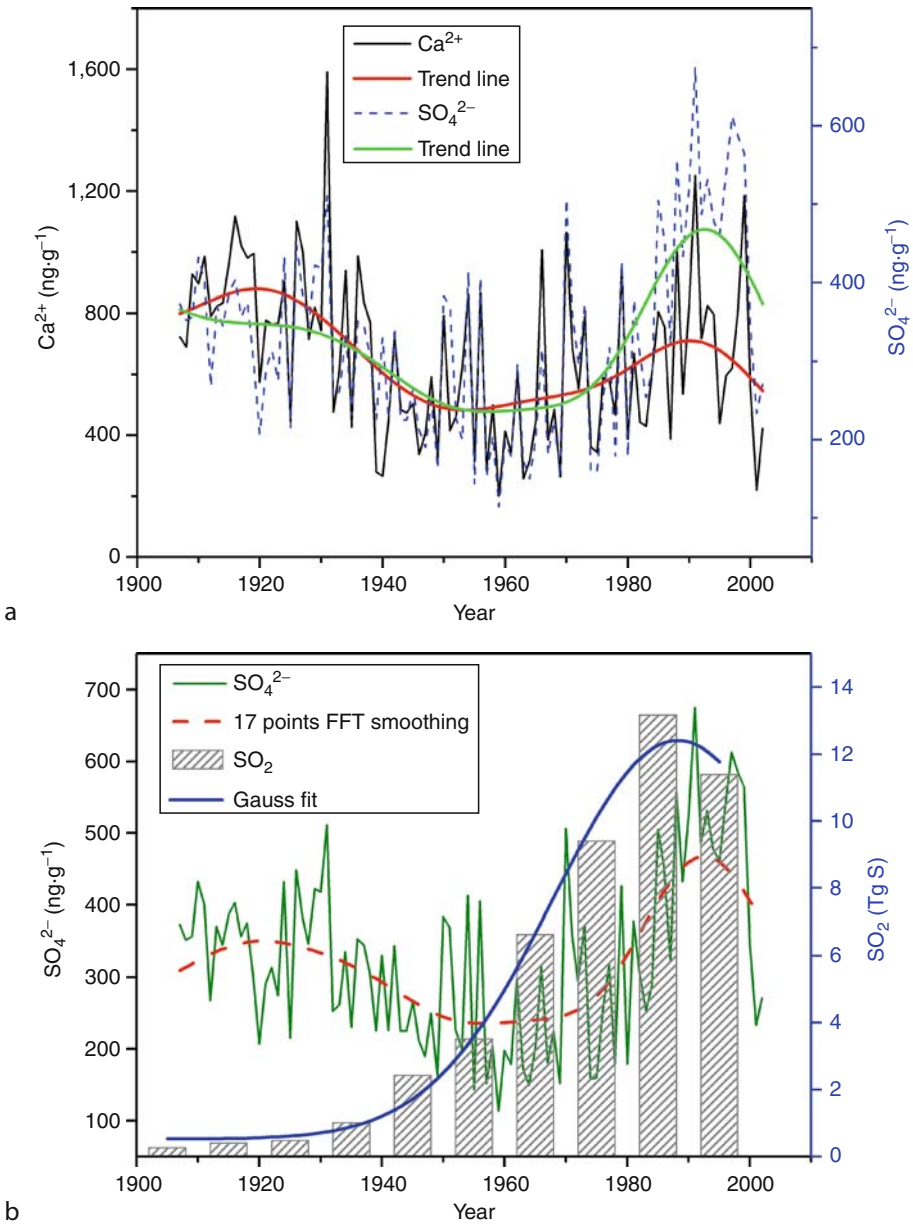
The ionic concentration records from high-resolution ice cores in High Asia can provide valuable contributions for documenting and understanding decadal-to-century-scale variability of the related atmospheric circulations. Through comparisons of the FER (Far East Rongbuk glacier, located on the northern slope of Mt. Everest) Ca^{2+} record with a variety of climate indices, Wake et al. (2001) established a relationship between dust deposition in the Himalaya and the strength of the Asian Low. A strong Asian Low corresponds to a strong Asian monsoon. This relationship indicates an increase in the strength of the Asian monsoon during the second half of the twentieth century. Glaciochemical records from an 80.4-m ice core on the East Rongbuk glacier (also on the northern slope of Mt. Everest) demonstrate that the majority of the crustal ions relate to the winter Mongolian High and the remainder of the crustal species relate to the summer Mongolian Low (Kang et al., 2002a). Kaspari et al. (2007) reconstructed the atmospheric circulation over the eastern Himalaya prior to the instrumental record based on the relationships between the May–October pressure in the Mongolian region and Ca^{2+} and $ssCl^-$ concentrations from another East Rongbuk ice core. This reconstruction shows a decrease in large incursions of marine air masses ($ssCl^-$) since ~1330 AD and an overall increase in incursions of continental air masses (Ca^{2+}) since ~1420 AD, indicating a weakening summer monsoon influence in the Everest region since ~1400 AD.

Given the sparse population and minimal industrial activity on the Tibetan Plateau, the area contributes no significant local pollutants to the atmosphere. However, pollutants resulting from the acceleration of industrialization and explosion of population in south Asia can be transported to the Himalayas by favorable circulation patterns (Shrestha et al., 2000; Hindman and Upadhyay, 2002) and deposit onto the glaciers. A doubling of Cl^- concentrations in the Dasuopu (on the north side of Mt. Xixiabangma) ice core since 1860 AD may reflect increased land use, widespread biomass burning, and increased industrialization in Nepal and India during the twentieth century (Thompson et al., 2000). The close correspondence of the SO_4^{2-} concentration trend in the same ice core to SO_2 emissions over southern Asia indicate that south Asian anthropogenic sources have dominated the SO_4^{2-}deposition on Himalayan glaciers since the 1930s (Duan et al., 2007). The sharp increase of annual NH_4^+ concentrations from the 1940s to the 1980s in an East Rongbuk ice core may correspond to the explosion of population resulting in enhanced agricultural activities (Kang et al., 2002b; Qin et al., 2002; Hou et al., 2003).



Geochemistry of Snow and Ice, Figure 4 Comparison of ion concentrations between monsoon and pre-monsoon fresh snow samples collected in the vicinity of Mt. Everest, central Himalayas. (From Kang et al., 2004 (copyright Elsevier).)

Although dust-related species dominate the major ion components of snow in central Asia and could mask the anthropogenic signals recorded in the glaciers, information regarding anthropogenic impacts on glaciochemistry can still be recovered. The chemical record from a shallow firn core from the Inilchek glacier (in the Kyrgystan Tien Shan) indicates that a summer increase in atmospheric NH_4^+ may be related to regional agricultural activities (Kreutz et al., 2001). Variations of SO_4^{2-} and NO_3^- records from a Belukha (in the Siberian Altai) ice core reflect SO_2 emissions in Siberia and Kazakhstan from traffic growth and enhanced fertilizer application (Olivier et al., 2003, 2006), respectively. Comparison of SO_4^{2-} and Ca^{2+} concentrations in a Muztagata (in the eastern Pamirs) ice core shows that they shared common trends before mid-1970s because of the masking effect from large terrestrial inputs. But then the SO_4^{2-} concentrations increased more rapidly than Ca^{2+} (Figure 5a), which may indicate that the SO_4^{2-} concentrations in the ice core have been dominated by anthropogenic emissions. Coherent changes between SO_4^{2-} concentration records and SO_2 emission estimates in the CIS (Commonwealth



Geochemistry of Snow and Ice, Figure 5 (**a**) The profiles of annual concentrations for SO_4^{2-} and Ca^{2+}, the trend line represents 15-point FFT (Fast Fourier Transform) smoothing; (**b**) Comparison between the SO_4^{2-} concentration record and SO_2 emission estimates in the CIS (Commonwealth of Independent States).

of Independent States) from EDGAR-HYDE 1.3 (Van Aardenne et al., 2001) (Figure 5b) further confirm this conclusion. Of course, quantitatively extracting anthropogenic inputs in central Asian glaciers will require innovative approaches, such as developing detailed records of trace elements, rare earth elements, and sulfur isotopes (Wake et al., 2004).

Multi-parameter glaciochemical records provide the basis for identifying potential sources and transport pathways for major ions and thereby understanding the causes for spatial variability in the major ion records preserved in glaciers. Despite this, there remain considerable gaps in our understanding of the details of climatic and environmental changes in mid- and low-latitude regions. More detailed glacier investigations will be required to resolve these issues.

GEOCRYOLOGY

Amit Kumar
Department of Geology, Centre of Advanced Study in Geology, Panjab University, Chandigarh, India

Geocrology is a branch of a more general science which has come into common usage to describe processes and properties of resources having temperatures $<0^\circ$C, and the term frozen is suggested to illustrate the solid phase of water. Geocryology was developed as an integrative discipline with links to geography, geology, engineering,

hydrology, and ecology. The Polish geologist Walery Lozinski used the term "periglacial" to describe the deposits and landforms believed to be the result of frost weathering.

GIS IN GLACIOLOGY

Jacob Napieralski
Department of Natural Sciences, University of Michigan-Dearborn, Dearborn, MI, USA

Synonyms

Geographic information science (GISc); Geographic information technologies (GIT); Remote sensing

Definition

Geographic Information Systems (GIS) are designed for interactive queries of data, spatial autocorrelations and pattern analyses, integration, storage and dissemination of data and information, and interactive maps and visualizations. Geographic Information Science (GISc) refers to the study of the theory, development, and application of GIS (Goodchild, 1992).

Introduction

Glaciologists aim to study the nature and distribution of present-day ice or the remnants of paleo-ice sheets and glaciers, with an overall goal of understanding the behavior and patterns of the cryosphere and of glacial landforms. This is best accomplished using technological tools to monitor, measure, manage, and model enormous amounts of spatial data. Consequently, geographic information technologies (GIT), such as global positioning systems (GPS), satellite and aerial imagery (i.e., remote sensing), and GIS, provide an effective tool to process, manage, disseminate, and analyze digital glacial data and assemblages of glacial landforms. In general, glaciologists use GIS to compile and analyze data that represent glacial characteristics and features in time (e.g., chronology of events and radiocarbon dates), space (e.g., position of ice margins and alignment of crevasses), and space-time (e.g., change in ice sheet geometry during stages of growth and decay).

Geographic information systems

Real-world objects, such as glacial features and landforms, are represented in a GIS using two main data models: vector and raster. Raster data, which are comprised of grid cells, are an abstraction of reality and typically associated with remote sensing and elevation datasets. Each grid cell has a spatial location (x, y) and one value (z) that might indicate ice surface elevation, thickness, or velocity. In particular, digital representations of surface topography, referred to as digital elevation models (DEMs) or digital terrain models (DTMs), are used to map surface features and characteristics using techniques such as hillshading, contouring, aspect, slope, and flow accumulation. These techniques have helped identify and locate glacial boundaries, determine the location and elevation of the equilibrium line, and calculate glacier and ice sheet mass balances (Gao and Liu, 2001). DEMs are vital tools in studies of ice surface processes (e.g., modeling flow of supraglacial meltwater), visualizations of glacial geometry and patterns, and the identification and extraction of glacial landforms (e.g., drumlins and moraines). However, it is important to consider the limits of raster datasets in glacier studies, including grid cell size, mixed pixel classification, storage size, and inability to update or modify with relative ease.

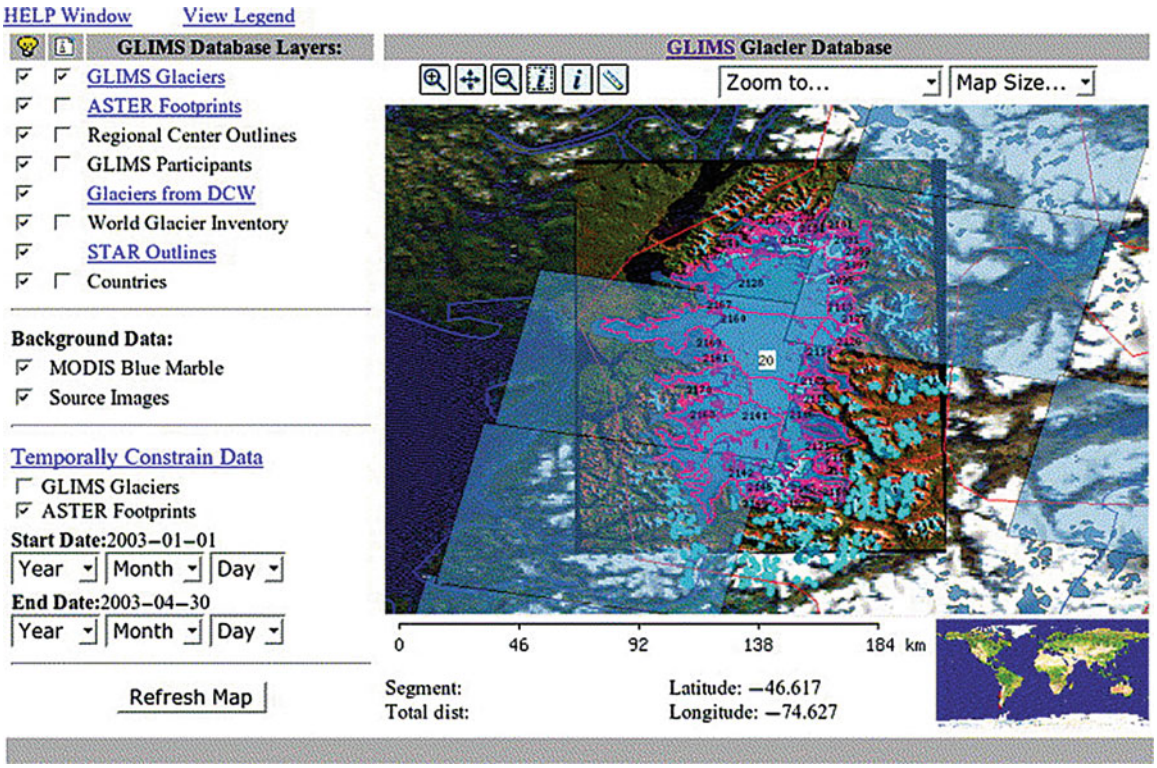
Vector data, which represent discrete objects, are frequently associated with glacial boundaries (especially related to change detection of glacial margins), location of linear features (e.g., crevasses and moraines), and orientation data, such as till fabric analyses (a proxy for ice movement). The basic building blocks of vector data are points (a single coordinate feature) which, when combined and connected, can construct lines (multiple points) and polygons (multiple lines). Each feature is spatially referenced (x, y) and dynamically linked to an entry in an attribute table. Vector data are separated into common layers (i.e., thematic layers), such that each layer is a compilation of similar glacial features or landforms. In contrast to raster data, vector data generally require less storage space, are easier to update, register, and reference, and are more compatible with attribute tables and data. However, there are analytical limitations with vector data, especially when exploring continuous data (e.g., ice surface topography).

Data acquisition and distribution

Digital data of glacial features and landforms derive from several sources, including aerial and satellite images, field observation and GPS measurements, and digitization. Most influential to the study of glaciers and glacial terrain has been the acquisition of data using satellite systems, such as Landsat, the Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER), and the Ice, Cloud, and land Elevation Satellite (IceSAT). Through various image-processing techniques, such as image restoration, enhancement, and classification, glacier dynamics can be monitored and analyzed over time (i.e., change detection). As a result, background data on ice behavior in isolated and inhospitable regions of the world are captured remotely, including the elevation, thickness and extent of ice, ice velocity, delineation of snow zones, and mapping of glacial features. In addition to spatial extent and ice thickness, analyses of ice surface produce maps of slope angle, profile curvature, aspect,

and flow accumulation, which contribute to glacial mass balance studies and, consequently, studies of the feedbacks between climate forcing and glacier changes. Through the processing of satellite images, supraglacial features, alpine snow, and glacier ice and snow facies have been mapped and analyzed in detail (Bishop et al., 2004). GPS, another common source of glacial data, can assist fieldwork by demarking locations of features and, more commonly, the movement of features over time, such as ice features or crevasses. A series of reflective prisms and an engineer's level, combined with GPS readings, can support the development of a DEM representing land or ice surface or be converted to vector format to study paths and rates of movement. GPS function in all weather conditions, regardless of visibility, which is a valuable attribute when mapping glacial environments. Finally, digitization is the process by which objects from maps or other sources are transferred into a GIS. A static paper map is converted to digital data and is then integrated with other interactive datasets in GIS (e.g., Clark et al., 2004; Napieralski et al., 2007a).

Once digital data are developed and entered into GIS, they can be organized, queried, and distributed with relative ease and efficiency. Spatial and temporal data are interactively queried and revised, a valuable tool for continuous updating and revising to glacial data as data acquisition continues to increase and as the description and classification of glacial landforms and processes evolves. Many organizations share in the compilation of such databases, including ice sheet topographic data, annual extents of sea ice and frozen ground, and global glacier inventories (National Snow and Ice Data Center, NSDIC), glacio-tectonic landforms (International Work Group on Geospatial Analysis of Glaciated Environments, GAGE), and glacial landforms compiled from hundreds of sources from the British Ice Sheet from the Last Glacial Maximum (LGM) (Clark et al., 2004). For example, operating under the auspices of the NSDIC, the Global Land Ice Measurement from Space (GLIMS), an international collaboration to acquire and inventory the world's glaciers, provides GIS and satellite data to visualize and download, including the distribution and visualization of vector glacier data and footprints of satellite images from which data were derived, using a Web-Mapping Service (WMS) (Figure 1). A primary goal of GLIMS, and the aforementioned organizations, is to distribute generic and software-specific formatted data in order to facilitate glacial research and education.



GIS in Glaciology, Figure 1 Example of the GLIMS MapServer interface in a browser. All layers are displayed, and are labeled in the column of check-boxes. Data layers include GLIMS glaciers and program participants, ASTER footprints, and political boundaries. Data received by the GLIMS team are ingested into a spatially enabled database and made available via a web site featuring an interactive map, and a web-based GIS (Web-Mapping Service: WMS) (Raup et al., 2007).

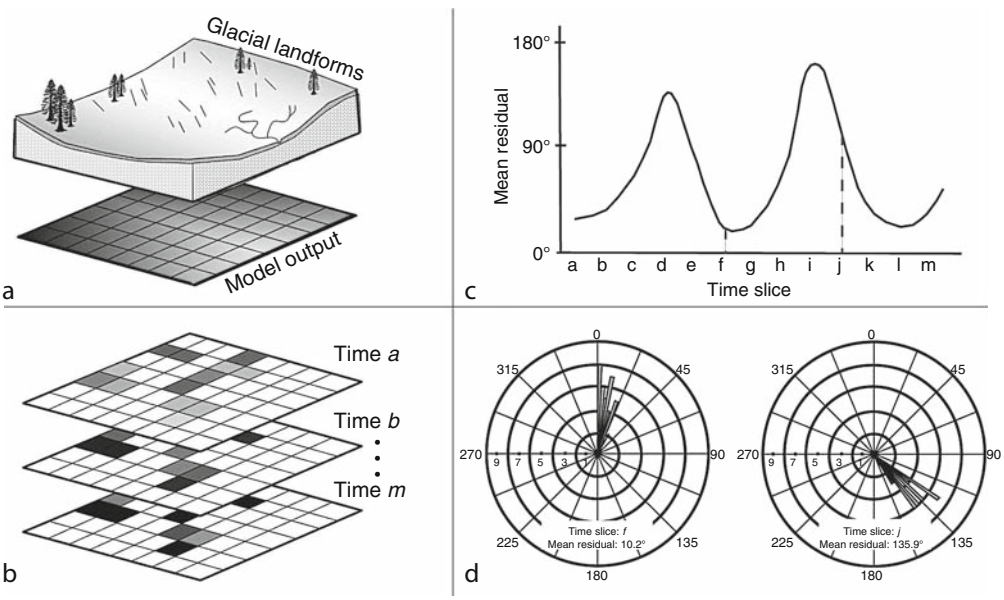
Spatial analyses and modeling

Most GIS contain an abundance of spatial, geostatistical, and modeling functionalities that support the calculation of glacier and landform size, shape, height, orientation, and location. More complex spatial tools, such as density, parallel conformity, distance measuring, and hierarchal clustering (i.e., cluster analyses) have been customized to study patterns in glacial data (Napieralski et al., 2007a). Glacial features and landforms can be digitized (i.e., traced) along the boundary, providing measurements of area or perimeter, or along the spine or long axis, providing length or orientation of a feature or feature group. A GIS can also demark the geographic center (centroid) of a feature. Many of these spatial analyses are used to reevaluate previous studies and to help redefine glacial features based on morphological characteristics. Dunlop and Clark (2006) mapped ribbed moraines (i.e., subglacially formed, transverse ridges) covering over 81,000 km^2 in Canada, Ireland, and Sweden. Their objective was to produce a representative dataset of ribbed moraine morphometry to better assist the ongoing debate regarding moraine formation. In this study, GIS increased analytical efficiency, provided specialized tools to measure landform symmetry and connectability (jigsaw matching), and correlated the distribution of glacial landform structures to elevation.

Morphometric descriptions of glacial landforms also play a critical role in the reconstruction of paleo-ice sheet geometry and behavior, such as suggesting ice flow direction during landform development, locating ice sheet divides and domes, and linking temporal or spatial patterns of erosion–transportation–deposition beneath the ice sheet throughout stages of growth, maximum extent, and decay. To better understand the linkage between ice sheet behavior and the geographic distribution of landform assemblages, two tools developed in ESRI's ArcGIS allowed for an iterative verification of ice sheet model output against sets of glacial landforms (i.e., moraines and lineations). Revised Automated Proximity and Conformity Analysis (R-APCA) and Automated Flow Direction Analysis (AFDA) were specifically developed to quantify the level of correspondence between model output and sets of moraines and flow sets of glacial lineations. R-ACPA systematically quantifies the level of agreement between simulated and observed features using a series of buffers, common GIS tools designed to calculate the distance between features, and overlays (Li et al., 2008). AFDA calculates the offset between the orientation of landforms from each set with the simulated ice flow direction of the ice sheet during different time slices (Figure 2; Li et al., 2007). These two spatial statistical tools compared marginal positions of major end moraines and glacial flow sets against simulations of ice extent for the Scandinavian Ice Sheet during the LGM and Younger Dryas (Napieralski et al., 2007b).

Outlook: future of GIS in glaciology

As GIS continues to evolve, its place in glacial and cryosphere studies will likewise progress, influenced by improved data acquisition techniques (e.g., satellites



GIS in Glaciology, Figure 2 Steps of AFDA. (**a**) Field-based glacial lineations and model outputs used in analysis. (**b**) Overlay model outputs and field evidence to produce series residual datasets for different time slices. (**c**) Plot resultant mean of residual values against their corresponding time slices to identify temporal patterns of correspondence between predicted directions and field observations. (**d**) Frequency analysis (*rose diagram*) of selected time slices (e.g., f and j) provides detailed information on distribution of residuals across area and can be used to evaluate level of correspondence (Li et al., 2007).

specifically designed for studying polar regions), improved computing technologies, and increased demand for managing and analyzing an ever-growing global collection of spatial data. Only until recently have there been attempts to study glacier evolution and morphology and to link process models to landform assemblages using GIS. Many of the new ideas and tools developed in other disciplines (e.g., hydrology, land use change, remote sensing) can be integrated into glaciology to support complex studies of glacier form and behavior and technological advances, such as web-based GIS (e.g., GLIMS) and mobile GIS, can stimulate data acquisition, dissemination, and collaboration. Overall, future integrations of GIS in glaciology will continue to "make glaciology more dynamic, more analytical, more global, more exploratory, and more predictive in the future" (Gao and Liu, 2001).

GLACIAL DRAINAGE CHARACTERISTICS

Richard A. Marston
Department of Geography, Kansas State University, Manhattan, KS, USA

Synonyms

Glacial hydrology; Glacial meltwater; Supraglacial streams

Definition

Supraglacial water. Water that is stored and moves on the surface of the glacier.
Englacial water. Water that is stored and moves within the glacier.
Subglacial water. Water that is stored and moves underneath the glacier.

Glacial drainage characteristics

Water on glaciers moves and is stored on the surface (supraglacial water), inside the glacier (englacial water), and beneath the glacier (subglacial water). Sources of supraglacial and englacial water include melting, precipitation, discharge from water-filled crevasses and moulins, plus small amounts by the heat in supraglacial streams. Basal water can be produced by the geothermal heat flux, which can melt 6 mm/year when the ice is at the pressure melting point (Sugden and John, 1976). Also, basal sliding can produce frictional heat that may melt ice, particularly with pressure melting as the moving ice encounters at topographic obstacle. Most water is produced in the ablation zone of a glacier. Rates of meltwater production are generally highest in martime climates and higher on valley glaciers than on ice sheets because of the longwave radiation from valley sidewalls. One can measure a delay between the maximum daily downsky radiation and the maximum runoff generated on a glacier surface. This lag time varies with meteorological conditions (Marston, 1983). Water that is stored in the subglacial, englacial, and supraglacial environment can be released suddenly, which can generate outburst floods. This hazard, plus the general increase of glacier meltwater production with climate warming are ample reasons to devote attention to the processes and modeling of glacial drainage characteristics. Longwave radiation from valley walls can be an important driver of melting along the margins of alpine glaciers. Glacier meltwater production can be important in late summer months for water users beyond the mountain front after snowmelt and rain have decreased in importance as sources of runoff.

Supraglacial streams form on the glacier surface and are more pronounced when carved in firn than in ice, and when formed in stagnant ice areas. Indeed, supraglacial water leaves the surface via moulins and crevasses, a process that limits development of a surface stream network. In order for supraglacial streams to form, the rate of channel incision must be greater than the rate the glacier

surface is ablating. Some supraglacial streams can incise several meters (Figure 1). Kinetic energy dissipation and frictional heat may be responsible for the small increment of temperature needed to cause this melting (Marston, 1983). When supraglacial streams are not controlled by structures in the ice, they frequently develop a striking meandering pattern (Figure 1). As the streams downcut, they also migrate downglacier, leaving a three-dimensional record of their recent course. The rate and direction of meandering is controlled by meander geometry and stream discharge, as it is for meanders in alluvium.

Englacial water behaves in a manner analogous to groundwater in karst terrain, especially as it moves through spaces connected by structural weakness in the ice. Fountain et al. (2005) found that the majority of englacial water flows through englacial fractures rather than through tunnels. The shape of englacial tunnels will depend on whether hydrostatic pressure exists. Large englacial tunnels grow at the expenses of small ones. A perched water table may exist in glaciers that fluctuates with meteorological conditions and glacier movement. When crevasses are closed at the bottom, meltwater and rainwater can partially or completely fill them. As the glacier moves, crevasses open and release the temporarily stored water into the englacial drainage system. The englacial network of tunnels is best envisioned as a three-dimensional honeycombed network. The tunnels enlarge by melting but can be closed by creep deformation in the glacier. Englacial drainage has been studied by drilling boreholes into the glacier, using ground-penetrating radar and tracers and by lowering cameras into moulins and crevasses.

Glacial Drainage Characteristics, Figure 1 Supraglacial stream meanders, Dinwoody Glacier, Wind River Range, Wyoming. Photo by author.

Subglacial water commonly moves in a dispersed, braided pattern, although subglacial tunnels can form and eventually lead to the formation of fluvial deposits as eskers. Subsurface water can also lubricate the base of the glacier, accelerating ice movement. In Antarctica, large subglacial lakes have been discovered that store water and contribute to basal sliding, which accelerates the velocity of ice streams and outlet glaciers (Bell, 2008).

The runoff from glaciers generally follows a diurnal cycle, increasing during the day as meltwater increases. The timing of peak runoff each day depends on weather and travel time of supraglacial, englacial, and subglacial water to the glacier snout. Glacial meltwater is responsible for creating a variety of erosional and depositional landforms beneath glaciers and ice sheets, in contact with the ice, and in front of the ice (proglacial landforms), discussed elsewhere in this volume.

Summary

Glacial drainage is integrated between the supraglacial, englacial, and subglacial environments. Efforts to develop computer models to describe, explain, and predict glacial drainage have been limited by the availability of careful field measurements. Access to englacial and subglacial environments is especially difficult. Recent developments in field instrumentation are allowing greater access to the three-dimensional glacial drainage systems. Improved modeling will allow more accurate estimates of glacial water discharge for water supply and mitigation of outburst flooding.

Glacial ecosystems. A concept to consider glaciers as ecosystems consisting of ice mass and biological community of cold-tolerant organisms.

Introduction

Glaciers have been believed as inhospitable and abiotic environments because of extreme conditions, such as low temperature, high UV radiation, and limited nutrients. However, various organisms have recently been reported to live on glaciers. Photosynthetic microorganisms, such as snow algae and cyanobacteria, grow on the surface of glaciers, and sustain heterotrophic organisms, such as insects, ice worms, rotifers, tardigrada, fungi, and bacteria. These organisms are cold-tolerant special species and adapt their lives to the special conditions of glaciers. Thus, we can consider glaciers as ecosystems consisting of such biological communities and ice mass.

Photosynthetic organisms on glaciers

Photosynthetic organisms, such as snow algae and cyanobacteria, are primary producers in glacial ecosystems. They photosynthetically produce organic matter on snow and ice surfaces of glaciers, and sustain heterotrophic organisms living there. Snow algae and cyanobacteria are commonly observed in most of the glaciers in the world.

Most snow algae found on glaciers are taxonomically green algae (Chlorophyta). More than 100 taxa of green algae have been reported on snow and ice. Visible snow algal blooms are well known as red or green snow. The red snow is caused by red-pigmented cells of the green algae (usually *Chamydomonas nivalis*).

Cyanobacteria are also common photosynthetic organisms on glaciers. They are usually found on ablation ice surface and in cryoconite holes on glaciers. Filamentous cyanobacteria usually form a small granular algal mat with mineral particles and organic matter. The granules are called as cryoconite granules.

Snow algae and cyanobacteria grow in the season when temperature is above freezing point and melt water is available. Although there are still limited measurements on photosynthetic rate of snow algae and cyanobacteria on glaciers, the rate is comparable to other aquatic ecosystems in polar regions (Hodson et al., 2008). For example, the rates of carbon fixation range as 0.63–156.9 μg C L^{-1} h^{-1} on cryoconite on an arctic glacier. The areal rate ranges up to 1,200 mg C m^{-2} h^{-1} on cryoconite, and up to 10 mg C m^{-2} h^{-1} on wet snow surface.

Communities of heterotrophic organisms on glaciers

Cold-tolerant invertebrate and bacterial communities have been reported on most of the glaciers worldwide (Hoham and Duval, 2001). Collembola (springtails or snow flea) are one of common insects on glaciers. Wingless midges and copepods are living on Himalayan glaciers. Stoneflies are found on Patagonian glaciers, and ice worms on North American glaciers. Major microscopic invertebrates on glaciers are tardigrada and rotifers. They are commonly observed on worldwide glaciers. Yeasts also live on snow and ice of glaciers. All these heterotrophic organisms are sustained by algal production and wind-blown organic matter.

Bacteria and virus are also alive on glacier surface (Hodson et al., 2008). The bacteria that grow on the snow and ice are called psychrophilic bacteria. Bacteria can be found in fresh snow, englacial ice, as well as glacier surface. Bacterial concentration ranges from 1 to 4×10^4 cells mL^{-1} on snow or ice surface. Some bacteria are often observed to be attached to cells of snow algae and cyanobacteria. They seem to exchange organic matter and nutrients to live together. This is a concept of "phycoshere" proposed by Jones (1982).

Glaciers as habitats of organisms

The distribution of melt water determines habitable parts for the organisms on glaciers, since liquid water is vital for all organisms (Vincent, 1988; Hodson et al., 2008). The major habitats of organisms with melt water on glaciers are wet snow, bare ice surface, cryoconite holes, streams, and ponds. For example, snow algae grow in the water film of snow grains on glaciers. *Cryoconite* holes, which are cylindrical water-filled holes on glacier ice, are important habitats for many organisms with semi-stagnant liquid water and nutrients on glaciers.

Melt water also exists at the glacier bed and within glacial ice of temperate glaciers, and microbes live in such parts of glaciers. The microbes consist of aerobic and anaerobic bacteria, and virus, and their communities are distinctive from those on the glacier surface. These communities and such environments were proposed as subglacial and englacial ecosystems by Hodson et al. (2008).

Physical conditions as a habitat of organisms on glaciers differ significantly between accumulation and ablation areas. The accumulation area is located at the upper part of glaciers, where the surface condition is usually snow, and air temperature is colder than lower part. Furthermore, frequent snowfalls often cover the glacier surface and prevent photosynthesis of snow algae on the surface. On the other hand, the ablation area is located at the lower part of glaciers and surface condition is bare ice. Since air temperature of the area is higher than in the accumulation area, meltwater is abundant and the growth season of organisms is longer. Therefore, conditions for organisms are generally favorable in the ablation area

compared to the accumulation area. These gradients of conditions on glaciers determine the altitudinal variation of community structures. For example, snow algal biomass on Himalayan glaciers decrease as elevation increases (Yoshimura et al., 1997). Also, species composition changes with elevation. The community in the ablation area mainly consists of ice environment species that prefer to grow on the ice surface. The community in the accumulation area consists of snow environment species that prefer to grow on the snow surface.

Although the velocity of glacial movement is very slow, organisms living on glaciers adapt to the movement. Since the glacier flows downward by gravity, organisms living on the glacier surface have to migrate upward to stay on glaciers. For example, a wingless glacial midge living on a Himalayan glacier walks upward of the glacier in adult stage to recover the distance of movement by glacial flow and meltwater during egg and laval stages (Kohshima, 1985). Microbes may be relocated on a glacier by wind after they are washed out of the glacier by meltwater and dried on the ground. Upstream migration is one of the unique characteristics of glacial ecosystems.

Nutrients, such as nitrogen and phosphorus, are essential for organisms, but usually very limited on glaciers because of a lack of litter and other debris (Hodson et al., 2005). Nutrients are supplied onto the glacier surface by dry and wet depositions. Snow and rain include small amounts of nitrate, ammonium, and phosphate. Marine and terrestrial aerosols are also important sources of these solutes. The nutrient supply may also be episodically enhanced by extreme events. Cryoconite holes play an important role in nutrient cycling in glacial ecosystems. The holes trap nutrient-rich particles, prevent nutrients washout by meltwater, and provide nutrients for various algae and animals in the holes. On mountain glaciers, such as Asian glaciers, a large amount of terrestrial dust is supplied from desert by wind and is deposited on the surface, thus nutrients are relatively abundant. Larger biomass of microbes noted on the Asian glaciers is probably due to the abundant nutrients.

Effect of climate change on glacial ecosystem

Recently, glacial changes, such as alterations in mass balance, snow chemistry, and/or dust concentration have been reported in many parts of the world, and such changes may affect a biological community on the glacial surface (Hodson et al., 2008). In the last few decades, the mass balance of most glaciers worldwide is negative, possibly due to climate warming. More melting of glaciers may enhance the production of photosynthetic microbes, and expand the habitable area on glaciers. The elevation of equilibrium line of such glaciers usually rises upward. The altitudinal distribution of microbial community would also shift upward on the glaciers accompanied by the rising of the equilibrium line. The relative importance of snow and rain in summer may also affect significantly the community of microbes on the glacier surface. The change of windblown solutes and dust due to pollutant, forest fire, and land cover change around glaciers is likely to have a significant impact on biological communities on glaciers. However, evaluation of these effects of climate change on glacial ecosystems is still underway. Ice core studies may reveal how biological communities on a glacier changed in the past. Analyses of snow algae and bacteria in some ice cores have shown that their abundance and community structure have temporally changed with climate (e.g., Yoshimura et al., 2006).

Summary

Glaciers can be considered as ecosystems consisting of ice mass and biological community of cold-tolerant organisms living there. The glacial ecosystems have very unique characteristics, which cannot be seen in other ecosystems. The distribution of melt water determines habitable parts for organisms on glaciers, since liquid water is vital for all organisms. Organisms have to migrate upward to stay on glaciers, since their habitat on the ice moves down by glacial flow. Furthermore, since snow and ice can easily be modified by physical conditions, such as solar radiation, air temperature, and precipitation, glacial ecosystems are highly sensitive to climate change. However, there is still only a few studies on glaciers to regard them as ecosystems, thus further studies are required to understand them.

Definition

Glacial erosion includes the loosening of rock, sediment, or soil by glacial processes, and the entrainment and subsequent transportation of this material by ice or meltwater.

Introduction

The wide range of easily recognized landscape features produced by the action of glaciers and ice sheets include many classic landforms produced by glacial erosion, including U-shaped valleys, cirques, arêtes, roches moutoneés, hanging valleys, striations, glacial polish, rock steps, fjords, and glacial grooves. These landforms, which span scales from millimeters to kilometers, result from differential patterns of rock loss. These patterns reflect spatial variations in the glaciological controls on glacial erosion, combined with the history and extent of ice advance and retreat, as well as spatial variations in rock and sediment resistance to erosion.

Some of the earliest published research on glacial erosion identified specific landforms as characteristic of glacial action, and then inferred glaciological variables that must control erosion to produce these specific forms. For example, in the late 1800s W J McGee considered the pattern of erosion necessary to create a glacial U-shaped valley and concluded that glacial erosion rates at different locations are controlled by the weight of the overlying ice and the velocity of the ice movement over the underlying bedrock (reviewed in Harbor, 1989). Subsequent research has considerably increased our understanding of the detailed mechanics of how ice, entrained material, and meltwater all act to loosen and remove rock, sediment, and soil. Combined with the knowledge of glacier and ice sheet history and dynamics, understanding erosion processes is the basis for evaluating how a range of glaciological variables control glacial erosion.

Erosion processes

The primary processes of glacial erosion are plucking, abrasion, and physical and chemical erosion by subglacial water.

Plucking (quarrying)

Plucking, which is also sometimes called quarrying, includes both the fracture of underlying rock and the entrainment by basal ice of rock fragments that result from glacial action or that are due to preexisting fractures in the rock. The results of plucking are seen particularly well on the down-glacier (lee) side of bedrock outcrops where commonly there is angular, fractured bedrock (Figure 1). In some cases, large rock fragments removed from the outcrop occur as a tail of boulders deposited in the down-glacier direction.

Glacial Erosion, Figure 1 Plucking features on the down-glacier side of the bedrock steps.

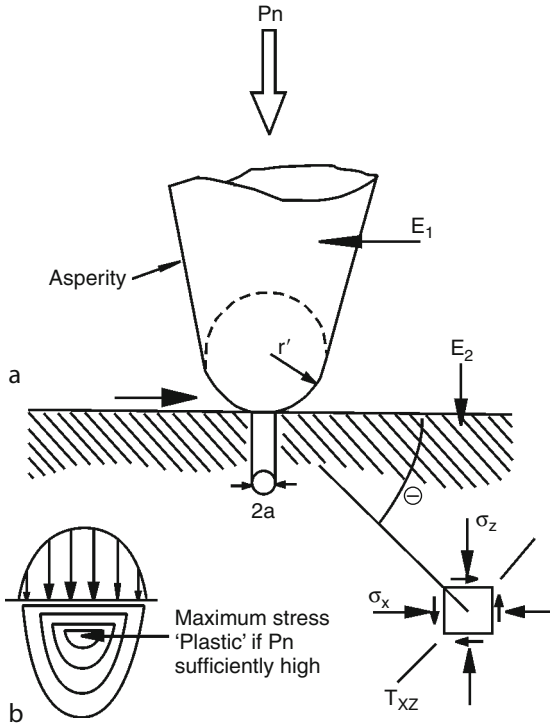
Fracture of subglacial bedrock

Although plucking can exploit preexisting fractures and joint patterns in rock, active fracture of bedrock under ice is important to maintain erosion once the surface zone of pre-glacial weathered and fractured rock has been removed. Subglacial fracture of bedrock occurs when the pattern of stress induced by the ice and by any clasts embedded in the basal ice causes a tensile stress component in the rock that exceeds the fracture strength of the rock, usually at the tip of a microcrack. The fracture pattern can produce clasts that range in size from very fine rock fragments to large boulders. In addition, as rock is removed by glacial erosion, changes in the in situ rock stress field due to the overall change in load pattern can produce large-scale fracture patterns (Augustinus, 1995).

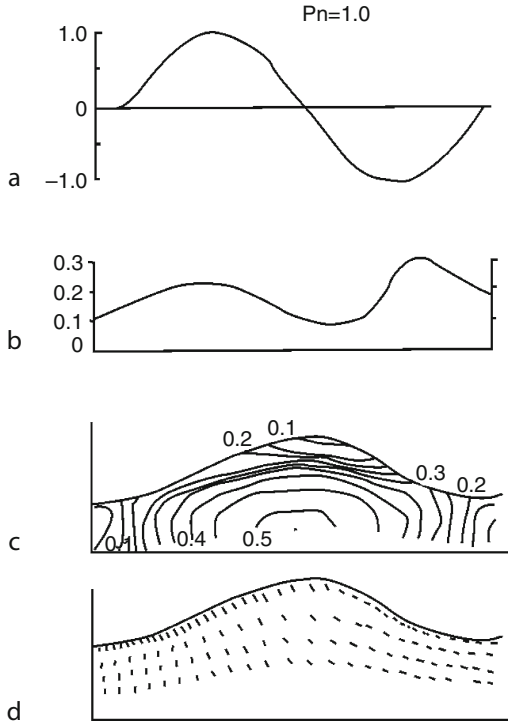
For a clast embedded in basal ice, a simple model illustrates the stress pattern caused by a normal pressure (Pn) forcing a point on the clast down into the underlying bed (Figure 2a) which induces a shear stress $T_{\max}$ (Equation 1) in the bedrock, as shown in Figure 2b.

$$T_{\max} = -\left(\frac{P_n}{\pi r'}\right)\cos\theta \tag{1}$$

In more realistic conditions of ice flow over an uneven bed, the force applied at the ice-bed contact and the clast-bed contact is tangential to the bed. Thus the surface stress pattern has its maximum down-glacier of the contact point. For ice flowing over a bedrock bump (Figure 3), the maximum stress on bedrock surface occurs on the lee side of the bump, where fractures are most likely to be produced.



Glacial Erosion, Figure 2 Contact of a spherical asperity with bedrock under a load (Pn). (**a**) The asperity tip has a radius r′. The asperity and bedrock possess Young's moduli of E_1 and E_2, respectively. The pattern of loading through a cross section of the contact area (2a) is shown. Shear (T) and normal (σ) stresses in bedrock resulting from surface loading are also indicated. The load is separated into normal and horizontal components. (**b**) Shows the contours (isolines) of constant maximum shear stress beneath the point (for a normal load only). From Drewry (1986, p. 33).

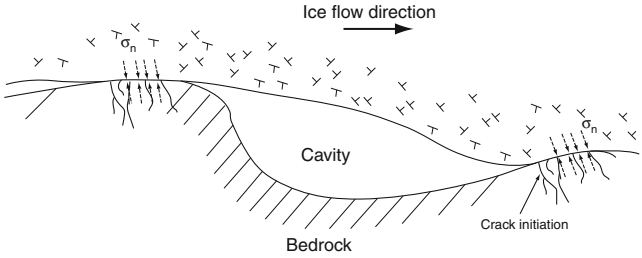


Glacial Erosion, Figure 3 Stress patterns induced in a subglacial bedrock undulation for normal pressure *Pn* = 1.0. Ice flow is from left to right. (**a**) Distribution of normal stress at the interface; (**b**) maximum shear stress at the bedrock surface; (**c**) maximum shear stress contours at depth (MPa); and (**d**) orientation of principle stress axes. From Drewry (1986, p. 41).

Strength and resistance of bedrock. Failure of a rock mass occurs when the shear stress applied is higher than the rock mass' confined or unconfined yield stress (rock strength). The strength of rock is affected by several factors, including the properties of the preexisting discontinuities, degree of weathering, presence and flow of water, presence and properties of material infilling discontinuities, and the loading cycle. In addition to direct glaciologically induced fractures, bedrock areas that are glaciated will have preexisting weaknesses related to the bedrock structure and its history of weathering, which can be exploited by glacial processes (Sugden and John, 1976).

Effective pressure. The force applied to the ice-bed contact or a clast-bed contact is a function of the effective pressure (P_E), which is the difference between the ice overburden pressure (P_i) and the basal water pressure (P_w): $P_E = P_i - P_w$. High effective pressures, and, thus, high fracture rates occur when ice is thick and water pressure at the bed is low. In some cases there are cavities at the glacier bed, resulting from ice flow over bumps at a speed that does not allow deformation of the ice to keep the basal ice in contact with the underlying rock (Hallet, 1996) and (Iverson, 1991). High velocity and low pressure favor the growth of cavities. Cavities reduce the contact area between the ice and the bed, and thus increase the average stress on areas that are in contact. Temporal variations in basal water pressure in cavities also lead to large short-term increases in local stress. In Hallet's model of glacial quarrying (Hallet, 1996), high plucking rates occur at low effective pressure (0.1–1 MPa) and fast sliding velocities, and large stresses are concentrated on bedrock ledges, causing crack propagation (Figure 4).

Fracture growth is enhanced by refreezing of meltwater in cracks resulting from variations in basal pressure and temperature over time at different points on the bed. For example, basal ice melts preferentially on the stoss (up-glacier) side of bedrock bumps because of locally increased pressure, and this meltwater then flows to the lee (down-glacier) side of the bump where pressures are lower and the water refreezes in joints and fractures. Expansion of the water during freezing acts to widen and extend fractures. Cyclic loading of the bed over time increases failure due to fatigue effects (Drewry, 1986), and when a glacier or ice sheet retreats the area that is exposed undergoes an unloading effect (as the weight of



Glacial Erosion, Figure 4 Stresses and location of probable fracture initiation near the corner of a ledge when ice is flowing over bedrock bumps (modified after Hallet, 1996).

the ice is removed) which can result in additional fracture and expansion of joints.

Entrainment of rock fragments by ice

For erosion to occur, material that has been loosened or weakened by fracture must be removed from its original location. The primary mechanism of removal involves incorporation of fragments into basal ice as a function of patterns of melting and freezing.

- Heat-pump effect

  When ice near the pressure-melting point flows over a bedrock bump or step, locally higher pressure occurs on the up-glacier side and produces melting. Meltwater flows around the bump to the lee side region of lower pressure where a cavity may exist. When the lower pressures on the lee side are below the pressure-melting point, the meltwater refreezes forming a frozen ice patch or regelation layer on the down-glacier side of the bump or step. This refreezing of water to the bed incorporates fragments at the bed loosened by fracturing, and these fragments are then removed from the bed as the ice moves further down the glacier. The freezing of meltwater on the lee side releases heat, which is conducted through the bump to the up-glacier side in a positive feedback loop called the heat-pump effect.
- Freeze-on

  In addition to the heat-pump effect, there are larger spatial and temporal changes in basal thermal conditions that produce regions and periods where there is a change from net melting to net freezing of subglacial water, including across boundaries between warm- and cold-based ice patches. Where and when this occurs, clasts and areas of subglacial sediment become frozen in to the basal ice, and are removed from the bed as the ice flows down-glacier. Freeze-on from rising supercooled subglacial water can also significantly affect basal ice growth in some areas and entrain large amounts of basal sediment into the basal ice (Cook et al., 2006).
- Thrust planes

  Large thrust planes in subglacial sediment also form in some cases, in particular at the boundary between areas of warm- and cold-ice regimes, and can incorporate large clasts and blocks of sediment in to basal ice.

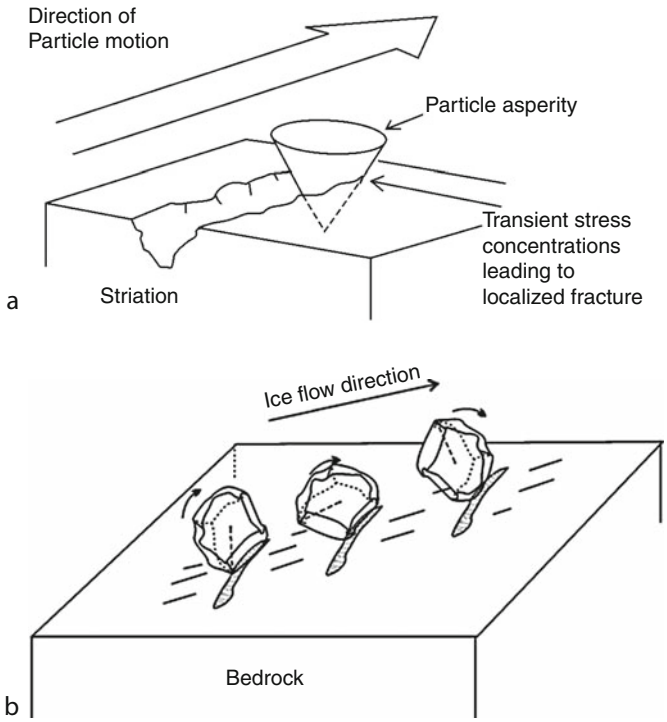
Abrasion

Abrasion involves clasts embedded in basal ice scratching and wearing down bedrock over which they pass. It involves small-scale fracture and crushing at the point where a clast touches underlying bedrock, and is most commonly seen where debris-laden ice is forced toward the bed. It is rarely found on the down-glacier side of bedrock humps (where plucking is most common) because the presence of cavities and ice flow away from the bed creates conditions where clasts embedded in basal ice are not forced toward the bedrock. The most common features produced by abrasion are striation marks, which are longitudinal scratches on the order of millimeters across and with lengths from centimeters to meters. Striations are the sum of numerous discrete crushing events at the micro scale, and the removal of the fine rock fragments that are produced. Seen under a microscope, striations consist of numerous crescent-shaped fractures (Benn and Evans, 1998; Iverson, 1995; Liu et al., 2009). Glacial polish is another common feature on glacially eroded rock surfaces, and is generally considered to be the sum of a large number of very small individual striations. However, additional ideas include the removal of large numbers of small protuberances from the bed surface.

Several models have been proposed for the basic mechanics of glacial abrasion; although they have similar basic structure, they differ in conceptions of how the force that is applied to the clast is controlled. In a simple abrasion model (Figure 5a) a clast embedded in basal ice is both forced downward into the underlying bedrock and at the same time moved along the bed by the down-glacier component of ice motion. This results in an indentation in the bed if the clast is harder than the bedrock. As the clast moves across the bed, it leaves a groove behind. The depth of the groove is controlled by the force directed on the clast toward the bed and the relative hardness of the clast and the bedrock, and the bed-parallel velocity controls the length of the striation produced per unit time. As the clast moves across the bed, wear products resulting from erosion, changes in the shape of the asperity, and increased friction between clast and bedrock can inhibit motion of clast causing rotation or lodgment that ends in a particular striation. When a clast rotates (Figure 5b) each time an asperity on the clast contacts the bed, the stresses induced by the contact allow cracks or failures to grow beneath or around the contact point. Discrete contacts between a clast and the bed produce a series of several marks on the bed, called chattermarks. The series continues until the clast is lifted into ice and no longer hits the bed or the clast is totally crushed.

The abrasion rate is affected by

- The force pressing the clast against the bed (defined in various ways in different models), F
- The velocity of the clast relative to the bed, U_p



Glacial Erosion, Figure 5 (**a**) Simple model of the striation process. (From Benn and Evans, 1998, modified from Drewry, 1986). (**b**) Set of chattermarks produced by a rolling pattern of movement of a clast across bedrock.

- The concentration of clasts in basal ice, C_o
- The relative hardness of the clast and the bedrock, ΔHd

Three different abrasion models have been developed, reflecting different ways of considering the mechanics of the interaction between sediment in basal ice and the underlying substrate.

Boulton's model

Boulton (1974, 1976) developed a model of glacial abrasion based on an assumption that clasts at the bed of a glacier support the overlying weight of ice: somewhat analogous to sandpaper being rubbed across a surface (Drewry, 1986). For temperate glaciers, basal water pressure in cavities and spaces between clasts also supports some of the weight of the overlying ice; thus, in Boulton's model, the force pressing clasts against the bed (F) is a function of effective pressure, and is given by:

$$F = (\rho_i g h - P_w) A_i \quad (2)$$

where ρ_i is ice density, P_w is water pressure, and A_i is a measure of the contact area between clasts and the bed. In this model, abrasion rates are high under thick ice with low basal water pressure, although under very high effective pressures the velocity of the clast is reduced by friction with the bed and abrasion ceases. Boulton's conception is of a fairly rigid contact interface between the base of a glacier and the underlying bedrock. Although such a situation has been observed in certain field settings (Anderson et al., 1982; Souchez and Lorrain, 1987) and laboratory experiments (Iverson, 1993), in other cases basal ice deforms around basal clasts, suggesting an alternate model for basal conditions and abrasion mechanics is also necessary for some situations.

Hallet's model

In Hallet's conception of conditions at the bed of a glacier, ice behaves as a viscous fluid and deforms around basal clasts (Hallet, 1979, 1981), to create a condition somewhat like a pebble resting on the bottom of a lake (Benn and Evan, 1998). Thus one component of the force between a clast and the underlying bed is the buoyant weight of the clast. However, for clasts at the bed of a temperate glacier, melting of basal ice causes a component of ice flow toward the bed. As ice moving toward the bed deforms around basal clasts, viscous drag results in a bed-directed force on clast. In this case, the force on the clast directed toward the bed is the combination of two components, the buoyant weight (F_b) of clast in ice and viscous drag (F_i) (Equations 3–5), which together exert a tangential force on the contact point. In this model, an increase in clast concentration initially increases the abrasion rate, until the concentration is large enough that it interferes with the flow of ice around clasts toward the bed. This model is considered to be most appropriate for conditions with a relative low basal clast concentration (Schweizer and Iken, 1992).

$$F = F_b + F_i \quad (3)$$

$$F_b = \frac{4}{3}\pi R^3(\rho_r - \rho_i)g\cos\theta \quad (4)$$

$$F_i = \frac{f 4\pi\eta R^3}{R_*{}^2 + R^2} v_n \quad (5)$$

where R_* is the transition radius, which affects regelation and creep and R is the asperity radius, θ is the local down-glacier inclination of the bed, η is the effective viscosity of the ice, $v_n$is the ice velocity normal to the bed, ρ_r, ρ_i are the density of rock and ice, respectively, and f is a parameter describing the bed influence on modifying the viscous drag for a clast in ice (Hallet, 1979).

The primary controlling factors for the Hallet abrasion rate model include:

- Basal melt rate
- Clast concentration
- Clast properties: size and density

According to this model, high abrasion rates will occur with high basal melting rates and clast concentrations that do not impede ice flow toward the bed. The buoyant force is normally insignificant except for very large clasts. For a low roughness bed, Hallet argues that U_p approximately equals U_s (the velocity of ice).

Sandpaper model of Schweizer and Iken, 1992

In a variant of Boulton's conception of bed conditions, Schweizer and Iken (1992) considered a clast-rich sediment layer at the base of the ice that is deformable, in contrast to the rigid contact model of Boulton. In this model, the deformable basal layer is able to adjust to bed undulations. In a similar formulation to Boulton's model, the force pressing the clast to the bed depends primarily on the effective pressure, but this is adjusted by a factor s which is the proportion of the basal layer occupied by water-filled cavities.

$$F = (\rho_i g h - sP_w)A_i \quad (6)$$

Since the force is transmitted to the bed only through the contact points of the asperity and the bed (the real contact area), so larger average normal stress will occur on the contact points when the real contact area is much smaller than the apparent contact area.

On basis of the different conceptions of the abrasion process, abrasion rate tends to (1) for Hallet's model, increase with basal melting and ice velocity and be independent of normal pressure and water pressure, and (2) for Boulton's model and sandpaper model, increase with ice velocity, ice thickness, and lower water pressure. Materials produced by abrasion are removed by subglacial water or entrained in sliding basal ice through the same entrainment mechanisms described in the section on Plucking.

Erosion by glacial meltwater

Glacial meltwater is produced by the melting of surface ice due to heat transfer from contact with air and rain at temperatures above freezing point, and from the energy of incoming solar radiation, or by the melting of basal ice due to pressure, friction, and geothermal heat. Meltwater is important in the evacuation of sediment and rock fragments produced by processes such as abrasion and fracturing. In addition, meltwater flowing in subglacial channels or as films at the ice-rock interface and the sediment carried by meltwater cause erosion of bedrock or sediments by mechanical and chemical processes. Water flowing in subglacial channels responds to the overall pressure gradient in the glacier hydraulic system, which in some cases can result in water flow that is "uphill" relative to the local topography (but down-pressure with respect to the subglacial water system). Thus, channels produced by subglacial water flow can produce erosion in parts of the landscape that would not be likely to be impacted by fluvial action in normal subaerial conditions.

Mechanical erosion

Crushing and abrasion. Crushing and abrasion associated with meltwater are most effective in subglacial streams in which water flows with high velocity and carries a large sediment load. Erosion mechanisms in glacial meltwater streams are the same as in other streams and rivers (see *Glaciofluvial*; *Glacial Erosion*), and crushing and abrasion by clasts being moved by water flow share some of the same mechanics as crushing and abrasion by clasts being moved by ice flow. Clasts being moved by fluvial transport impact the channel bed and produce failures or fractures on the bed and/or the clasts, depending on their relative hardness and preexisting fractures and weaknesses. Flowing water also exerts spatially and temporally variable pressures on the bed directly that in some cases can induce fracture. Factors controlling the effectiveness of crushing and abrasion resulting from glacial meltwater include (Drewry, 1986):

- Water flow velocity
- Angle of attack
  Turbulent flow and winding channels produce large angles of impact, and thus higher erosion rates.
- Clast size, hardness relative to rock hardness, concentration
  High erosion tends to occur with large clast sizes and high clast hardness values relative to the bedrock. Erosion rates increase exponentially with clast concentrations on the order of 1%, which are typical values, and decrease for concentrations over 20%.

Cavitation. When gas bubbles created by turbulences in water flow collapse the resulting pressure wave can damage the surrounding bedrock in a process called cavitation. Gas bubbles form due to low pressures that are produced locally when water flows over an obstacle. These gas bubbles then collapse when water flow takes them into high

pressure regions. This collapse can impart large forces on channel walls and produce failures. The amount of damage caused by cavitation is dictated by the volume and content of the gas, the compressibility of the fluid, and the hardness and preexisting weaknesses of the channel bedrock (Drewry, 1986). Because turbulence favors the growth of bubbles and the collapse of bubbles increases turbulence and rock failure, there is a positive feedback that increases the amount of cavitation that occurs in a meltwater channel.

Chemical erosion

When water freezes, dissolved material in the water is preferentially excluded from the ice that is produced. When this ice melts, it produces water that is relatively pure and reactive, and which has considerable capacity to incorporate and remove material from bedrock and sediments through chemical reactions that, in aggregate, are classified as chemical erosion. Meltwater exiting a glacial system is thus commonly rich in dissolved matter, which primarily reflects exchange between meltwater and the bed and basal sediment. There are three primary mechanisms of chemical erosion:

Dissolution. Chemical dissolution is a process in which water molecules attract ions from minerals that they are in contact with and bond to them, forming ions. Water molecules bond very tightly with positively charged ions, and many common ions in minerals are soluble in water, including calcium (Ca^{2+}), sodium (Na^{+}), potassium (K^{+}), magnesium (Mg^{2+}), and ions of iron (Fe), aluminum (Al), and silica (Si). The removal of these ions is a direct loss of material from the bedrock and sediment, and weakens the remaining structure. Contact with fresh bedrock provides undersaturated meltwater with an abundant supply of ions, but once the most soluble minerals on the bed surface have been dissolved and primarily insoluble minerals, like quartz, remain, dissolution will decrease. However, because the crystal matrix on the rock surface is weakened by the dissolution of soluble ions, the remaining rock is more easily fractured by ice or meltwater, which exposes more fresh rock to dissolution. During periods when the rate of melting is low, the meltwater can become saturated which reduces the rate of dissolution; during seasons of high melt, dissolution is not limited by saturation and maximum rates depend on bedrock mineralogy, and water temperature, acidity, and pressure.

Carbonation. Carbonation is a process in which dissolved carbon dioxide (CO_2) undergoes exchange with Ca from calcite, producing free Ca^{2+} and HCO_3^{-}. As the capacity of the water to hold calcium is pressure- and temperature-dependent, when meltwater flows to lower pressure areas some of the calcium will precipitate. Thus there can be small-scale patterns of solution and precipitation under a glacier in response to local changes in basal water pressure. In terrains with calcite-rich rocks and glacial systems with high discharges of meltwater, chemical erosion can be the most significant component of total erosion.

Cation exchange. Cation exchange takes place on the surfaces of fine sediments, principally clay minerals that contain a high proportion of colloidal-sized material (Drewry, 1986). Clay minerals with negative electrical charges attract dipole water molecules and positive charged ions. The ions absorbed on the surfaces tend to exchange with other cations in meltwater. The large surface areas of fine sediments allow efficient absorption of ions.

In summary, several factors control chemical erosion by meltwater.

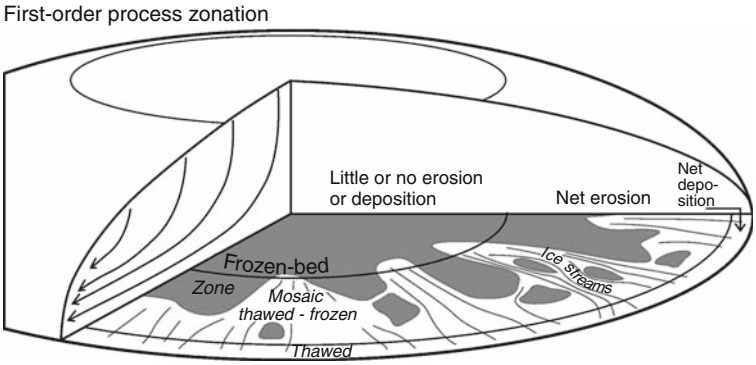
- Water flux and degree of undersaturation water
- Large contact surface and time of contact
- Available amount of fresh rock surface
- Concentration of free hydrogen cations
- Dissolved carbon dioxide
- The abundance of fine-grained sediments

Glacial erosion at the landscape scale

The role of basal thermal regime

In addition to considering the details of glacial erosion processes at the scale of millimeters to meters, there are larger-scale patterns of glacial erosion that are also controlled by glaciological variables (Benn and Evans, 1998). One of the primary controls on large-scale patterns of glacial erosion is basal thermal conditions. The glacial erosion processes described above have been widely assumed to be only effective under warm-based ice, because it is under these conditions that basal sliding and meltwater occur, and these are central to the erosion mechanisms described earlier in this entry. Cold-based ice is not at pressure-melting point, and under these conditions there is almost no movement between ice and the underlying bed, and thus there is little or no erosion on the bed. In fact, the traditional view has been that cold-based ice essentially protects and preserves the underlying landforms and landscape. Although this is largely true, detailed studies of erosion beneath cold-based ice have found that basal sliding, abrasion, and bed deformation do exist in these conditions. Echelmeyer and Wang (1987) and Cuffey et al. (1999) demonstrated basal sliding beneath a cold-based glacier, and Cuffey et al. (2000) presented evidence for entrainment of clasts under cold-based ice. Davies et al. (2009) have developed a model for boulder and clast entrainment, and substrate deformation by cold-based glaciers on the basis of the field observations of glacial erosion and deposition. However, although erosion can occur under cold bed conditions, the rate is believed to be very small compared to under temperate ice.

Mountain glaciers can be categorized according to their basal ice temperatures which are controlled primarily by the dominant climate system. For example, glaciers on the southeastern Tibetan Plateau and in the southern

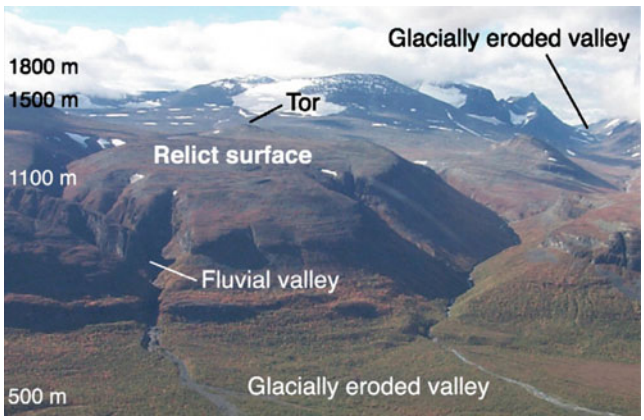


Glacial Erosion, Figure 6 The first-order organization of erosion and deposition zones under a steady-state polythermal mid-latitude ice sheet from Kleman et al. (2008).

Himalaya under monsoon-dominated climates have largely warm-based ice, while glaciers on the central Tibetan plateau under continental westerly dominated climates are typically primarily cold based or polythermal. Consequently, glaciers in the monsoon-dominated areas typically have high rates of glacial erosion and leave behind well-developed glacial landscapes including over-deepened cirques and broad and deep U-shaped valleys, whereas the continental glaciers have low rates of glacial erosion and leave behind landscapes with shallow cirques and poorly developed U-shaped valleys. Such contrasts also occur between areas of differing thermal regimes under past ice sheets. Because of the large scale of ice sheets and variations in underlying topography, different basal ice regimes can exist across the base of an ice sheet. The complex pattern of warm- and cold-ice regime patches and associated landscapes of glacial erosion and protection have been well studied for areas impacted by past ice sheets in Scandinavia (e.g., Kleman and Stroeven, 1997; Kleman et al., 2008; Figure 6). In a region that was covered by multiple past ice sheets occur uplands that have glacial erratics juxtaposed with well-preserved pre-glacial landscape features (such as tors and U-shaped valleys, Figure 7), as well as areas with deep U-shaped valleys and distinctive glacially sculpted bedrock. By comparing this landscape pattern with results from ice-sheet modeling, Napieralski et al. (2007) showed both that large-scale patterns of basal thermal regime under ice sheets likely control such landscape patterns (see also extensive discussion in Sugden and John, 1976), and that such landscape patterns can be used to help refine and calibrate ice sheet models.

The role of ice flow patterns

Ice thermal regime broadly determines whether glacial erosion occurs under a particular region of a glacier or ice sheet, whereas ice flow patterns and velocities exert a control on rates and total amounts of erosion and some of the details of the spatial patterns of glacial erosion. Five distinctive landscapes of glacial erosion have been identified, linked to broad ice-flow pattern types (Sugden and John, 1976; Benn and Evan, 1998; Table 1).



Glacial Erosion, Figure 7 Patchwork of landscape types typical of the northern Swedish mountains. Glacially eroded valleys are juxtaposed with rounded relict surfaces and V-shaped fluvial valleys (from Harbor et al., 2006, after Fabel et al., 2002).

Ice domes and sheet flow

As discussed above, under cold-based ice there is little or no erosion (Figure 7). However, under ice sheets and caps in regions of warm-based ice, relatively uniform flow across large areas produces landscapes with large-scale scouring (Figure 8) in which any major differences in topography relate to patterns of bedrock resistance to erosion. Landscapes of areal scouring include features such as rock knobs, roches moutoneés, and over-deepened rock basins, indicating extensive glacial abrasion and plucking.

Ice stream flow

Large-scale flow patterns under some current and former ice sheets include regions of ice convergence that produce high-velocity streams of warm-based ice, including outlet

Glacial Erosion, Table 1 Classification of landscapes of glacial erosion (after Sugden and John, 1976)

Glacier system	Glacier type	Process	Landscape types
Ice sheets and ice caps	Ice domes Outlet glaciers	Sheet flow Stream flow	1. Little to no erosion 2. Areal scouring 3. Selective linear erosion
Glaciers constrained by topography	Valley glaciers	Stream flow	4. Alpine landscapes 5. Cirque landscapes

Glacial Erosion, Figure 8 Areal scoured formed by ice cap on Haizi Shan Plateau of SE Tibetan Plateau.

Glacial Erosion, Figure 10 Glacial valley formed by paleo outlet glacier on the southeastern Tibetan Plateau.

Glacial Erosion, Figure 11 Deep glacially eroded fjords with non-eroded uplands, Meta Incognita Peninsula, Baffin Island (from Kleman, 2008).

glaciers as well as regions of high velocity within an ice sheet (Figure 9). Such ice streams produce large-scale glacial troughs, including some classic fjord landscapes (Figures 10 and 11), and typically are areas of maximum erosion by glacial ice (Hambrey, 1994a). As these troughs deepen, the increase in ice thickness and change in thermal gradient can produce a positive feedback with the deeper trough experiencing higher erosion, which in turn increases the depth of the trough. The contrast in erosion rates between the areas of streaming flow and adjacent areas produces a strong contrast in erosion rates that results in landscapes of selective linear erosion.

Summary

Glacial erosion involves a variety of physical and chemical processes that are controlled by glaciological variables on a range of spatial and temporal scales. Abrasion is a commonly recognized process of glacial erosion, and results from clasts embedded in basal ice scratching and wearing bedrock, as a clast at the base of a glacier is forced toward and moved over the bed. Abrasion acts to reduce bed roughness and is involved in features that range from small-scale striations, to larger-scale features that include whalebacks, rock drumlins, and crag and tail. Plucking involves fracture of bedrock due to impact and differential stresses applied by the ice on bedrock, followed by entrainment of the material that is released by fracturing. Plucking typically occurs on the lee sides of obstacles and bedrock steps where tensile stresses fracture large fragments and basal ice entrains the fragments by freeze-on. Glacial plucking tends to maintain roughness of a bed by producing relief in contrast to the abrasional reduction of roughness. Plucking plays an important role in shaping many large-scale landforms; many classic features such as cirques and roches moutoneés are products of a combination of abrasion and plucking (Hambrey, 1994b). Meltwater is important in glacial erosion, both as a mechanism for removing sediment and clasts created by other physical processes, and in removing material by both physical subglacial fluvial processes and chemical erosion. Based on an understanding of how glacial erosion processes work, it is possible to summarize the major glaciological controls on patterns and rates of glacial erosion as:

- Basal thermal dynamics

  Glacial erosion processes are only effective when the basal ice is sliding and there is meltwater, so warm-based ice is of prime importance to glacial erosion. Although there is some evidence that erosion beneath cold-based ice can occur, it is minimal compared to erosion under warm-based ice. Large-scale patterns of erosion are strongly influenced by areas of warm-based ice.
- Basal ice–sliding velocity

  For abrasion, the ice-sliding velocity may play a role in the force that is applied to the bed (Hallet model) and in all models of glacial abrasion it is important in determining the rate at which a clast moves across the bed, and thus striation length per unit time. For plucking, high ice velocity increases the frequency of high stress contacts between the ice or clasts, increasing the rate of fracture of bedrock and producing more rock fragments. The sliding velocity is also an important term in the rate of removal of material produced by plucking or abrasion. Thus glacial erosion is strongly dependent on sliding velocity, and, in erosion equations, the velocity term may be raised to a power greater than 1 to reflect this strong dependence. Large-scale patterns of erosion are strongly influenced by areas of high sliding velocity.
- Availability of meltwater and variability of meltwater pressure

  Meltwater plays an important role in the sliding velocity, but also can enhance fracture as a result of freeze-thaw effects in joints or fractures. In Boulton's abrasion model meltwater pressure is important in reducing effective pressure and in plucking models variability of water pressures over short time periods can produce transient stresses and load effects that enhance rock failure. Meltwater also plays a role in the efficient removal of debris produced by other physical erosion mechanisms, and creates additional erosion through fluvial abrasion, cavitation, and chemical erosion.
- Ice thickness

  Erosion process models that include effective pressure or normal pressure are dependent in part on ice thickness, and Boulton's model of abrasion is particularly sensitive to ice thickness (abrasion increases initially with increasing ice thickness, but then decreases under large ice thicknesses because the large effective pressure causes deposition of basal sediment). Ice thickness also plays a part in controlling sliding velocity, which is important in almost all of the glacial erosion processes.

GLACIAL ERRATIC

D. P. Dobhal
Wadia Institute of Himalayan Geology, Dehradun, India

A glacial erratic is a piece of rock that has been eroded and transported by a glacier to a different area and left behind when the glacier/ice melts. Glacial erratic gives information about the direction of ice movement and the distances of the transport of former glacier. Glacial erratic can be of any size from small boulder to large boulder in the size of a house or so.

GLACIAL GEOMORPHOLOGY AND LANDFORMS EVOLUTION

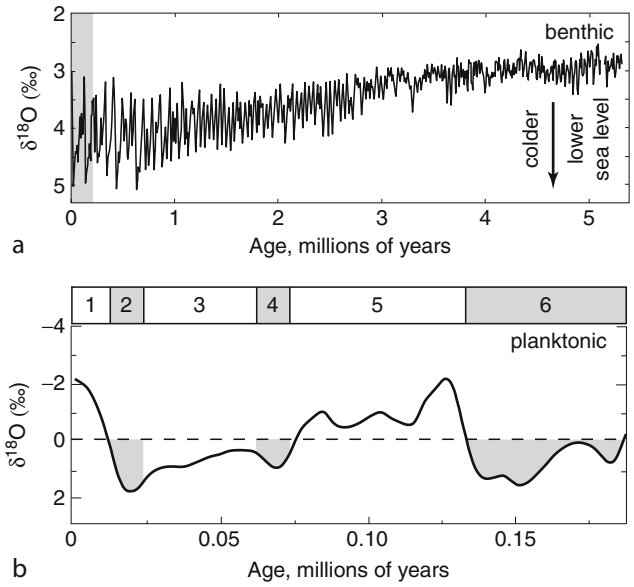
Evolution: maturation; Geomorphology: physiography; Transformation

Definition

Geomorphology. The study of the surface of the Earth: of surface elements (landforms) and the processes that create and shape them.
Glacial geomorphology. The study of the Earth's surface where it is formed or affected by flowing ice, or by water released by and in the vicinity of flowing ice.
Landscape. The community of landforms and the biological systems they support, generally at the scale of what can be seen and encompassed by an observer on a promontory.
Landscape evolution. The systematic modification over time of the systems of landforms and biota comprising the landscape; here only the systems of landforms are considered.

Introduction

Beginning about 3 Ma, the Earth's climate began a transition from the warm, humid Tertiary Period to the colder, drier Quaternary. This transition is captured in the $^{18}O/^{16}O$ ratio of benthic foraminifera extracted from marine sediment cores (Figure 1). The $^{18}O/^{16}O$ ratio is sensitive to water temperature and, especially, to the global volume of sea level, such that lowered sea levels and lower water temperatures are reflected in greater ratio values. Over the course of the Pleistocene Epoch (2.6 Ma – 11.4 ka) eustatic sea level oscillated in increasingly wide swings, but overall it dropped as more and more ice was captured in the polar ice caps and



Glacial Geomorphology and Landforms Evolution, Figure 1 Marine oxygen isotope data. (**a**) Sea-level proxy record from 57 globally distributed $^{18}O/^{16}O$ ratios from benthic foraminifera (after Lisiecki and Raymo, 2005). The oxygen ratio is expressed as $\delta^{18}O = 1000\left(\left(\frac{^{18}O}{^{16}O}\right)_s \left(\frac{^{18}O}{^{16}O}\right)_{ref}^{-1} - 1\right)$ where *s* is the sample and *ref* is a reference standard. ^{18}O and ^{16}O are both present in seawater; ^{16}O is preferentially removed during evaporation. During ice ages, water from the oceans is sequestered in ice sheets and the $^{18}O/^{16}O$ ratio in the oceans is increased. This is reflected in the $^{18}O/^{16}O$ ratio in foraminifera; hence $\delta^{18}O$ is a measure of ocean volume. (**b**) Record of the past 0.2 Ma, from $^{18}O/^{16}O$ ratios from planktonic foraminifera. The record shown corresponds to the time covered by the gray bar in a. Marine oxygen isotope stages 1–6, defined by these data, are shown in the horizontal bar above the curve and by shading on the curve itself. The $\delta^{18}O$ of planktonic foraminifera is used as a record of sea surface temperature, which fluctuates along with ocean volume during climatic fluctuations. However, it is problematic because planktonic foraminifera are also sensitive to salinity and other environmental changes. Benthic records are also complex, sensitive to changes in evaporation rates and salinity during deep-water formation.

high-latitude ice sheets. Thus, minima in sea level are associated with glaciations, and maxima are associated with interglacial conditions such as we enjoy now, in the Holocene (11.4 ka – present).

Despite complexities in the interpretation of the $\delta^{18}O$ data shown in Figure 1, these data are commonly used to provide a framework for the discussion of climate during the Quaternary Period, which is divided into odd- and even-numbered marine oxygen isotope stages (MIS) (Figure 1b). During odd-numbered stages, the oceans are high and warm; during even-numbered stages, the ocean levels are low and cool. Although the stages are taken to correspond roughly to glaciations worldwide, the greatest correspondence is to the high-latitude ice sheets. Mountain glaciations show some regional and local variations in the timing of the maximum advances (e.g., Gillespie and Molnar, 1995).

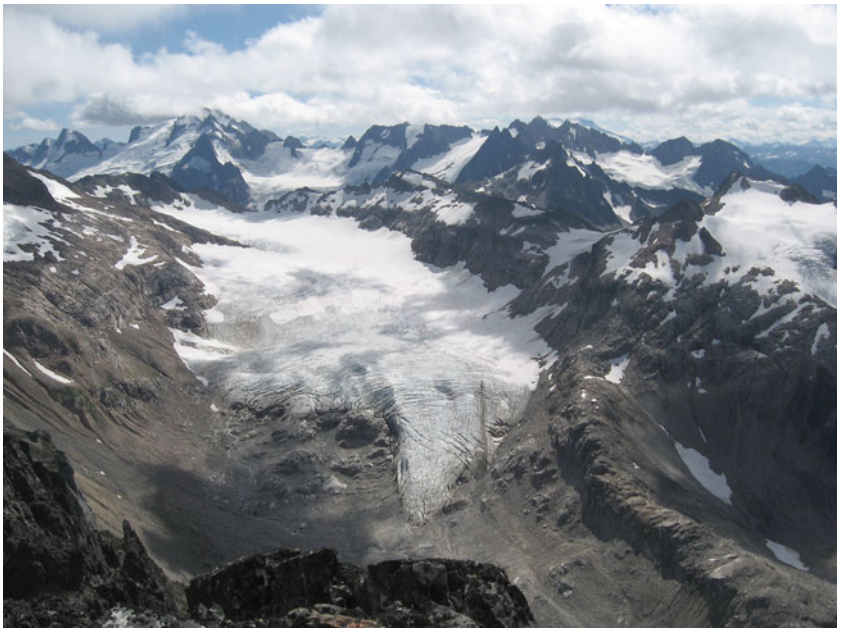
Especially during the latter part of the Quaternary Period, mountain ranges around the world were glaciated repeatedly, along with the expanded high-latitude ice sheets (see entry *Ice Sheet*), during the increasingly cold intervals. This was even true in the tropics, provided the mountains were high enough – for example, >4,000 m in Papua New Guinea (Prentice et al., 2005) and Hawaii (Porter, 2005). During the Quaternary, there have been over 50 oscillations of sea level, and therefore glaciers advanced dozens of times from the mountainous peaks and ridges, down valleys, and sometimes onto the piedmonts. Thus, even if individual glaciers accomplished little, over time they have had the opportunity to modify the landscape of a significant fraction of the land area of the Earth (~20%).

In this entry, the geomorphology of glaciated regions will be reviewed first, with an emphasis on alpine or mountain glaciers. This describes how glaciers modify landscapes and fine and coarse scales. The modification of these landscapes after the glaciers have retreated will then be summarized. More coverage is available in any of several texts, for example, *Glaciers* (Sharp, 1960), *Glacial Geomorphology* (Embleton and King, 1975), *Glaciers and Landscape* (Sugden and Brian, 1976), *Glacial Geology* (Bennett and Glasser, 1996), *Glaciers and Glaciation* (Benn and Evans, 1998), *Surface Processes and Landforms* (Easterbrook, 1998), and *Process Geomorphology* (Ritter et al., 2002).

Glacial geomorphology

Glaciers modify the landscape in characteristic ways, by deposition, by erosion, and even by protection from paraglacial erosion that may affect landscapes in the vicinity of the glaciers themselves (Figure 2). The way in which the landscape is modified depends on the position relative to the glacier, the slope of the land beneath the glacier, and the temperature and thickness of the glacial ice. Thus glacial sculpting of bedrock is most pronounced near range crests, but deposition of till in constructional landforms such as kames (see entry *Kame and Kettle Topography*) and moraines (see entry *Moraine*) is concentrated near the lower part of the glacier where melting of the ice is occurring. Avalanche chutes terminate at the elevation of the glacier's surface; lower down, the glacier shields the mountain wall from the falling snow and rock.

Under very cold conditions, the temperature of the glacier ice may be below 0°C even at its base, and is frozen to the bedrock floor. Such "cold-based" glaciers (see entry *Cold-Based Glaciers*) flow by shear within the ice, and not by basal sliding facilitated by liquid water. Therefore, erosion at the glacier bed is much less than for warm-based glaciers, for which temperatures are at the freezing point, adjusted for the pressure of the overlying ice, for which ice and water can coexist. Erosion on the beds of



Glacial Geomorphology and Landforms Evolution, Figure 2 Landscape modified by repeated glaciation. South Cascade Glacier from Le Conte Mtn, Cascade Mountains, Washington, USA. The steep cliffs above the lateral margins of the glacier ("trim lines") were produced by glacial erosion and mark the height of the glacier during the last ice age. The crevassed ice (see entry *Crevasses*) at the toe of the glacier is darker than the snow-covered ice at higher elevations. It absorbs more sunlight and ablates more quickly than the reflective snow. View to SE. Photograph: Kurt Parker, 2007.

warm-based glaciers can even take place fluvially, from the flow of subglacial streams.

Hallet et al. (1996) have estimated glacial sediment yields (see entry *Sediment Yield*), including sediment stored in glaciated basins, and find that they vary by orders of magnitude, from 0.01 mm year^{-1} for polar glaciers, to 0.1–1.0 mm year^{-1} for temperate valley glaciers (see entry *Temperate Glaciers*) on diverse bedrock, and to 10–100 mm year^{-1} for large and fast-moving temperate valley glaciers in the tectonically active ranges. Together with solute yields, a small fraction of the suspended load, these sediment rates comprise the erosion rate beneath glaciers (see entry *Glacial Erosion*).

Glacial climate and response

Glaciers advance when more snow falls than can be melted during the summer. For maritime regions, conditions that promote glacial growth are primarily low summer temperatures and high precipitation. Low wind speeds and high humidity also promote accumulation. At high altitudes in arid conditions (<150 mm year^{-1}) where sublimation can be a significant cause of ice mass loss, cloudiness may enhance glacial growth. Summer rain may increase ice melting. The region in which snow accumulates from year to year is called the accumulation zone. As the snow thickens, pressure on the base of the snowfield increases, and the snow is compacted into firn (see entry *Firn*). With further accumulation, the ice exceeds a critical pressure and it begins to creep downhill. The thickness required for this is proportional to the topographic slope:

$$\tau = \rho g\, z \sin(\theta) \tag{1}$$

where τ is the shear stress, ρ is the ice density (0.93 g cm^{-3}), g is gravitational acceleration (9.8 m s^{-2}), z is the depth of the ice in meters, and θ is the topographic slope. Ice begins to slide with a basal shear of about 10^5 Pa (1 bar). Thus, if the bedrock slope is 10°, the glacier will be about 65 m thick. Additional snowfall will lengthen the glacier and may increase the speed of its flow, but will not thicken it. The speed of the flowing ice is determined by the topographic slope, among other factors (see entry *Glacier Motion/Ice Velocity*).

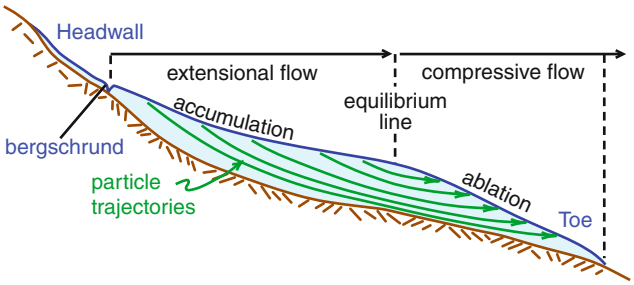
As the ice moves downhill, the atmosphere warms, promoting ablation or melting. At some altitude, the rates of accumulation and ablation balance: this is called the equilibrium line altitude, or ELA (Figure 3) (see entry *Equilibrium-Line Altitude (ELA)*), and is an important measure used in estimating past climatic conditions from the outlines of vanished glaciers. The ELA differs from the snowline in that it represents a long-term average altitude, whereas the snowline fluctuates annually and on shorter timescales. The snow–ice transition shown in Figure 2 corresponds approximately to the snowline.

Below the ELA, ablation dominates, and the glacier loses mass, slows down, and finally stops. As this happens, flow lines rise to the glacier's surface, carrying rock debris to the sides and end of the glacier. They are

left behind as the ice melts, forming moraines of till (Figure 4) – rocky debris with a roughly uniform grain-size distribution and a general lack of fabric.

Most of the erosion by the glacier of its bed occurs because the glacier drags rocky debris over the rock. This is maximized anywhere the flow lines are directed downward, thus especially in the accumulation area.

If the temperature at the base of the glacier is below freezing, such that flow occurs only by deformation within the ice (creep) and not by basal sliding, the glacier will advance much more slowly (by ~2 orders of magnitude: cm day^{-1} instead of m day^{-1}) and may become thicker than if the glacier is warm-based. However, because the freezing temperature is depressed due to the weight of the overlying ice, as the ice continues to thicken ultimately basal melting will occur and the glacier will then advance rapidly and thin (e.g., Meir and Post, 1969). The depth at which the glacier base melts is lessened because of geothermal heat trapped beneath the insulating layer of ice, and therefore the transition from cold- to warm-based glaciers can occur at a range of depths depending on both ambient temperature and heat flow.

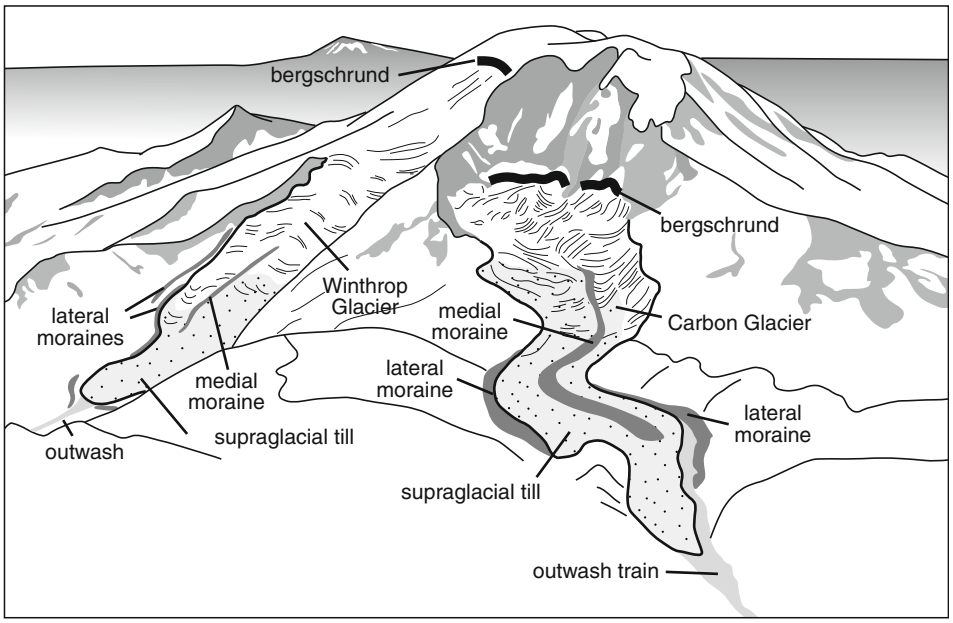


Glacial Geomorphology and Landforms Evolution, Figure 3 Schematic long profile of an alpine glacier. The bergschrund is a crevasse separating the firn and snow mantling the headwall from the moving ice of the glacier. Ice particles in the accumulation area have a downward component to their flow direction as they are buried by new snow. Near the toe of the glacier the flow has an upward component as the ice is ablated from the top of the glacier.

Glacier taxonomy

The unifying characteristic of glaciers is creep or flow under their own weight. Because of the diverse settings in which glaciers are found, and the wide range of climatic conditions under which they exist, a rich descriptive nomenclature has been developed over decades of study. An abbreviated treatment is given here.

Temperature regime... Glaciers are often classified according to their temperature profiles relative to the melting point of ice. Glaciers that are at least seasonally above the melting temperature of ice at the ice/rock interface are called "warm-based." Such glaciers commonly move relatively quickly (e.g., m/day) and erode large amounts of rock. Glaciers that do not exceed the melting point at their bases are called "cold-based" (Figure 5) and are slow moving.



Glacial Geomorphology and Landforms Evolution, Figure 4 Temperate alpine glaciers. Lateral moraines border the glacier below its equilibrium line, where ablation exceeds accumulation and debris entrained in the ice is brought to the surface and left behind as the ice melts. Medial moraines can occur below bedrock obstructions when debris-rich concentrations of ice intersect the ablating surface, or when two glaciers and their lateral moraines merge. Entrained debris may mantle the glacier (supraglacial till) in its ablation zone. Meltwater charged with silt and rocky debris leaves outwash, or reworked till, in valleys below the toe of the glacier. Winthrop (*left*) and Carbon (*right*) glaciers, Mt. Rainier, Washington (USA).

Glacial Geomorphology and Landforms Evolution,
Figure 5 Cold-based Glacier #1 at the head of the Ürümqi River in the Tianshan range of Xinjiang, P. R. China (Echelmeyer, 1987). The glacier today carries very little debris, but the dark-colored Little Ice Age moraines below the glaciers point to earlier times when the glaciers transported more. Photograph: Dr. Ping Kong, Chinese Academy of Sciences, Beijing, China.

The melting temperature of ice depends in part on salinity, which affects sea ice, and pressure, and therefore ice density or porosity. The "pressure melting point" decreases with depth in a glacier at a rate of 0.07 K MPa^{-1}, or about 0.6 K km^{-1}. Glaciers that are below freezing throughout are called "polar," and glaciers that are at the melting point throughout are "temperate." Glaciers that are below the melting point at their base but are at the melting point in their interiors are "subpolar." Many glaciers exhibit considerable spatial complexity, and are "polythermal." For example, since glaciers flow downhill from colder to warmer conditions, some glaciers are cold-based at their tops, and warm-based near their ends. The transport of heat in percolating meltwater plays an important role in controlling the temperature profiles of glaciers.

Their temperature profiles may also change over time. Although these classifications present a simplified picture of glaciers, they form a useful and conventional framework for discussion.

Topographic constraint: Many glaciers occupy canyons or valleys, and may be referred to as "valley glaciers." Ice may also accumulate on an approximately flat upland surface, however. If ice begins to build up on a plateau, it is regarded as a firn cap (firn is intermediate between snow and glacial ice). Eventually, the deepening firn will flow outward under its own weight, driven by the weight and slope of the ice. This body of ice, not confined in a valley, is a kind of glacier called an "ice cap" and has a convex profile (Figure 6a). Larger masses of interconnected glaciers that do not overtop peaks (nunataks) and ridges are known as "ice fields," and coalesced masses of ice that do overtop the terrain are called "ice sheets." These can be very large: during the Pleistocene Epoch ice caps covered much of northern Europe (Fenno-Scandian Ice Sheet) and much of North America (Laurentide and Cordilleran ice sheets).

Coalescence: Distinction is commonly made between isolated and coalesced glaciers even in alpine settings. From the geomorphological viewpoint, this distinction is helpful because the impact of glaciers on the landscape depends in part on whether or not the ridges separating glaciers – commonly sources of rock debris transported to the glacier surface by avalanches and rockfall – are exposed and prone to avalanching, are frozen year round and largely protected by snow or firn cover from mass wasting by firn, as is sometimes the case in cold settings, or are submerged beneath flowing ice and being eroded. Because glacial flow is driven by the slope of the ice surface, and not the bedrock surface, the terrain beneath vanished ice fields and sheets can be complex, with interconnected glacial troughs and modern stream flow sometimes running contrary to the direction of ancient ice flow.

Outlet glaciers and ice streams... As ice caps thicken and coalesce, it is likely that pressure melting and enhanced sliding will occur. This leads to the formation of streams of more rapidly moving ice within the slower-flowing ice field or ice sheet. Some of these emerge from the ice cap as outlet glaciers, usually occupying valleys. In their lower reaches, these may not be easy to distinguish from trunk glaciers – large valley glaciers fed by multiple simple glaciers – but they are treated separately here because of their importance in modifying the landscape underneath the ice sheets themselves, as discussed below.

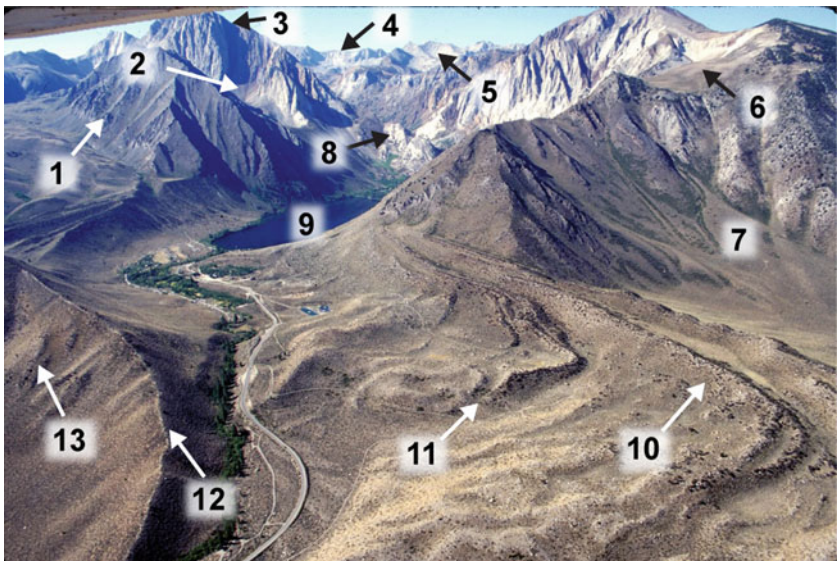
Glacial modification of the landscape

Fine-scale features

Most people who are casually familiar with glaciated landscapes probably envision temperate alpine glaciers as the responsible geomorphic agent. Glacial modification comprises the construction of relatively minor, short-lived landforms such as moraines, but also coarser-scale, longer-lived erosional features resulting from repeated glacial cycles. Examples of these can be seen in Chamonix (French Alps), Yosemite (Sierra Nevada, California, USA), and many other settings. Downstream from the glacier, glacially eroded and transported rock, gravel, sand, and silt are deposited fluvially as outwash plains that grade to the toe of the glacier. Because available sediment commonly exceeds the capacity of the glacial meltwater to transport it far from the glacier, the glacial streams are meandering and anastomosing, leaving an intermittently flooded plain of gravel bars and channels, intermixed with reworked debris-flow deposits.

The toe of the glacier is often fronted by a terminal moraine, or by a series of recessional moraines if the glacier is in retreat (Figure 7). Moraines (see entry *Moraine*) are one of the most distinctive landforms left by glaciers.

Glacial Geomorphology and Landforms Evolution, Figure 6 An ice cap on Sutai, a 4,226 m peak of the Altai range in western Mongolia. (**a**) Upper ends of the valleys have steepened headwalls and are ice-filled; the lower, V-shaped sections may appear to have been unglaciated, but low moraines at the range front suggest otherwise. (**b**) Lateral moraine left by an outlet glacier from the Sutai ice cap. Notice the linear slopes of the valley walls.



Glacial Geomorphology and Landforms Evolution, Figure 7 Geomorphic features near the toe of an ancient glacier at Convict Creek, California, USA. *1*: Trim line marking upper limit of glacial erosion and height of the ancient glacier. *2*: Hanging valley. *3*: Horn, or sharp peak sculpted on all sides by glacial erosion. *4*: Arête marking a drainage divide – a sharp ridge glacially eroded on both sides. *5*: Cirque. *6*: Felsenmere, a plateau of rocks shattered by freeze/thaw action. *7*: Debris-flow fan. *8*: Cliffs at the site of an icefall. *9*: Lake filling an overdeepened glacial trough. *10*: Recessional end moraine of LGM (MIS 2) age. *11*: Fluvial breach in recessional moraine. Road passes through another breach occupied by the modern stream. *12*: Right-lateral moraine. *13*: Remnants of largely buried older moraine. From a photograph by D. H. Clark.

Because the lateral moraines are deposited only below the ELA (see entry *Equilibrium-Line Altitude (ELA)*), their highest occurrence is one estimate of the ELA of ancient, now-vanished glaciers. Estimating the ELA this way is sometimes referred to as the "maximum elevation of lateral moraine" or MELM technique. Other techniques are also used, based on the ratios of the areas of ice accumulation and ablation, or a known fraction of the elevation difference between the toe of the glacier and the cirque headwall (Meierding, 1982; Selzer, 1994; Benn and Gemmell, 1997).

Moraines are composed of rocky debris ("till") (see entry *Till*) transported within or on top of the glacier and deposited around its perimeter below the ELA. Till is also deposited on the bed of the glacier, especially near its terminus, or mantles the glacier (supraglacial till). During glacier advance, the supraglacial till ultimately becomes part of the end moraine.

Occasionally, supraglacial till is thick enough that the glacier has the appearance of a slow-flowing river of rock: such debris-mantled glaciers are sometimes referred to as rock glaciers. Similar landforms can be created from the

growth of interstitial ice in talus and its subsequent mobilization (Barsch, 1996) (see entry *Rock Glaciers*). A good summary of rock glacier dynamics is found in Haeberli et al. (2006).

Together, primary till left directly by the glacier and till fluvially reworked as outwash are referred to, especially in the classical literature, as "glacial drift." The origins of this term lie in the early history of glacial study, when it was thought that "erratics," or out-of-place boulders littering the glaciated landscape long after the ice is gone, had "drifted" to their resting places during the Noachian Flood. Later, it was recognized that erratics had actually been moved by glaciers (cf. Lyell, 1833).

Large accumulations of drift are common only below the ancient ELA, where the glacial flow lines (Figure 3) are directed upward and where deposition is a dominant geomorphic process. Above the ELA, the ice flows downward and abrades the rocky bed. This leads to an erosional environment anywhere once covered by the flowing ice in the accumulation zone.

In its accumulation zone, the bed of an ancient glacier is rocky and irregular. Roches moutonnées are bedrock knobs that were streamlined by the flowing ice. However, larger resistant bedrock knobs may reverse this asymmetry, with steep upglacier faces and gently sloping lee tails ("crag and tail"). In this case, the crag blocks the flowing ice and reduces its erosive power immediately downglacier.

Cliffs and hollows or basins, now commonly filled with lakes, remain under ancient zones of extending and compressing flow, respectively. The top of the glacier is characteristically marked by a high cliff that once separated the snow and firn high on a mountain from the flowing glacial ice. This cliff is known as the headwall, and forms part of the uppermost basin, or cirque.

Post-glacial modification of glaciated landscapes

During and following glacial retreat, large portions of the once-glaciated landscape are susceptible to modification at a range of scales. This environment is described as "paraglacial" (see entry *Paraglacial Landscape Transformations*). Without the support of the ice and lacking vegetation to retard runoff, for example, moraines are susceptible to rilling and also undercutting by trunk streams meandering in the outwash. This leads to the formation of a catena in which the toeslope of the moraine (in lateral section) is built up at the expense of the upper slopes, which are degraded. Exposed tillstones are also eroded.

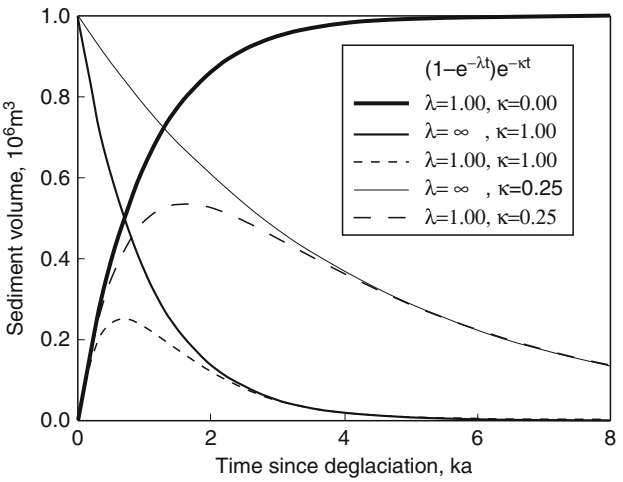
Much deglaciated terrain is subject to strong cryoturbation and solifluction, caused by the action of freeze/thaw on soils. Such cryoprocesses can move vast amounts of material downslope, a shallow (~10 cm–1 m) at a time. In this way, the appearance of the glaciated landscape is gradually smoothed.

This smoothing is not restricted to depositional landforms such as moraines, but includes the steep bedrock knobs and cliffs uncovered by the melting of the ice. The fresh bedrock characteristically spalls due to freeze/thaw cycling, and rocky talus and scree slopes build up at the foot of cliffs.

Mass wasting acts at the local scale, but running water redistributes some of the drift downriver far from the glaciated regions, much as outwash itself is transported downstream.

Paraglacial processes

Paraglacial processes (see entry *Paraglacial Landscape Transformations*) are defined by Church and Ryder (1972: 3059) as "nonglacial processes that are directly conditioned by glaciation." The same processes operate in the periglacial environment (see entry *Periglacial*) but their effects are most significant where retreating glaciers have left large supplies of unstable till together, initially, with a large flux of meltwater that can transport it down valley. As might be expected, paraglacial modification of the once-glaciated landscape is greatest immediately after glacial retreat, and diminishes thereafter as slopes and river systems achieve a new equilibrium (Figure 8). Sediment yield for local basins is thus a relaxation phenomenon, but the initial amplitude and the timescale of the relaxation are dependent on local conditions, including lithology



Glacial Geomorphology and Landforms Evolution, Figure 8 Sediment yield from two basins following glacial retreat: a small basin in which unstable till is being reworked, and a larger basin downstream in which sediment is deposited and also eroded and transported downstream. The thick solid curve describes the cumulative amount of the total sediment available upon deglaciation at t = 0 ka (10^6 m^3) that has been removed or stored in the basin over time, for erosion and transport at a constant rate specified by λ = 1.0 ka^{-1} (sediment volume = 10^6 $(1-e^{-\lambda t})$). The two descending solid curves (10^6 $e^{-\kappa t}$) describe sediment loss from the system for two values of κ (1.00 and 0.25 ka^{-1}, for the large and small basins, respectively), where κ is the rate of sediment loss from the sediment store, assuming that no sediment is stored in the basins. The sediment storage over time in the two basins is given by 10^6 $(1-e^{-\lambda t})$ $e^{-\kappa t}$ – after the general steady-state model of paraglacial sediment storage proposed by Ballantyne (2003).

(Ballantyne, 2002a). An excellent summary of paraglacial geomorphology is given by Ballantyne (2002b).

Sediment flux from deglaciated basins: Figure 8 shows the model behavior of two simple steady-state basins following deglaciation, at which time ($t = 0$) it is assumed the 10^6 m^3 of sediment is available for distribution. The amount of sediment remaining after time t is given by 10^6 $e^{-\lambda t}$, where λ is a constant rate of accumulation that is characteristic of the particular basin. The amount of sediment lost to storage or transport downstream is thus 10^6 $(1-e^{-\lambda t})$. The volume of stored sediment is given as 10^6 $(1-e^{-\lambda t})$ $e^{-\kappa t}$, where κ is the rate of loss from the sediment store. Both λ and κ may differ from basin to basin, and application of steady-state models such as this one offers a way to understand how landscapes have responded to glacial inheritance. A detailed treatment is presented by Ballantyne (2003).

The sediment flux from larger basins is also controlled by storage from upriver. Essentially, a wave of sediment moves down the fluvial system as sediment is first transported and then deposited as outwash terraces and fluvial bars and terraces near the glaciers, and then reworked and transported farther downstream. Therefore, the paraglacial sediment erosion and deposition history may be quite varied and complex.

Mass wasting: Paraglacial processes include mass wasting on hillslopes and mixing of the soil or regolith by freeze/thaw – cryoturbation. For example, mountain ridges are commonly scarred by avalanche chutes scoured by falling snow, ice, and rock. The controlling factors are slope, snowfall, and freeze/thaw cycling to loosen the rock. In some areas, such as the Cascade Range of North America, avalanche erosion is active today; in more arid areas such as the Sierra Nevada, avalanching may have been more common in glacial times (Figure 9). In such areas, relict avalanche chutes in cirques and glacier valleys are commonly bottomless, because the rubble ran out on the ancient glacier surface and was carried away. During interglaciations, rocky avalanche debris builds up as talus beneath the chutes. The bottom line of chutes marks in a general way the height of the ancient glacier. Talus from isolated rockfall also builds up beneath cliffs, locally as arcuate or sinuous side-valley ridges known as protalus ramparts (Ballantyne and Benn, 1994). These occur when there is rockfall onto snowbanks at the foot of a slope: the falling rock slides down the snow bank and accumulates at its foot, away from the rock slope.

Mass wasting need not be sudden. Loose rubble and soil is also translated down slopes by soil creep, or solifluction (see entry *Solifluction*). Creep generally occurs in the top few meters of the surface and can be accomplished by expansion and contraction of the soil, for instance by wetting or by freeze/thaw. When soils expand, particles are moved outward perpendicular to the slope, but during contraction (drying or melting) the particle moves downward under the force of gravity, with a resultant in the horizontal direction. Mass wasting can be greatly accelerated by saturated flow in the periglacial environment. Gelifluction (see entry *Gelisols*) is the creep of saturated soil within the active layer above permafrost. Because the viscosity of saturated soil is low, solifluction can occur even on gentle slopes of a degree or less.

Glacial Geomorphology and Landforms Evolution, Figure 9 Avalanche chutes in the Sierra Nevada, California, USA. Most chutes terminate above the cliff that marks the glacial trim line. Absence of talus below them indicates that most chute development preceded deglaciation. One chute (lighter, center) extends through the trim line, and avalanching there appears to have continued during the Holocene. Photograph by D. H. Clark.

Gelifluction and solifluction leave characteristic marks on the landscape. At the fine scale, these marks include headwall scarps and sediment lobes. At the landscape scale, they include hillslope smoothing, tors, and flat-floored box canyons that collect and channel flowing regolith. Figure 10 shows an unglaciated periglacial landscape that has been heavily modified by solifluction and freeze/thaw processes. The top of the mountain is a cryoplanation surface, flanked by two or three large terraces as the slope steepens toward the viewer. Most of the regolith has been stripped from the surface, leaving relatively smooth bedrock. Isolated bedrock knobs, or tors, have been left behind by the general lowering of the surface.

About two-thirds of the way down, the mountain flanks in Figure 10 are stubby valleys with linear slopes, convex only near their tops. Although these valleys host underfit ephemeral streams, they owe their existence and shape to long-term slope-parallel erosion. The regolith is moved down the sides of the valleys to their axes, mainly by solifluction. The sediment temporarily stored on the floors of the stubby valleys is then moved out of the mountain to the broad valley in the foreground by a combination of solifluction and occasional fluvial transport or debris flows. Solifluction is a dominant process of erosion in vast tracts of cold, arid lands where fluvial erosion is suppressed, and is also an important paraglacial process in modifying glaciated terrain.

Modeling sediment flux from hillslopes: Sediment flux from slopes is commonly estimated with diffusion-like models. For low-angle slopes, a linear diffusion equation in which flux q_s is proportional to the topographic gradient ($q_s = KS$) is commonly used, where S is the tangent of the slope angle $\left(S = \frac{dz}{dx}\right)$. This is Fick's Law for diffusion, and the empirical proportionality constant K is the diffusivity. The units of q_s are $m^3\ m^{-1}\ year^{-1}$, or $m^2\ year^{-1}$; values of K vary with lithology, vegetative cover, and other conditions, but for some slopes in unglaciated mountains $K \approx 0.0036 \pm 0.0016\ m^2\ year^{-1}$ (Roering et al., 1999). Hillslopes that erode by linear diffusion should have constant curvature, and should appear parabolic in cross section. However, for soil-mantled slopes curvature approaches zero, and the slopes are linear as in Figure 10. The V-shaped glaciated valley of Figure 6b also has linear slopes, although they are mantled by talus rather than soil.

For steep valley walls such as those in Figures 6b and 10, diffusional sediment flux is more appropriately modeled as a nonlinear function of slope (Roering et al., 1999):

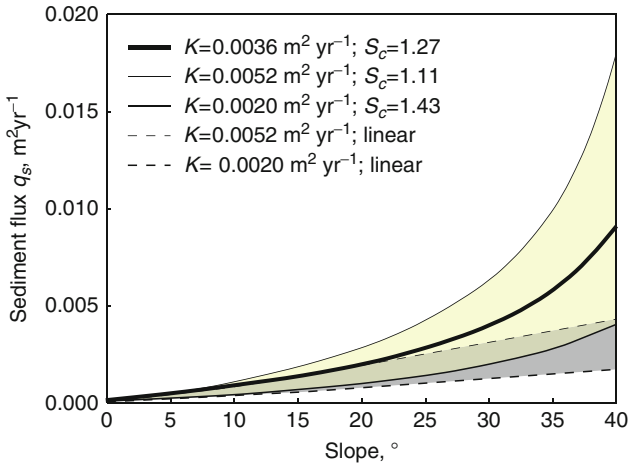
$$q_s = \frac{KS}{1 - \left(\frac{S}{S_c}\right)^2} \tag{2}$$

where S_c is a critical hillslope at which soil flux becomes infinite. Physically, S_c is related to μ, the effective coefficient of friction of the regolith material. Empirically, it has been found that $S_c \approx 1.27 \pm 0.16$. Equation 2 reduces to the linear diffusion model for large values of S_c or for shallow slopes. The diffusion-like models account for creep but not for sediment transport by overland flow.

Sediment fluxes q_s calculated for different diffusivities K and critical slopes S_c are shown in Figure 11. The curve for $K = 0.0036\ m^2\ year^{-1}$ and $S_c = 1.27$ m represents typical values for mountains in the unglaciated Coast Range of Oregon, USA, where much of the analytic work in support of the flux model has been done. The production of sediment from hillslopes becomes increasingly nonlinear with slope for high diffusivities and low critical values (S_c). The hillslopes in the Oregon Coast range are linear, not convex (Roering et al., 1999), like the hillslopes of the glaciated and unglaciated valleys shown in Figures 6b and 10, suggesting that similar models might apply in these cold regions.

The slopes on the stubby valley walls shown in Figure 10 average ~21°, the depths of the valleys are 100–200 m, and the regolith thickness is ~0.5 m. For these slopes, assuming that values of S_c and K found elsewhere apply, the model sediment flux q_s of $\sim 0.002\ m^2\ year^{-1}$

Glacial Geomorphology and Landforms Evolution, Figure 10 Mountain slopes of ~21° at ~2,250 m AMSL extensively modified by prolonged or repeated solifluction in an area of modern discontinuous permafrost in west central Mongolia (48.575° N, 97.225° E) south of Telmen Lake. Vehicles provide scale. Photograph by J. Batbaatar.



Glacial Geomorphology and Landforms Evolution, Figure 11 Sediment flux from hillslopes as a function of steepness for different soil diffusivities K and critical slopes S_c. bracketing those derived for the Coast Range in Oregon, USA (Table 1: Roering et al., 1999). For high values of S_c sediment production is closely approximated by linear Fickian diffusion.

would be sufficient to erode the entire volume of the valleys since ~200 ka. This is likely an overestimate, suggesting that the regolith has been frozen or inactive much of the time, such that K assumed above was too high or S_c was too low. However, low-diffusivity hillslopes should be convex. It may be that the steady-state sediment flux model may be overly simplified in this setting, as also suggested in general by Whipple (2001).

Nivation: Nivation represents a suite of processes that operate under and below snowfields that develop in the same place year after year. These processes include chemical weathering, creep, and erosion from meltwater flow from beneath the snowfield. Nivation operates in glaciated terrain, but it is not restricted to it.

The main effect of nivation is to create and remove fine sediments. Weathered particles are moved downslope by creep, solifluction, and rill wash. Over time, this leads to the formation of nivation hollows which, when enlarged, can be the beginnings of a cirque. Thorn (1976) reports headward erosion in nivation hollows of 0.0075 m year^{-1}. Maximum erosion requires complete seasonal meltout.

Icing: Icing ("aufeis" or "naled") accumulates during winter along stream and river valleys in arctic and subarctic environments, where it forms by extrusion of water into a freezing environment. It can reach thicknesses of several meters. The source of water may be springs or river water behind ice dams. Aufeis is commonly ephemeral, melting during the summer. As with nivation, aufeis may occur throughout the periglacial environment, but it is a common paraglacial process. For example, it may be found at the toes of glaciers in the winter, where subglacial water emerges into subzero temperatures.

Aufeis may block stream channels and cause their flood plains to widen as spring floodwaters are forced to flow around the ice (Harden et al., 1977). This may also lead to steep bedrock notches at the bottom of V-shaped river canyons. The depth of the notches is roughly the depth of the aufeis, unless the river is actively downcutting. In that case, the depth may be greater, on the order of 10 m.

The bedrock notches commonly show little or no sign of fluvial polishing. It may be that the aufeis serves mainly to hold meltwater between it and the developing notch, leading to enhanced freeze/thaw erosion and plucking of loose rock there.

Landscape-scale features

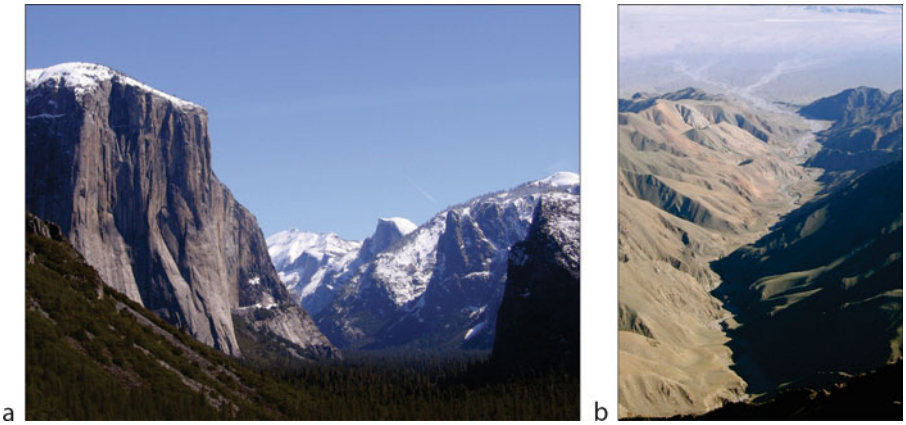
Above ("Fine-scale features"), some of the prominent effects of glaciers on their beds and immediate vicinities are described. At the coarser scale of landscapes, glaciers also have an impact. Although there is overlap in scale, it is helpful to view suites of the terrain elements, such as roches moutonnées, together with interspersed or adjacent unglaciated landforms such as ridges, as comprising the landscape.

Glaciated landscape is most obviously the work of warm-based glaciers, because they erode more rock quickly and supply larger fluxes of meltwater with which to transport sediments than to polar glaciers. In warm-based glaciers, there is liquid water at the ice/rock interface. Water enables sliding of the ice over the bedrock beneath the glacier, and consequent abrasion of the bedrock. It also enables meltwater erosion there. Although temperate glaciers commonly are warm-based, polythermal glaciers with large parts of cold ice may also have water at the ice/rock interface, and abrade the bedrock.

Glacial valleys and troughs: Perhaps the landscape signature most familiar to many is the straight, wide, parabolic or "U-shaped" valley. Figure 12a shows an example of one glacial trough, Yosemite Valley, viewed from a point just downriver of the late Pleistocene glacier. Near the terminus of the Pleistocene glaciers, as in Figure 12, Yosemite Valley is flat-floored instead of truly parabolic because of in-filling of sediment. The modern Merced River is underfit to the glaciated Yosemite Valley. In Yosemite, the steepening of the walls is enhanced by prominent master joints in the granite, making quarrying by glaciers easier.

Fluvial canyons, in contrast, are taken to have cross sections that are more nearly V-shaped although, as discussed above, the actual shape is determined in large part by hillslope processes that transport sediment from the hillslopes to the river. The contrast of the glacially eroded Yosemite Valley (Figure 12a) with a fluvially eroded canyon, in this case with linearly sloping sides, is shown by an example from the Gobi Desert in Figure 12b, but the same canyon cross section can also be seen in the unglaciated canyon of the Merced River west of the glacial terminus.

How does the glacier work on the landscape to transform a fluvial valley into a parabolic trough? The principal mechanism is the abrasion of the valley walls by the



Glacial Geomorphology and Landforms Evolution, Figure 12 Glaciated and unglaciated valleys. (**a**) Yosemite, California, USA, a "classical" U-shaped glacial trough of the Merced River. View is to the east, upriver. Glaciers of the last glacial maximum terminated in the foreground. The steep-sided bedrock walls are due to glacial erosion; the flat valley floor is due to filling of a glacially overdeepened basin that hosted a lake following glacial retreat. (**b**) An unglaciated valley on the northern flank of Ih Bogd, Gobi-Altai. Rapid uplift of the massif along the Gobi-Altai fault on the range front has led to recent incision at the bottom of the V-shaped canyon. The shape of the regolith-covered hillslopes is determined by mass-wasting processes such as debris flows and creep.

glacial ice, especially ice with entrained rocks that are dragged across the rock of the glacier bed. The abrasion is proportional to the ice velocity, which is not everywhere the same, but it also increases with the amount of debris content in the basal ice layer via the influence of friction on sliding (e.g., Schweizer and Iken, 1992). Quantitative models describe two endmember behaviors: one in which rock grains are completely encased by ice and are isolated from each other ("Hallet friction"), and one in which there are so many that they are in contact ("sandpaper friction"). A major difference is that in the former case, glacial sliding may be continuous, whereas in the latter it may be seasonal, stopping in winter when basal water pressure is low. Schweizer and Iken (1992) described the basal sliding velocity μ'_b for "sandpaper friction" by

$$u'_b \approx \left(\frac{\tau'_b}{P'_c - P'_s}\right)^n \; for\, P_{w_s} \le P'_s;$$
$$u'_b \approx \left(\frac{\tau'_b}{P'_c - P_w}\right)^n \; for\, P_{w_s} > P'_s \qquad (3)$$

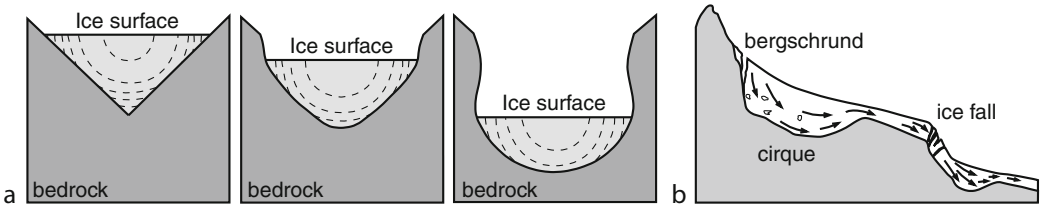
where τ'_b is the effective basal shear stress, P'_c is the critical pressure at which sliding becomes unstable, P_w is the water pressure, P'_s is the separation pressure necessary to lift the ice from the bed, n is a flow-law parameter (generally 3 or less), and primes ($'$) denote variables depending on friction. As long as $P_w < P'_c$ sliding will be continuous, but when $P_w > P'_c$ sliding will stop. Hallet et al. (1996) estimated that abrasion ranges from 0.01 to 10 mm year^{-1}.

As shown in Figure 13a, when clean ice fills a fluvial valley, the greatest ice velocity – and the greatest erosion – will occur midway up the glaciated sides of the valley. At first, erosion widens the valley more than it deepens it, and moves the locus of erosion farther down the valley walls. Ultimately the walls are steep, and the greatest effect of glacial erosion is then to deepen the valley. However, subglacial erosion proceeds not only from the abrasion by the ice itself, but also by subglacial meltwater flowing in channels under the ice. Meltwater within the glacier, or flowing along its base, can significantly modify the cross section of the glaciated valley, both by erosion of the walls and valley floor and by redistribution of upslope sediment. Strong basal flow can explain glacial erosion far below sea and lake levels (e.g., Zemp et al., 2005), and the sediment from the base of the glacier that occupied the Puget Sound in the northwestern USA was primarily evacuated by subglacial waters (Booth and Hallet, 1993).

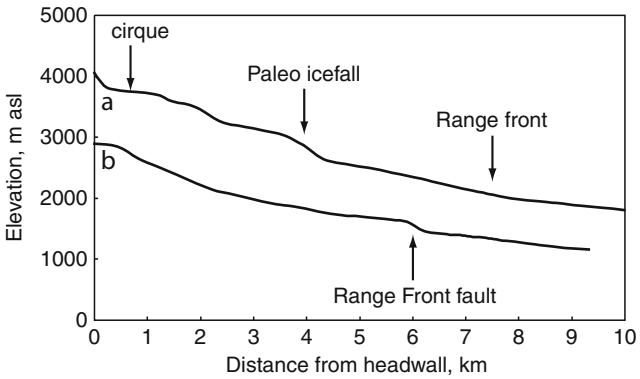
Glacial troughs flooded by sea water after glacial retreat, especially in mountainous terrain such as the west coast of Norway or Canada, are known as fjords (see entry *Fjords*). Their overdeepened basins store a significant fraction of the sediment produced by the glaciers (e.g., Cowan et al., 2010), which otherwise would have been transported onto the continental shelves.

The head of the glacier also modifies the landscape characteristically, ultimately producing a wide, steep-headed hollow or cirque, commonly overdeepened. Cirques enlarge laterally as well as deepening. Ultimately, cirques from opposite sides of a mountain meet, leaving only a thin septum (arête) between them. Peaks similarly are eroded into rocky spires or horns, as the three (or more) cirques they shelter enlarge.

Figure 13b depicts the long profile of a glacier in its cirque. Glaciers start when ice accumulates in the head of a fluvial canyon or in a nivation hollow. Modification of the cirque area begins when ice is deep enough to begin flowing. Glacier ice separates from firn at the headwall bergschrund, where blocks are incorporated into the glacier and transported away, steepening the headwall. Downward ice flow in the accumulation area further



Glacial Geomorphology and Landforms Evolution, Figure 13 Glacial erosion. (**a**) Schematic cross sections of a warm-based alpine glacier evolving over time from an initial V-shaped fluvial valley to a parabolic glacial trough (*left* to *right*). Dashed lines indicate loci of equal ice speed, decreasing from the inner part of the glacier to the contact with the walls. Erosion is proportional to ice speed; therefore, the middle parts of the glaciated valley wall are eroded most quickly at first. As the valley widens, the ice speed over the bottom increases and deepening quickens. After Harbor et al. (1988). (**b**) Schematic long profile of the upper reaches of an alpine glacier. The direction of ice flow is shown by arrows. Glacier ice separates from firn at the headwall bergschrund, where blocks are incorporated into the glacier and transported away, steepening the headwall. Downward ice flow in the accumulation area further erodes and overdeepens the cirque where the ice flow is redirected (*arrows*). Other overdeepened basins (*right*) occur downglacier, typically beneath ice falls or at the confluence of ice streams.



Glacial Geomorphology and Landforms Evolution, Figure 14 Long profiles of (**a**) glacially eroded and (**b**) fluvially eroded valleys (schematic). Lone Pine Creek (**a**) and Olancha Peak (**b**), Sierra Nevada, California (USA). Elevation data: Google Earth.

erodes and overdeepens the cirque where the ice flow is redirected (arrows in Figure 13b). Other overdeepened basins occur downglacier, typically beneath ice falls or at the confluence of ice streams.

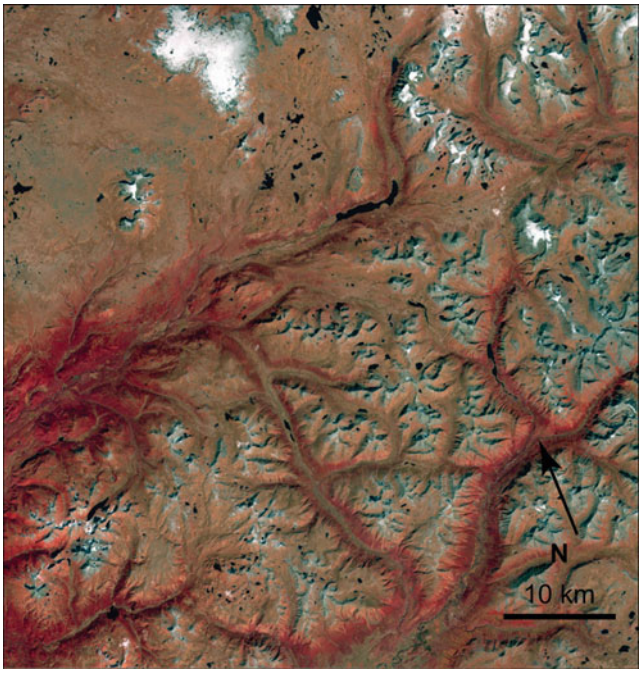
Overdeepened basins are a signature for glaciated valleys, although they are not ubiquitous in lightly glaciated regions. Their presence distinguishes glaciated valleys clearly from fluvial valleys. Figure 14 contrasts the long profiles of nearby glaciated and fluvial valleys from the Sierra Nevada (USA). After retreat of the glaciers, the basins are filled by lakes (strings of such lakes are called "paternoster" lakes (see entry *Paternoster Lakes*)). The lakes ultimately trap sediment and become meadows, but until they are filled they ensure that the only sediment transported by the river out of the mountains originates below the lowest step in the glaciated zone.

Ice caps and ice fields: During glaciations, plateaus above the ELA may become covered by ice caps. Valley glaciers themselves may overtop their ridges and coalesce, as is happening today on Mt. Rainier (Figure 4), for example, between the Winthrop Glacier and the Emmons Glacier (unlabelled in the figure) to its left. Figure 15 is a satellite image of a large area of the deglaciated Sayan mountains of Siberia (see entry *Altai-Sayan Glaciers*) that was covered by a large ice field at the end of the Pleistocene, perhaps ~15 ka.

Subglacial rivers and ice streams within the Sayan ice field eroded wide troughs in the bedrock as the ice field thickened and pressure melting caused the basal ice to slide over the bed. These are readily distinguished from the smaller, simple hanging valleys that once contained glaciers tributary to the ice streams. Ultimately, the troughs hosted outlet glaciers that reached beyond the edge of the ice field itself. The traces of such ice streams are locally anastomosing and reflect pressure gradients within the ice cap (i.e., rather than bedrock topography), and therefore appear to run uphill. Some are continuous across modern fluvial divides. In all this they differ dramatically from fluvial networks in unglaciated terrain and from simple drainages once occupied by individual, isolated glaciers. The complex, crossing traces of the abandoned glacial troughs, 2–4 km across, are obvious in the bottom right of Figure 15.

Because erosion of large subglacial troughs may be accomplished by pressurized subglacial fluvial flow (e.g., Piotrowski, 1997; Zemp et al., 2005), it is reasonable to ask what fraction of their erosion was fluvial and what fraction was due to glacial abrasion. In the Sayan mountains, the answer is uncertain, but there seem to be few subglacial channels cut within the trough valleys, and it is clear from moraines along their sides that at least some were occupied by debris-carrying glaciers.

In Figure 15 is a large complex valley trending northeast-southwest. This valley, nearly 8 km across, today hosts an underfit southwest-flowing stream. In its lower elevations (reddish because of increased vegetation cover) are numerous streamlined ridges and knobs, glacially sculpted. The broad valley also hosts smaller canyons with twisting paths, some of which start and end abruptly. These probably were cut by water flowing beneath the glacial ice.



Glacial Geomorphology and Landforms Evolution, Figure 15 NASA ASTER false-color image (vegetation is red) of the Sayan mountains on the Mongolian-Siberian border (52.2°N, 98.5°E), which were mantled by a large Pleistocene ice field. Ice streams within the Sayan ice cap eroded wide troughs in the bedrock that deepened to hoist outlet glaciers reaching beyond the edge of the ice cap itself. The traces of such ice streams may be anastomosing and reflect pressure gradients within the ice cap (i.e., rather than bedrock topography), and therefore appear to run uphill. Image is ~60 km across.

Only the highest terrain protruded from the Sayan ice field, and other ice fields like it, as nunataks. In Figure 15, these ridges appear sharp relative to the smoothed bed of the ancient ice field. Some of these nunataks are snow covered white in (Figure 15) and some are above tree line and appear bluish in the ASTER image, in contrast to the reddish-appearing vegetated slopes. The narrow arêtes and numerous well-developed cirques suggest a terrain heavily modified by glacial erosion.

Cryoplanation surfaces: Nunataks are common in terrain mantled by ice sheets; however, flattened terrain with tors or nunataks can also result from parallel slope erosion due to permafrost action (e.g., Washburn, 1979; Czudek, 1995) and nivation (Reger and Pewe, 1976), which causes mass wasting promoted by the presence of meltwater from permanent snow banks. Such surfaces are called cryoplanation surfaces or terraces. Cryoplanation proceeds in the absence of glacial cover, for example, between glaciations.

The next step in evolution of the glaciated landscape would be the complete erosion of the nunataks, leaving a nearly continuous ice field during glaciations and a smoothed, subdued bedrock topography during interglaciations. Such are terrain can be seen in the northwestern quadrant of Figure 15, in the vicinity of the single isolated nunatak.

A detailed view of an unusual nunatak of schist bedrock that emerged from a different ice field on the southern edge of Siberia is shown in Figure 16. The hanging valleys now filled by lakes are cirques that were occupied by small glaciers after the main ice cap melted. The trunk valley (leading down and to the right in the figure) has a complex long profile (similar to the one in Figure 14a) and bedrock hollows are now occupied by paternoster lakes. The high mountain center is the nunatak. Although its flanks have been sculpted by cirque glaciers, its top is a plateau, possibly a cryoplanation surface but little affected by glacial erosion.

The flanks of the nunatak consist of stepped subhorizontal terraces, themselves a kind of cryplanation terrace (e.g., Figure 9: Lauriol and Godbout, 1988). They are widely – but not ubiquitously – present where there were ice fields in the mountains of northern Central Asia (e.g., Figure 17). The stepped terraces shown in Figure 16 are of interest because they appear to record episodes in the thinning of the ice field (see entry *Thinning of Glaciers*) during deglaciation when freeze/thaw fracture of the exposed bedrock could occur (e.g., Komatsu et al., 2008). In general, however, stepped cryoplanation surfaces can also develop in the periglacial environment.

Loess: Many glaciers produce an abundance of silt-sized finely ground rock during the erosion of their beds, and this silt ("rock flour") is transported to their outwash plains ("sandurs") as long as the glaciers are active. It is this rock flour that colors glacial lakes light blue and green. After deposition with the outwash, this silt is available for aeolian transport and redeposition as loess.

This redeposition is one process by which the influence of glaciers can be felt over great distances. Glacial loess is found on the perimeter of the Laurentide Ice Sheet, in the Mississippi River valley and on the perimeter of the Fenno-Scandian Ice Sheet, for example, in northern Europe. The loess of the Ukranian steppes is as much as ~500 km from the edge of the ice sheet. Glacial loess is also found against smaller ice fields and systems of alpine valley glaciers.

Loess drapes the landscape, changing its form and character. Local drainage networks in loess can be trellised and intricate. Loess deposits hold cliffs especially well, and people have carved houses into them. Loess provides a large surface area of fresh rock, which can weather quickly to provide nutrients for vegetation. However, the organic content is negligible and it therefore takes thousands of years to develop good soils for agriculture. As it erodes, loess can choke river systems, leading to braided channels and rapidly growing deltas, far from the source glaciers.

Not all loess is glacial. The association of loess with warm deserts and drylands has caused some of these deposits to be called "desert loess," and the silt from these

Glacial Geomorphology and Landforms Evolution, Figure 16 Deglaciated terrain near the edge of a former Pleistocene ice cap of the Ulaan Taiga mountains, northern Mongolia (51.43°N, 99.88°E). View is to the south; the central mountain is ~5 km across. Vertical exaggeration: 3×. Image courtesy of Google Earth.

may be created by mechanical weathering of sands caused when the sand grains strike each other and break during wind transport (e.g., Whalley et al., 1982).

Some loess deposits, such as the famous ones of the Loess Plateau in China, are regarded as desert loess because they are downwind from huge sand sheets and dune fields. However, in the source regions of the Taklimakan desert of central Asia, silts are also produced glacially in the high mountains rimming the desert, and the outwash has also provided at least some of the desert sands from which silt is created. Thus, some desert loess may be in part glacial in origin.

Lakes: During and after glacial retreat, one of the main processes of landscape modification is the impounding of water in lakes. The impounding occurs at all scales. As viewed from space, the most obvious of the glacial lakes are the five Great Lakes – Superior, Michigan, Huron, Erie, and Ontario – of North America. These lakes occupy tectonic basins deepened by the Laurentide Ice Sheet. Together, they cover more than 245,000 km^2 and contain a fifth of all the unfrozen fresh water in the world. However, during the retreat of the Laurentide Ice Sheet, much of central Canada was covered by glacial Lake Agassiz. Although largely drained today, at its peak Lake Agassiz covered over 350,000 km^2 and contained half again as much water as the modern Great Lakes.

The effect of glaciocenic lakes was threefold. When they were filled, they acted as sediment traps for glaciogenic silt. Upon their draining, this silt remained behind and – as in the loess belts – formed a rich soil. The lakes also modified the local climate directly, by the "lake effect" in which water was evaporated from the lakes and precipitated downwind. In the case of such large lakes as Lake Agassiz (~600 km diameter), the scale of the lake effect must have been roughly comparable to the scale of cyclonic storms. Lakes also reversed drainages, sending water once bound for one ocean to another. Several examples come from northern Europe, where the Finno-Scandian Ice Sheet impounded north-flowing rivers forming lakes that deepened and finally overflowed down south-flowing rivers such as the Volga until the water flowed south (Arkhipov et al., 1995). Similarly, the Great Lakes once drained down the Mississippi River to the Gulf of Mexico, only switching to the St. Lawrence River and the North Atlantic with the collapse of the Laurentide Ice Sheet. This switching of large volumes of freshwater is thought to have triggered a major climate excursion at the end of the last deglaciation (Rooth, 1982; Broecker et al., 1989).

Not only are large lakes impounded glacially, but numberless smaller ones, too. Often these are in a setting with higher relief, and these lakes are prone to sudden draining. The resulting outburst floods can modify landscape far from the glaciers themselves.

Outburst floods (see entry *Glacier Lake Outburst Floods*): Outburst floods (e.g., O'Connor and Baker, 1992; Komatsu et al., 2008) are among the most dramatic and transformative of the paraglacial processing modifying landscapes. Although they originate near glaciers, they affect not only the near field, but also cause erosion and deposition far from their source.

Outburst floods are of two main kinds: those originating as meltwater stored within glaciers and those from lakes impounded by glaciers. Meltwater can be trapped

in crevasses or thermokarst ponds, and between glaciers and valley walls. Sooner or later, this water escapes subglacially, or as an ice-marginal river. Water can also accumulate in subglacial lakes. It may originate as ice melted by volcanic heat, or simply by pressure melting as the burden of ice above it increases in thickness. Sudden floods erupting from underneath glaciers are called jökulhlaups.

Lakes are also created by glaciers advancing down tributary canyons, damming rivers. The giant Missoula Floods across the state of Washington (USA) are an example (Bretz, 1923). The impounded lake was 2,220 km^3 in volume. It apparently drained catastrophically and refilled more than 40 times between 23 ka and the final retreat of the Cordilleran Ice Sheet in North America (Waitt 1985; Benito and O'Connor, 2003). More than 25 floods had discharges ranging from 10^6 to 10^7 m^3 s^{-1}, and the advancing wall of floodwater where the Columbia passes through the Cascade Mountains was as high as ~200 m. In sum, more than 200 km^3 of rock was eroded in flows exceeding 30 m s^{-1} and deposited downstream as far as the Pacific Ocean. Floods on this scale are transformative events at the landscape scale that widely scour the landscape of soil, widely erode bedrock, and cut new river channels.

Geochronology

Dating is the way we correlate spatially separated landforms and deposits, and the way we link glacial history to global and other records of climate, for example, to the climate and sea-level proxy of Figure 1. There are many techniques that are used to determine the age of deposits in glaciated terrain, such as optically stimulated luminescence and radiocarbon. In geomorphic studies, it is often as important to learn something of the dynamic behavior of landforms as it is to learn their age. The standard approach is to obtain dates in a deposit, from which an age–depth curve can be constructed. The slope of the curve gives depositional rates over time, but the depositional age of the material currently at surface is only a maximum age for the surface itself, since it might be eroding. Furthermore, unless the actual time at which deposition ceased can be established, estimating the rate of erosion is not feasible. Analysis of rock surfaces is likewise difficult and indirect.

Below, one approach that can be used to date the age of eroded surfaces and moraines and other depositional landforms, and also to measure erosion rates directly is briefly reviewed. The approach is based on the concentration of rare nuclides produced by the interaction of cosmic neutrons with atmospheric and earth materials. ^{14}C is one such nuclide, produced in the atmosphere and incorporated in living matter until death, after which concentrations decrease at a constant rate due to radioactive decay. The equation describing the concentration of cosmogenic nuclides such as ^{14}C is

$$N = \frac{N_o}{\lambda} e^{-\lambda t}; \quad \lambda = \frac{\ln(2)}{t_{1/2}} \tag{4}$$

where N is the concentration of the cosmogenic nuclide (e.g., ^{14}C) (atoms g^{-1}), N_o is the concentration at death of the organism, P is the production rate (atoms g^{-1} $year^{-1}$), λ is the decay constant for the radioactive nuclide ($year^{-1}$), t is time elapsed since exposure (year), and $t_{½}$ is the half-life of the nuclide. For ^{14}C, $t_{½} = 5{,}730$ year and $\lambda = 0.000121$ $year^{-1}$. The age can be estimated via inversion of Equation 4 since there is one unknown, t, and one measurement, N.

Other cosmogenic nuclides are produced by exposure of minerals to cosmic rays, for example, ^{10}Be from the silicon in quartz. In this case, the rock absorbs the neutrons such that the production of the cosmogenic nuclides decreases exponentially with depth below the free surface. For eroding surfaces, the growth equation is thus complicated by inclusion of factors describing the shielding and the erosion of the surface since exposure, since erosion will reduce the concentration N of the nuclide available to measure:

$$N = \frac{P}{\left(\rho\varepsilon\Lambda^{-1} + \lambda\right)}\left(1 - e^{-(\rho\varepsilon\Lambda^{-1}+\lambda)t}\right) \tag{5}$$

where ρ is the mineral density (g cm^{-3}), ε is the erosion rate (cm $year^{-1}$), and Λ is an attenuation coefficient (g cm^{-2}) that describes the absorption of neutrons. The exposure age t for a surface sample is calculated from the measured isotope abundance (N) after a correction has been made for radiogenic and geologic background concentrations not shown in (Equation 6) and the decay of the nuclide if it is unstable (Lal, 1988).

For ^{10}Be, $t_{½} = 1.6 \times 10^9$ year ($\lambda = 4.56 \times 10^{-7}$ $year^{-1}$) such that meaningful ages could be found for surfaces hundreds of thousands of years old. However, over most of the Earth erosion is great enough that it precludes simple calculation of age for surfaces older than ~50,000 years. For the geomorphologist, Equation 5 presents an opportunity to measure long-term landscape denudation rates (Bierman, 1994) because, for constant erosion, Equation 5 asymptotically approaches an equilibrium limit between nuclide production, decay, and surface erosion. This can be seen by substituting $t = \infty$ into Equation 6, which then reduces to

$$N = \frac{P}{\left(\rho\varepsilon\Lambda^{-1} + \lambda\right)} \tag{6}$$

from which the erosion rate can be calculated.

The opportunity to measure ε provides the geomorphologist with the opportunity to determine denudation rates for landscape elements for which rates previously had to be inferred less directly. In a study of old landscapes in Namibia, for example, Bierman and Caffee (2001) determined that the surface there was lowering at 3.2 ± 1.5–3.6 ± 1.9 μm $year^{-1}$, consistent in a general way with independent measurements.

Equation 5 is underdetermined, with two unknowns (ε and t) for each measurement (N). By measuring two

nuclides with different decay constants, for instance ^{26}Al and ^{10}Be, from the same sample, it is possible to balance the number of knowns and unknowns, and solve for both ε and t. With the improvements in analytic precision of the past decade, this approach has potential in the analysis of rapidly eroding, youthful terrains, for which it the erosion rate cannot be assumed, and the age is less than several half-lives (e.g., Gillespie and Bierman, 1995).

Concluding comments

Glaciers are powerful forces that have shaped and reshaped a significant fraction of the land surface of Earth during the Quaternary Period, since 2.6 Ma. They occur as high-altitude alpine glaciers even at low latitudes, and as continental-scale ice sheets at high latitudes. Glaciers modify the landscape in characteristic ways by erosion in their upper reaches, and deposition near and below their toes. Glaciers also promote the activity of other powerful forces acting on the landscape, for example, outburst floods.

The overall effect of glaciers on landscapes depends on the amount of time the landscape has been glaciated, and the intensity of competing effects such as tectonism. However, the first stages of alpine glaciation tend to increase terrain relief and straighten and widen glaciated drainages. In the limit, terrain is subdued as the mountain horns and arêtes and other relict terrain features are encroached on by cirques and widening valleys from all sides. Under the limits of former ice fields and sheets, especially at high latitudes, deglaciated terrain is commonly subdued.

Glacial geomorphology is the study of landforms in and around glaciated terrain and the processes of deposition and erosion that create and modify them. The study of these landforms and processes addresses the complex response of the Earth system to climate at the high elevations and latitudes that have experienced glaciation today or in the past.

The motivation for studying glacial geomorphology has changed since it began. Originally, the main goal was to understand in a general way how the landscape came to be the way we found it, and in doing this taxonomic classification was a big early step. Later, analysis shifted in favor of quantitative mathematical models that were based on physically meaningful equations, with values for coefficients empirically determined from field study. Especially for studying vanished ice sheets and glaciers, that could not be inspected directly, the mapping of glacial geomorphologic traces has been of great value for such parameterization and numerical model simulation.

In the context of recent concerns about climate change and the role human activity has had in causing it, glacial geomorphology is important because it is a record of the "natural" climate baseline – the way the Earth's climate system has behaved in the past before the effects of industry, and within what limits. Without this baseline, it is hard to assess the significance of the changes that are occurring today. The predictive forward models discussed in the paragraph above are now called on in a different way, to help with the inference of the past conditions that led to the creation of the evidence. The quantitative models are necessarily simplifications of the "real world" and this model inversion is difficult to the extent that quantitative modeling has not captured the whole picture.

Thus a major challenge lies in inversion of the process models that describe the advance of glaciers in terms of climatic parameters – summer temperatures and cloudiness, and winter precipitation. This inversion is inherently an underdetermined problem: there are too many unknowns and too few meaningful measurements to allow an unambiguous estimation of, for example, paleo precipitation from reconstructed ELAs. Nevertheless, in concert with other investigative approaches – palynology, for example – it is often possible to constrain paleo conditions in a useful way.

The geomorphic record is characterized by spatial detail – today there are 6,000 glaciers in Kyrgyzstan alone – but the record is often incomplete. Early glacial deposits, for example, are often obliterated by later, larger glaciers. In contrast, extracting sediment and ice cores can give a rich and detailed temporal record, but it is expensive and time consuming, and therefore it is hard to capture spatial heterogeneity. The combination of multiple complementary approaches is necessary to tell the whole story.

GLACIAL GROOVES

D. P. Dobhal
Wadia Institute of Himalayan Geology, Dehradun, India

A linear depression, centimeters to meters in length, produced by the removal of rock or sediment by erosive action of a glacier is termed as a glacial groove. Glacial grooves or shallow holes on the bed rock illustrate the movement of the sediment-loaded base of the glacier. Large amounts of coarse gravel and boulders carried along underneath the glacier provide the abrasive power to cut the grooves in the bed rock. This glacial feature is a useful indicator to evaluate the patterns, mass, volume, force/energy of former glacier flow.

GLACIAL OVERDEEPENING

Christopher Lloyd
Department of Geography, University of Sheffield, Sheffield, UK

Definition

Overdeepening. The excavation of the subglacial landscape by the processes of glacial erosion to a level below that which would be expected by other processes. The term is also commonly used to refer to the overdeepened cirques or troughs produced by such processes.

The distinguishing feature of a "true" overdeepening is the adverse slope that forms the lip of the basin or cirque (cirques are further characterized by a steep headwall). Such overdeepenings are characteristic features of almost all formerly glaciated landscapes, where they typically form deep lakes that may become filled with sediment over time. They are commonly found in locations such as cirques and troughs where patterns of ice flow have acted to focus glacial erosion; however, the ability of surface melt to access the glacier bed is also important for maintaining the processes of quarrying and basal sediment evacuation that allow the overdeepening to develop (Hooke, 1991; Alley et al., 2003). Theoretical analysis indicates that moulins and crevasses that form at the upglacier end of the overdeepening will focus water input and hence quarrying toward the head of the overdeepening, resulting in a longitudinal profile that is asymmetrical (Hooke, 1991). Overdeepenings may also be associated with the exploitation by glacial erosion of jointed lithologies.

The idea that valleys could be overdeepened by glacial erosion was first advanced by geographer Henry Gannett in his description of Lake Chelan (Washington State, USA) for the National Geographic magazine (Gannett, 1898). The following year, Albrecht Penck independently reached the same conclusion while studying the Bavarian Alps (see Davis, 1909). Interest in overdeepenings waned until the latter half of the twentieth century, when further descriptive accounts (e.g., Holtedahl, 1967) were followed by largely morphometric investigations (e.g., Aniya and Welch, 1981). Only later did work begin to focus on the importance of "true" overdeepenings in glacial systems (e.g., Rothlisberger and Lang, 1987; Lawson et al., 1998; Alley et al., 2003). Recently, there have been efforts to numerically simulate the evolution of the entire glacial longitudinal profile, including the phenomenon of overdeepenings (e.g., MacGregor et al, 2000; MacGregor et al, 2009). Nevertheless, overdeepenings remain largely a neglected area of academic study.

GLACIAL STRIATIONS

D. P. Dobhal
Wadia Institute of Himalayan Geology, Dehradun, India

Glacial striations are scratches on the bedrock created by the process of glacial abrasion. Glacial striations usually occur as multiple straight parallel lines, some time scour and polish the bedrock representing the flow direction of the former glacier level. Large amount of area vacated by glaciers due to melting leave behind such features indicating the last glacier maxima that include mass, volume, and energy of glacier flow of the former glaciers.

GLACIAL TROUGH

D. P. Dobhal
Wadia Institute of Himalayan Geology, Dehradun, India

The glacial trough is also called "U" shaped valley, relatively straight, flat-bottomed, deeper, and steep-sided valley formed by glacial erosion (Figure 1). Originally the valley would have in existence as stream/river valley prior to occupation by a glacier. But, after glacier occupies the valley, it modifies it and gives rise to characteristic features that are preserved and can be recognized even after the disappearance of the glacier (deglaciation) and used as a tool for evaluation of past glacier history in terms of existing, paleo-climatic studies. Important features of a glacial trough are as follows:

- A characteristic feature of mountain glaciations: these glacial troughs may be several hundred meters deep and tens of kilometers long.
- Within a glacial trough, several erosional and deposinal features are preserved.
- The main processes involved in the formation of glacial trough are abrasion and plucking.

GLACIAL/INTERGLACIAL CYCLES

Michel Crucifix
Georges Lemaitre Centre for Earth and Climate Research, Université catholique de Louvain, Louvain-la-Neuve, Belgium

Definition

Major waxing–waning cycles of large continental ice sheets in the Northern Hemisphere that characterized the late Pliocene and the Pleistocene Epoch since about 2.7 million years (Myr) ago. By extension, all expressions of environmental changes, including variations in greenhouse gases and ocean circulation that are associated with glacial cycles.

Glacial Trough, Figure 1 Broad view of "U" shaped glaciated valley (Glacial trough), Central Himalaya, India (Photo: Dobhal).

Discovery

The first detailed reports of Alpine Moraine, erratic boulders and "Roches Moutonnees" appear in field reports of the Swiss naturalist H.-B. de Saussure (1779–1796). (For brevity, the most ancient references are not listed in the bibliography list. Well-documented historical accounts are available in Imbrie and Imbrie (1979), Berger (1988), and Bard (2004).) John Playfair (1815) and K. Schimper (1837) (Ice Age) understood that their presence is due to the movement of glaciers, but this is not until Ignace Venetz (1833), Jean de Charpentier (1841) – both inspired by mountain guide J.P. Perraudin – and finally Louis Agassiz (1840) that the *glacial theory* was formulated, according to which ice once extended well outside the Alps. Independently, Esmark (1827) had reached the conclusion that ice once covered the major part of Norway. (cf. also Terraces). Later, Venetz (1861) and, independently, Archibald Geikie (1863) in Scotland concluded that sustained intervals of warm climate intervened between different ice ages. Parallel to these European discoveries, T.C. Chamberlain (1877–1886) and F. Leverett (1897–1935) systematically mapped the moraines of the USA and developed a classification supporting four previous ice ages: Nebraskan (oldest), Kansan, Illinoian, and Wisconsinian (youngest). On the other hand, Penk and Brückner (1909) identified four past Alpine fluvial erosion layers, which they interpreted as the indices of four Alpine glaciations named in alphabetical order according to river valley names: the Günz (oldest), the Mindel, the Riss, and the Würm. This stratigraphical model, used as a reference by W. Köppen and M. Milankovitch to affirm their astronomical theory of glaciations (Explicative Models), was later shown to be partly incorrect (Kukla, 1975).

The first continuous environmental records of the Pleistocene climatic cycles were obtained from sediments sampled in the deep ocean. These sediments are essentially composed of small calcite-shell organisms called foraminifera. Emiliani (1955) proposed a stratigraphic scheme still used today, based on the succession of minima and maxima in the oxygen-18/oxygen-16 isotopic ratio of foraminifera tests sampled from a Caribbean deep-sea core. Isotopic events were numbered from 1 to 16, starting from the most recent. Even numbers represent glacial peaks, the last glacial maximum corresponding to marine isotopic stage 2, and odd numbers point to interglacials. The present interglacial is marine isotopic stage 1. Shackleton (1967) showed that these isotopic fluctuations primarily reflect the effect of the changes in continental ice volume on the isotopic composition of water, although this interpretation was called into question in a later article (Shackleton, 2000) (Isotopic Characteristics of Ice, Snow, and Glaciers and Oxygen Isotopes).

The first reliable estimates of the *timing of glaciations* were permitted by the identification of the Brünhes–Matuyama magnetic reversal in deep-sea cores (–730 kyr, i.e. –730,000 years) and radiocarbon dating of the more recent tests. The latest four glacial–interglacial cycles were found to be roughly 100-kyr long, with glacial buildup taking about five times as long as deglaciation (Broecker and van Donk, 1970). The latter phase was termed "termination" (Broecker and van Donk, 1970; Kukla and Cilek, 1996). Higher-resolution records (Hays et al., 1976) indicated the presence of shorter climatic cycles with periods matching those of the astronomical parameters of precession and obliquity (Berger, 1977). A number of synthetic isotopic records have then been constructed by averaging ("stacking") different marine records. One currently used reference is the LR04 stack combining data from 57 benthic formanifera records dating back to up to 5 Myr (Lisiecki and Raymo, 2005).

Meanwhile, glacial cycles have been indicated in a myriad of paleoenvironmental indicators, just to cite a few: in the succession of paleosols and wind-blown sediments (loess) in China (Liu and Chang, 1964) and Eastern Europe (Kukla, 1975); in indicators of the surface and deep-ocean circulations of the Atlantic (Ruddiman and McIntyre, 1979; Raymo et al., 1989); and in greenhouse gas concentrations, dust, chemical tracers, and isotopic indicators sampled in Antarctica (Petit et al., 1999; Luethi et al., 2008). In particular, the atmospheric concentration in CO_2 oscillated between extremes of 172 parts per million (ppm) at stage 16 and 299 ppm at stage 7 (Luethi et al., 2008) (see *Palaeoclimate and Past Glaciations* for further details about the reconstruction and modeling of glaciers).

Phenomenology

General trends

The current marine isotopic stratigraphy includes 104 *marine oxygen isotopic stages* down to the Gauss magnetic boundary (−2.6 Myr), plus another 112 events numbered according to magnetic polarity, down to the Gilbert magnetic polarity zone, about −5.8 Myr (Shackleton, 1995).

The first major glaciation of the Northern Hemisphere is considered to be marine isotopic stage 100 (−2.5 Myr) (Quaternary Glaciation). This event, early identified as the first major marine oxygen isotopic excursion (Shackleton and Opdyke, 1976), also corresponds to the first major influx of ice-rafted detritus detected in North Atlantic sediments (Shackleton and Hall, 1984; Raymo et al., 1989). Since that period, the marine isotope record indicates an overall increase in amplitude and duration of glacial–interglacial cycles. Near –800 kyr, the glacial–interglacial oscillations shift from a 40-kyr symmetric oscillation to a sawtooth-shaped, 100-kyr cycle (Pisias and Moore, 1981; Ruddiman et al., 1986). This is the mid-Pleistocene transition. The mathematical characterization, timing and the attribution of this transition, remains an open problem (Clark et al., 2006; Lisiecki and Raymo, 2007). Lisiecki and Raymo (2007) suggest –1.4 Myr as the time at which the climate response shifted from a linear regime to a nonlinear one, compatible with the pacemaker theory (Explanations of the 100-kyr periodicity).

The ice-core record (Ice Core) from Dome C, Antarctica (EPICA community members, 2004; Luethi et al., 2008) confirms the significance of another transition near −400 kyr referred to as the mid-Brünhes transition. This event marks the strengthening of the asymmetric character of glacial-interglacial cycles (slow glacial buildup and abrupt termination) and a sudden increase in the greenhouse gases concentrations and Antarctic temperature of interglacial periods.

Sea level

Dated coral terraces and other shoreline geomorphological evidence are used to infer past changes in local sea levels. Their conversion into a global eustatic sea level (a measure of the total amount of ice accumulated on the continents) requires accounting for isostatic and gravitational effects by means of numerical models (Peltier, 1976; Marshall et al., 2002; Yokoyama et al., 2001; Peltier, 2004). The current consensus points to a Last Glacial Maximum eustatic sea level 125–140 m lower than today. This corresponds to about 50×10^6 km^3 of ice, two-thirds of which was located in the North American ice sheet.

Uncertainties in tectonic movements and the erasure of successive glacial terraces make it difficult to find direct sea-level evidence prior to stage 5. Sea-level estimates before that time rely on marine isotopic evidence, possibly complemented by air oxygen isotopic data available in the ice-core record. Fairly sophisticated inverse methods to infer past ice mass from the marine isotopic signal were developed (Bintanja et al., 2005). So far all evidence points to sea-level high stands similar to today ±20 m during the latest four interglacial periods (stages 1, 5, 7, and 9), and low stands of amplitude similar to the last glacial maximum at stages 6, 12, and 16 (Sea-Level).

Power spectrum

Estimating the power spectrum of continental ice-volume variations is a particularly difficult task, given the indirect character of ice-volume evidence (Sea-Level), in-situ perturbations of the sediment and dating uncertainties.

Hays et al. (1976) first observed in ocean records of the late Pleistocene the presence of harmonics matching the orbital periods of 41 (obliquity), 19, and 23 kyr (precession) calculated by Berger (1978). The influence of orbital variations on climate is now indisputable, but the *fraction* of climate change driven by the orbital forcing as well as the identification of the dominant mechanisms are still subjects of debate.

Variance related to the 40-kyr obliquity component clearly dominates the marine oxygen isotope record before the mid-Pleistocene transition (Pisias and Moore, 1981; Lisiecki and Raymo, 2007). After the mid-Pleistocene transition, the 40-kyr variance is still larger than the 20-kyr variance, both in the marine and the Antarctic ice-core records (Mudelsee et al. 2009), but these oscillations are topped by a 100-kyr sawtooth-shaped signal, characteristic of glacial–interglacial cycles.

It was also noted that the fraction of the oxygen isotope record linearly related to orbital variations during the late Pleistocene does not exceed 25% (Kominz and Pisias, 1979) or even 15% (Wunsch, 2003). The power spectrum of the *background noise* corresponds to that of red noise, with a plateau at periods over 100 kyr, and power decreasing almost with the square of the frequency at shorter periods (Kominz and Pisias, 1979; Pelletier, 1997; Huybers and Curry, 2006). Higher-frequency harmonics of periods between 5 and 11 kyr were found in ocean (Pestiaux et al., 1988) and ice-core records (Yiou et al., 1994). They were interpreted as upper harmonics of orbital frequencies excited by nonlinear interactions in the climate system.

Empirical investigation of causal mechanisms

Orbital pacing of terminations

There is statistical evidence that the timing of terminations is controlled by orbital elements. The phase of precession (Raymo, 1997) and obliquity (Huybers and Wunsch, 2004; Huybers, 2007) at the time of major terminations is generally consistent with the Milankovitch hypothesis according to which high summer insolation favors deglaciation (Explicative Models).

Inspection of leads and lags

The analysis of the chronology in the variations of different paleoclimate indicators, such as carbon dioxide, marine oxygen isotopes, and polar temperature proxies requires both a critical analysis of timing assumptions (taking care of avoiding circular reasonings) and state-of-the art time-series analysis methods suited to account for dating uncertainties.

There is firm evidence that the Antarctic deuterium record, which is a proxy for temperature in the Antarctic and over the Southern Oceans, *lead*s the CO_2 variations by about 1 kyr (Mudelsee, 2001). This observation suggests a control of the Southern Hemisphere on atmospheric carbon dioxide concentrations. The relationship between CO_2 and ice volume (or, equivalently, sea level) is more complex. On average over the last 400,000 years, CO_2 tends to lead ice volume (Mudelsee, 2001). The lead is robust over the latest four deglacial terminations (Hargreaves and Abe-Ouchi, 2003) and ranges between 1 and 4 kyr. By contrast, when global ice volume increased from its minimum after termination II, atmospheric CO_2 remained at a high level for about 8 kyr (Mudelsee, 2001).

Since the "Spectral Mapping" (Specmap) project (e.g., Imbrie et al., 1993), a common practice has been to filter paleoclimate time series in the different orbital bands (20, 40, and 100 kyr) and to inspect leads and lags independently in these different bands in order to learn about causal mechanisms. A recent review suggests that CO_2 leads ice-volume variations in the precession (20 kyr) band, while these two quantities are in-phase in the obliquity (40 kyr) band (Ruddiman, 2006). The result yields a conceptual model in which CO_2 responds independently

to precession *and* to ice-volume growth, and ice volume responds to precession, obliquity, and greenhouse gases. Ocean circulation patterns, as reconstructed from $\delta^{13}C$ of foraminifera, have differentiated responses to changes in precession and obliquity (Lisiecki et al., 2008).

Investigations based on filtering methods introduced above suggest a stable phase relationship between orbital eccentricity and climate at the eccentricity period (Imbrie et al., 1984; Raymo, 1997; Shackleton, 2000; Lisiecki et al., 2008). However, this result is difficult to prove rigorously, because the instantaneous phase of eccentricity has no unambiguous meaning in the mathematical sense.

Other time-series analysis

A range of more specialized nonlinear techniques were also applied, such as correlation dimension estimates (Nicolis and Nicolis, 1986; Mudelsee and Statteger, 1994), bicoherence spectra (Hagelberg et al., 1991), or detrended fluctuation analysis (Ashkenazy et al., 2003). Taking advantage of such techniques in the paleoclimate context is not trivial, in part because of the noisy, nonstationary characters of paleoclimate time series and of adverse effects of age uncertainties and sediment mixing.

Continuous or discrete wavelet transforms may constitute an avenue for further investigations, because they are more suited to analyze nonstationary and modulated signals.

Origin of ice ages

History

Joseph Adhémar (1842) formulated the conjecture that the precession of Earth's orbit caused ice ages, because of its effects on the seasonal distribution of incoming solar radiation (insolation). He realized that one season had to be critical given that the changes in winter and summer insolation caused by precession cancel each other (Herschell, 1830). James Croll (1875) further developed the theory and appreciated the importance of the three Earth orbital elements determining insolation: eccentricity, obliquity (angle between the equator and the ecliptic), and the longitude of the perihelion.

Milutin Milankovitch (1920, 1941) is quoted as the first one to have established a self-contained mathematical theory linking orbital elements to insolation and insolation to climate changes. On a suggestion of V. Köppen, he calculated the secular evolution of the summer radiation of the northern latitude (published in Köppen and Wegener, 1925), following the hypothesis that glacial cycles are driven by the effects of changes in summer insolation on snow ablation rate during this season (the conjecture had in fact been earlier expressed by Murphy, 1876, and it contradicted Croll's views). Summer insolation is largest when obliquity is large and/or when summer in the Northern Hemisphere corresponds to the time of perihelion passing. Milankovitch later substantiated the hypothesis by explicitly calculating the effects of radiation changes on the position of the snow line.

By the mid-seventies, the Earth's orbital parameters were known over the last million years to a good accuracy, thanks to the work of several generations of astronomers who based themselves on foundations lain by Laplace and Le Verrier. A decisive step was made by Berger (1978), who expressed in an analytical form the Fourier decomposition of the Earth's orbital parameters relevant for the astronomical theory of paleoclimates. This work constitutes the first demonstration that the spectrum of climatic precession is dominated by periods of 19, 22, and 24 kyr, that of obliquity, by a period 41 kyr, and eccentricity has periods of 400, 125, and 96 kyr. The most accurate solution to date is the La04 (Laskar et al., 2004).

Explanations of the 100-kyr periodicity

The correspondence between the periods found in marine records and astronomical calculations confirmed the existence of an influence of orbital elements on climate. At the same time, the discovery that late Pleistocene glacial cycles are dominated by a 100-kyr cycle constituted a challenge to Milankovitch's theory. Several models were therefore proposed to address this issue.

Quasi-linear forcing by insolation

In this approach, the climate system is effectively *driven* by insolation, but the relationship between insolation and ice growth or melt rate is nonlinear. One much-cited example is the simple dynamical system proposed by Imbrie and Imbrie (1980).

The nonlinearity embedded in this model effectively rectifies the precession signal, which causes a 100-kyr climatic cycle, at the cost of also causing a strong 400-kyr component in the modeled ice-volume time series that is not detected in paleoclimate records.

It was also observed that the fact that both obliquity and precession matter for the timing of glaciation implies that the time between terminations must approximately correspond to an integer number of precession cycles (Raymo, 1997) or both precession and obliquity cycles (Ruddiman, 2006). This idea leads to the concept of the "quantum nature" of glacial cycles, which is used to explain the 80–120 kyr duration of the late Pleistocene ice ages.

The major weakness of these models is that they do not easily explain the massive deglaciation that occurred 400 kyr ago (also called termination IV), a time at which precessional effects were minimal.

Models with instability at high ice volume

These models suppose that climate responds continuously to changes in insolation but there is a background tendency for ice growth. Instability mechanisms are activated when the continental ice volume is too large, causing the rapid collapse of ice sheets characteristic of terminations. This explanation of the 100-kyr cycle has been proposed under different forms including models inferred from

physical principles (Pollard, 1983), more abstract dynamical systems using threshold functions (Paillard, 1998), and more descriptive, empirical conceptual models (Imbrie et al., 1993). One possible instability mechanism is enhanced ice calving under depleted bedrock conditions (Pollard, 1983; Hyde and Peltier, 1987), but other mechanisms were proposed, for example, related to the effects of sea level on deep-water formation and/or carbon-cycle dynamics (Paillard and Parrenin, 2004). Such models claim to successfully explain termination IV.

Self-sustained oscillations (pacemaker)

The 100-kyr cycle may also be explained to some degree as a self-sustained cycle caused by dynamical, nonlinear interactions between the components of the climate system. The existence of runaway feedbacks (implying unstable, multiple equilibria) is now essential. An early attempt is the ice-bedrock model by Oerlemans (1980), but this required an unrealistic isostatic response time. Other models featuring a limit cycle were formulated, notably the ice-sheet–carbon-cycle–ocean models by Saltzman and colleagues (Saltzman et al., 1984; Saltzman and Verbitsky, 1993) and the sea-ice switch model by Gildor and Tziperman (2000). One interesting aspect of such models is that they explain the orbital pacing of terminations through the phenomenon of nonlinear phase locking, well known in dynamical system theory. This is generally referred to as the *pacemaker model*: glacial cycles would occur spontaneously, but the presence of orbital forcing controls the timings of termination and glacial inception (Tziperman et al., 2006).

Nonlinear resonance

The 100-kyr signal appears here as a combination of tones associated with the precession beating (1/109 = 1/23 – 1/19). The idea was proposed by Berger (1977), but formalized as a plausible atmosphere–ice-sheet model by Le Treut and Ghil (1983). For nonlinear resonance to occur, the climate response to orbital forcing must be strongly nonlinear, and this feature is not easily reconciled with the red-noise background of the ocean record. By contrast, it naturally explains the presence of upper harmonics observed in certain paleoclimate records (Power Spectrum).

Several of the above models disagree somewhat with the Milankovitch theory according to which summer insolation controls climate change through its action on the Ice Sheet Mass Balance. For example, Le Treut and Ghil (1983) and Gildor and Tziperman (2000) emphasize the effects of increased snow accumulation on ice sheets with increasing temperatures. Models assuming differentiated effects of precession and obliquity on the ice – carbon-cycle system, have been expressed at the conceptual level (Ruddiman, 2006) (Inspection of Leads and Lags above).

It was remarked that the dominance of the obliquity signal during the early- and mid-Pleistocene is another challenge to the Milankovitch theory (Raymo and Nisancioglu, 2003). One recently proposed explanation views the dominance of the obliquity signal in the ice-volume record as an artifact due to opposite effects of precession on ice-sheet masses lying on Southern and Northern hemispheres (Raymo et al., 2006).

The *mid-Pleistocene transition* is a relatively abrupt event. However, it may have been caused by very gradual changes in environmental conditions, which translated into a rapid variation through a phenomenon of bifurcation. Candidates are tectonically driven changes in carbon dioxide concentration and erosion-induced changes in the sedimentological properties of the bedrock of large ice sheets (Clark et al. 2006).

Physics-resolving models

The models mentioned above are derived from plausible physical hypotheses, but were reduced to small systems of ordinary differential equations. A modeling strategy attempting to resolve the spatiotemporal dynamics of the ice, atmosphere, and oceans is also necessary to deepen the understanding of the mechanisms of ice ages and confirm the relevance of low-order models.

The vertically integrated ice-sheet model by Peltier and Hyde (1984) was an important contribution in that direction. This model gave substantial credit to the hypothesis that large ice sheets may rapidly collapse due to the enhancement of the meridional ice flow under depleted bedrock conditions (Hyde and Peltier, 1987) (Deglaciation).

The model of Gallée et al. (1992) constituted another major step toward model complexity. Vertically integrated ice-sheets dynamics are asynchronously coupled to zonally averaged quasi-geostrophic atmospheric dynamics. The model reproduces the ice-volume record over the last 400 kyr. Experiments based on a three-dimensional ice-sheet model were presented by Tarasov and Peltier (1997, 1999). Progress in computer performance now permits more demanding experiments, either based on three-dimensional general circulation models of the atmosphere (Abe-Ouchi et al., 2007) or on a simplified atmosphere–ocean model synchronously coupled to ice-sheet dynamics (Calov et al., 2005). General circulation models of the atmosphere and ocean, sometimes coupled to global vegetation models, were used to better investigate the response of the complex Earth system to orbital elements (de Noblet et al., 1996; Khodri et al., 2001; Vettoretti and Peltier, 2003) but there is no consensus as whether one mechanism, more than the others, conditions the glacial inception process. A three-dimensional resolution of ice-sheet, ocean, carbon-cycle interactions spanning the Pleistocene still seems beyond reach.

Parallel to these ambitious programs, three-dimensional viscoplastic ice-sheet models were driven by reconstructed climatic scenarios in order to estimate the ice-sheet history over the most recent glacial–interglacial cycles (Huybrechts, 2002; Charbit et al., 2007).

Prediction of the next ice age

Ignoring the anthropogenic perturbation, some numerical models suggest a glacial inception in about 60,000 years from now (e.g., Berger and Loutre, 2002). The anthropogenic perturbation will affect the next glacial inception and possibly delay it by several hundreds of thousand years (Archer and Ganopolski, 2005). By contrast, more conceptual models based on the analysis of the past climate response to orbital forcing lead to the competing paradigm that, lacking an anthropogenic perturbation, glacial inception would have been imminent (Raymo, 1997) or even overdue (Ruddiman, 2007).

The reliability of such climate predictions is restricted by modeling errors, parameter uncertainty, observation errors, and uncertainty on the forcing and climate stochastic perturbations. Statistical methods for assessing the effective horizon of predictability at the glacial–interglacial scales are still in their infancy. A recent exercise drawing on principles of Bayesian statistics suggests that predictability of glacial cycles is poor beyond 60 kyr (Crucifix and Rougier, 2009).

Summary

Glacial–interglacial cycles have paced climate for 2.7 Myr. They are mainly documented from continuous records – marine, ice, and continental archives – but geomorphological and sea-level indicators remain a premium source of knowledge about the timing and amplitude of glaciations. The last glacial–interglacial cycle is one of the largest-amplitude cycles of the Pleistocene. Glacial–interglacial cycles continue to pose challenges at the most fundamental level: there is not yet any universally accepted model of climate response at the timescale of ice ages, even if it is now indisputable that these cycles are somehow controlled by Earth orbital elements. At the same time, these cycles constitute our main source of information about the dynamical and nonlinear interactions between the main components of the climate system at the multimillennium timescale.

GLACIATION DURING TIMES OF ENHANCED/REDUCED ATMOSPHERIC CARBON DIOXIDE

Andrew B. G. Bush
Department of Earth and Atmospheric Science, University of Alberta, Edmonton, AB, Canada

Definition

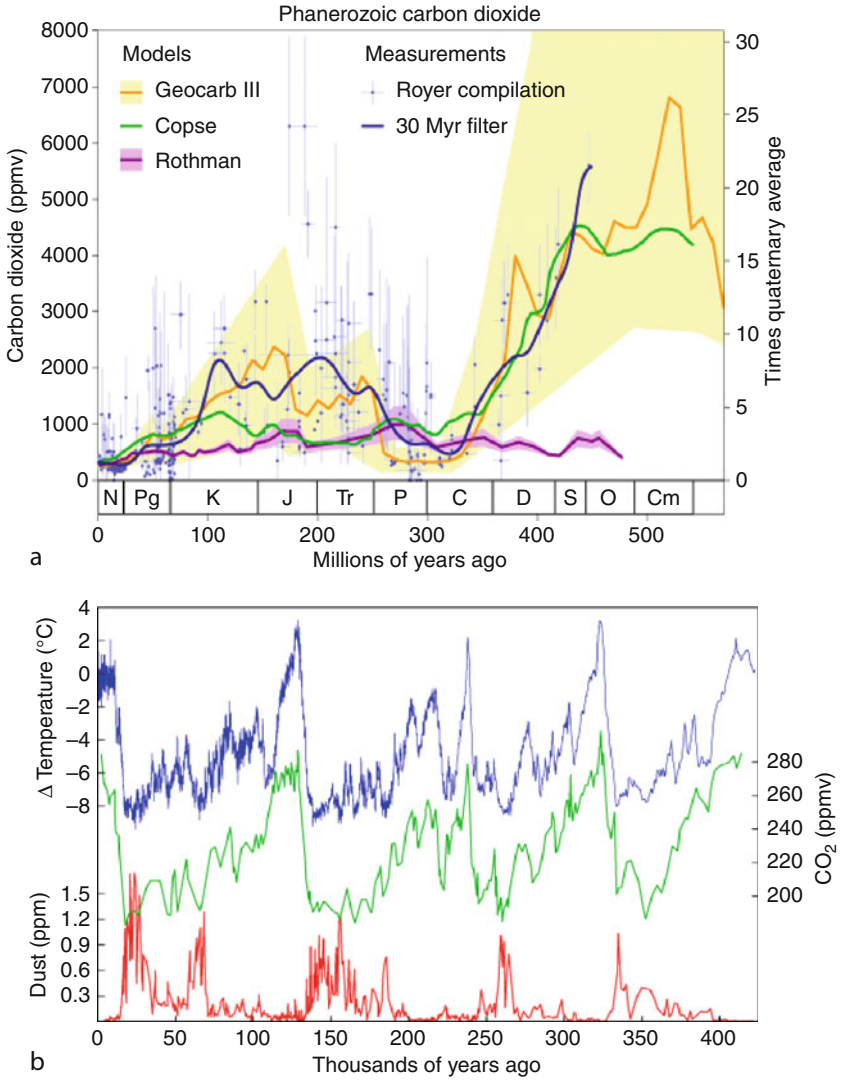
The impact that atmospheric carbon dioxide has on the extent of global glaciation is assessed. Known glacial periods during times of high atmospheric carbon dioxide are contrasted with glaciation during times of low atmospheric carbon dioxide. Mechanisms for the former are discussed.

Introduction and background

Evidence for glaciations has emerged from the geological record as far back in time as the Precambrian era, during the mid-Archaen glaciation approximately 2,900 million years before present (Ma; e.g., Eyles, 2008). In addition, a series of widespread and perhaps global glaciations occurred during the Snowball Earth events of the Neoproterozoic period (e.g., Hoffman et al., 1998; Hoffman and Schrag, 2002). Extensive glaciations occurred during the late Ordovician/early Silurian ~430 Ma (e.g., Le Heron, 2007), at the Carboniferous/Permian transition ~280 Ma (e.g., Bussert and Schrank, 2007) and, more recently, throughout the past 2 million years of the Pleistocene.

Glacial events occurring deep in geologic time, however, are harder to investigate because it is more difficult to reconstruct the environment in which these glaciations occurred. Paleomagnetic reconstructions of continental positions deteriorate in precision through the Paleozoic (~225–570 Ma), as does the proxy evidence for atmospheric composition, although estimates for the amount of atmospheric carbon dioxide through the Phanerozoic have been made (Figure 1a). Nevertheless, from a more theoretical standpoint it appears that there are many factors that can play a role in triggering widespread glaciation. Continental positions play a role, particularly if land exists in high latitudes to support large ice sheets (analogous to modern-day Antarctica and Greenland) or if extensive land with a high albedo exists in the equatorial region where it can reflect a significant amount of incoming solar radiation directly back to space (believed to have been important for the Snowball Earth glaciations; Schrag et al., 2002).

The amount of atmospheric carbon dioxide and other greenhouse gases is an important factor and is, at least for the relatively recent Pleistocene glaciations, highly correlated with the glacial–interglacial temperature cycles (Figure 1b). Solar luminosity, changes in Earth's orbital parameters, changes in ocean circulation due to plate tectonics, volcanism, and (for the more recent glaciations) surface vegetation are all believed to be influential factors.



Glaciation During Times of Enhanced/Reduced Atmospheric Carbon Dioxide, Figure 1 (**a**) Estimates of atmospheric carbon dioxide concentration through the Phanerozoic. Image created by Robert A. Rohde/Global Warming Art. Full details are available at http://www.globalwarmingart.com/wiki/File:Phanerozoic_Carbon_Dioxide_png. (**b**) Atmospheric carbon dioxide, temperature, and dust concentration through the late Pleistocene as determined from a Vostok ice core (Petit et al., 1999; data are from http://www.ngdc.noaa.gov/paleo/icecore/antarctica/vostok/vostok_ data.html). It is likely that more than one factor has contributed to the numerous glacial cycles deduced from the geological record. For example, during the early Pleistocene, glaciations had a ~41,000 year cycle, suggesting that they were regulated by changes in the Earth's angle of obliquity (e.g., Crowley and North, 1992). During the mid-late Pleistocene, however, the glacial cycle switched to a ~100,000-year cycle, suggesting that they were regulated by changes in the Earth's orbital eccentricity. The dynamic mechanism behind this switch to a 100,000-year cycle has proven to be elusive, particularly considering the relative weakness of insolation anomalies associated with the 100,000-year eccentricity changes. It is likely that some internal feedback within the atmosphere–ocean–cryosphere system caused this switch to the longer glaciation cycle. Nevertheless, it appears that the Pleistocene glaciations have been dominantly regulated by changes in the Earth's orbital parameters (the Milankovitch cycles).

The Ordovician/Silurian glaciation is a particularly fascinating one because it is believed to have occurred under times of high atmospheric carbon dioxide, perhaps as high as 10–15 times the preindustrial value (e.g., Berner, 1998; Figure 1a). It is one clear example of glaciation during which multiple factors were at play. Plate tectonic motion formed the supercontinent of Pangaea, which had a large

amount of land over the South Pole (which is now modern-day Africa, from which evidence for glaciation has been discovered in multiple places that are now tropical–subtropical (e.g., Le Heron, 2007; Le Heron et al., 2009)). In addition, solar luminosity was about 3% lower than its modern value (e.g., Endal and Schatten, 1982). The latter two factors, both conducive to glaciation, were sufficient to keep seasonal temperatures below freezing year round near the South Pole despite the enhanced long wave forcing due to the large amount of atmospheric carbon dioxide.

A considerable amount of numerical modeling work has focused on simulating the inception of the most recent glaciation during the Eemian (~116 kyr ago, see Figure 1b; for a review see Mysak, 2008). Milankovich forcing – in particular, high eccentricity, high precession, and low obliquity – reduced summertime insolation in the high northern latitudes during this time. Since glacial inception takes on the order of thousands of years, the numerical models that have been used to investigate the processes involved are referred to as Earth system Models of Intermediate Complexity (EMICs), meaning that the dynamics contained within the models are simplified compared to the fully coupled atmosphere–ocean general circulation models used for climate prediction, yet they retain many of the basic dynamical processes.

Sensitivity experiments using EMICs have determined that many factors in addition to Milankovitch forcing play a role in glacial inception: land surface vegetation and the vegetation-albedo feedback, moisture transport from the oceans to continental high latitudes, the global thermohaline circulation, and atmospheric carbon dioxide are all important factors in generating sufficiently cool conditions over land that perennial snow exists and can be transformed over the course of years into continental ice (Mysak, 2008).

EMICs have also been used to study the future in an attempt to determine whether the postindustrial rise in atmospheric carbon dioxide is sufficient to preclude the next glaciation predicted from Milankovitch theory at the next insolation minimum, 50 kyr from now. Since the uptake of atmospheric carbon by the oceans is a relatively slow process, these models predict that given the anthropogenic increase in atmospheric CO_2, the current interglacial period could last another ~100 kyr (Loutre and Berger, 2000; Archer and Ganapolski, 2005; Cochelin et al., 2006; Mysak, 2008).

Historically, continental ice sheets in general circulation models are static in the sense that they have specified topography and a suitable albedo but they are not allowed to respond to the atmosphere. Ice sheet models, in turn, are typically forced by fields derived from an atmospheric model but do not interact with the atmosphere. The disparity in timescales of large ice sheets operating on the timescale of thousands of years, and the surrounding climate operating on a seasonal timescale, provides some challenges in using a general circulation model to study the dynamic and thermodynamic interactions between continental ice sheets and the climate system. Nevertheless, such models have been recently developed and used to simulate the demise of large ice sheets (Pritchard et al., 2008; Otto-Bleisner et al., 2006; Ridley et al., 2005). Since there is abundant geological evidence for the timing of the demise of the Laurentide ice sheet (e.g., Dyke et al., 2002), one can employ a coupled atmosphere–ice model to determine the factors governing the rate of continental ice retreat. It is found that a critical feedback during deglaciation is a thermodynamic one in which the margins of the ice, during the melt season, have a lower albedo because of the presence of surface melt water (Pritchard et al., 2008). Without this melt water parameterization included, the Laurentide ice sheet does not melt, even under high values of obliquity (such as those found in the early Holocene) and modern carbon dioxide levels (Pritchard et al., 2008).

It is clear, then, that many factors play a role in glacial cycles and that atmospheric carbon dioxide levels are important but are not the only factor. To complicate matters, many of the factors that can regulate glaciations interact with each other creating either positive or negative feedback loops. One advantage of numerical modeling is that each factor can be examined in isolation, keeping the other factors fixed. This article presents general results from a numerical climate model configured for time slices of Earth's history and possible future. It is a fully coupled atmosphere–ocean general circulation model. Since boundary condition data must be known and input into the model (e.g., ice sheet extent and thickness) the representative low CO_2 state is chosen to be the Last Glacial Maximum (LGM), ~21,000 years ago, for which there has been extensive work done on reconstructing the ice sheets and atmospheric composition.

Model details

The global general cirulation model used is a coupled atmosphere–ocean model developed at the Geophysical Fluid Dynamics Laboratory in Princeton, New Jersey, USA. The atmospheric model (Gordon and Stern, 1982) has a spatial resolution of 3.75° of longitude by 2.25° of latitude at the equator. There are 14 levels in the vertical. The ocean model is the Modular Ocean Model v.2 (e.g., Pacanowski, 1995) with a spatial resolution comparable to that of the atmospheric model. The two general circulation models are dynamically and thermodynamically coupled together with an exchange of boundary condition information at 1-day intervals, and each integration simulates 70 years of climate. There is a thermodynamic sea ice formulation included in the model.

The time slices examined are the Last Glacial Maximum (LGM), today (representative of an interglacial period), and a hypothetical doubled atmospheric CO_2 scenario (which may be on the order of 100 years into the future). Ice sheet reconstructions for the LGM simulation are taken from Peltier (1994). The LGM simulation incorporates many of the factors influencing glaciation

discussed previously: Earth's orbital parameters were slightly different (Berger and Loutre, 1991), the continents, though in the same position as today, were more exposed because of the 120-m drop in sea level, surface vegetation was different, and atmospheric CO_2 was 200 ppm. Atmospheric CO_2 in the control simulation of today is 300 ppm, and 600 ppm in the doubled CO_2 experiment.

Since large ice masses are fixed in the model, and there is no parameterization for the snow–firn–ice transition, any potential changes in glaciers and ice masses must be inferred from changes in annual mean snow accumulation. In particular, for alpine glaciers this is all that can be done with a global model since details of mountains are smoothed out given the model's relatively coarse spatial resolution.

Results

Focusing on the pan-Himalaya range from 60 to 105 E, 25 to 45 N, annual mean snow accumulation (Figure 2) indicates large changes between the LGM and today (Figure 2b) and between a doubled CO_2 environment and today (Figure 2c). There is approximately 30% more snow along the Front Range at the LGM, and ~100% more accumulation in the eastern Himalaya. Conversely, there is a ~30% drop in snow accumulation (compared with today) in the center of the front range (~80 E) in a higher CO_2 environment but on the western (72 E) and eastern (90 E) flanks of the range the decreases are 100%. This result would suggest an overall shrinkage of the area in which glaciers could possibly exist, though they could still persist in the center of the range around 80 E where modern snow accumulation is maximum.

Simulated differences between the low CO_2 glacial state and the high CO_2 state (Figure 2d) show that the entire Himalaya is affected with much more snow nearly everywhere when CO_2 is low. This implies that transitions from low to very high CO_2 states are likely to have negatively affected glaciers across the entire Himalaya.

Simulated changes in annual mean snow accumulation are in accord with the annual mean surface temperature changes averaged over the region (Figure 3). The transition from a low CO_2 state to a high CO_2 state brings a warming of approximately 9°C on average. Note that the difference in temperature over this region between today and the LGM (3.8°C, which is close to the global mean value of 4°C) is less than that between a doubled CO_2 state and today (5.3°C) suggesting that potential changes in the area over the next hundred years may be greater in magnitude than between today and the LGM.

In the Arctic, annual mean temperature changes between low and high CO_2 states are also profound, with changes approaching 14°C (averaged over 0–360 E, 60–90 N; Figure 4). This large difference is because at these latitudes the snow/ice albedo feedback plays a stronger role than at lower latitudes, where the surface area of perennial snow and sea ice is relatively small (even

though insolation is higher). It is interesting to note that in a doubled CO_2 atmosphere, the annual mean temperature of the Arctic is just at the freezing level, implying significantly warmer summer temperature and high rates of ice melt.

Snow accumulation averaged over the Arctic (Figure 5) is in accord with the temperature changes and is not particularly surprising. However, an interesting point may be made with respect to the relatively small change between today and the doubled CO_2 simulation. In a warmer climate, there is increased moisture flux into higher latitudes (e.g., Ross and Elliot, 2001; Wetherald and Manabe, 2003) so if temperatures are sufficiently low that precipitation falls as snow (which, according to Figure 4, would still occur during the wintertime) then the increased moisture implies increased wintertime snowfall. The reason there is still a decrease overall (averaged over 60–90 N) is a combination of increased summertime melt (cf. Figure 4) and the fact that the southern margin of perennial snow migrates further north, thereby decreasing the areal extent of snow covered regions.

Results around Antarctica are fairly uniform through all three simulations, and that is a consequence of the Antarctic ice sheet being fixed in the model (and not that much different at the LGM). This is a weakness of the model where changes in Antarctic climate are likely to influence results for much of the southern hemisphere.

Although there are a number of glaciers in the Andes, the model only captures significant snowfall over southern Patagonia and there is a near 100% drop between the LGM and the doubled CO_2 simulation in that region (not shown).

Discussion and conclusions

Results from a general circulation model are useful in the sense that they give the range of climates under different forcing factors. The two "extreme" climates presented here, that of the LGM and that of a doubled CO_2 atmosphere, bracket the range of possibilities between glacial conditions and a potential future climate state, whereas comparison between the LGM climate and the control brackets the range between glacial and interglacial states (at least through the late Pleistocene).

Between glacial and interglacial states, the variation of atmospheric CO_2 is on the order of 100–150 ppm and in the study regions, this was the primary cause of annual mean temperature changes on the order of 4–5°C over the Himalaya and on the order of 9–10°C over the Arctic

region. The 400-ppm difference in CO_2 between the LGM and the doubled CO_2 simulation produces 9–10°C of temperature change over the Himalaya and 13–14°C of change over the Arctic.

In terms of implications for glaciers, these temperature changes are profound. The temperature dependency of the saturation vapor pressure of the atmosphere is exponential with temperature, implying much more atmospheric water vapor in warmer climates (since evaporation also increases with temperature). This implies more precipitation per event (an event meaning either a synoptic frontal system or, perhaps more importantly for glaciers, orographic uplift). The key issue is whether that precipitation falls as rain or as snow. In a warmer climate, the equilibrium line altitude will shift upward since the shift in precipitation type from rain to snow will shift upward. Theoretically, if the temperature were warm enough then no snow would fall at the highest elevations of the planet. However, the results presented here indicate that a doubling of CO_2 is not sufficient to prevent snow from accumulating at the surface in the Himalaya (cf. Figure 2) it just changes the spatial distribution as well as the net amount. It would be likely, then, that some glaciers could still exist at high elevations in a doubled CO_2 environment, though some that are presently at lower elevations would not be able to exist.

Conversely, in a low CO_2 environment such as that of the LGM, the saturation vapor pressure is lower and precipitation events do not produce as much, but more of what they produce falls as snow in the colder temperatures. As indicated in Figure 2, there is of course spatial variability to the changes in snowfall but on average the increase in snow accumulation at the LGM both over the Himalaya and the Arctic can be attributed primarily to the change in precipitation type. However, there are also changes in wind direction in the LGM simulation that enhances orographic precipitation, particularly in the eastern Himalaya (see Bush, 2002), and there is field evidence to support glacier advances there at the LGM (Richards et al., 2000).

Seasonality also plays a significant role in determining the type of precipitation. In a low CO_2 climate, snowfall events are more likely in the early and late summer months and conversely in a high CO_2 climate rainfall events are more likely in the early and late winter months. On geologic timescales, this fact becomes important on the timescale governing Earth's angle of obliquity (~41,000 years) since high obliquity implies a stronger seasonal cycle. In fact, 6,000 years ago when obliquity was higher than today, the increased seasonality enhanced the summer monsoon winds bringing more moisture to the western Himalaya, which would fall as snow at high elevations, and there is field evidence to support glacier advances at that time (e.g., Phillips et al., 2000; Richards et al., 2000).

The fact that the general circulation model results are in accord with field measurements, at least for the Himalaya (Bush, 2002), implies that the temperature and snow accumulation changes simulated by the model are sufficient to cause glacier advances/retreats. A drawback of the general circulation model is the lack of spatial detail that is necessary to infer changes in specific regions. This deficiency is at present being addressed through the use of regional modeling in which a regional model is driven by data produced by the general circulation model. While this area of research is relatively new, it should give spatial resolutions on the order of kilometers as opposed to the hundreds of kilometers of the general circulation model. Spatial resolution on the order of kilometers would vastly improve the representation of topography in the model (and hence orographic precipitation and topographic radiative shielding of mountain valleys) and should therefore lead to improved results for glacierized regions. However, even this spatial resolution is still relatively coarse compared with the spatial scale of individual alpine glaciers. As of yet there is no direct coupling between regional models and glacier models, so a methodology needs to be developed to take regional atmospheric data and drive some form of glacier model that spans a region large enough to be significant. Such a methodology is currently being developed under the auspices of the Western Canadian Cryospheric Network (http://wcn.unbc.ca).

Definition and introduction

Pleistocene glaciations had a profound influence on the dynamics of groundwater flow systems. Their impact has not been limited to glaciated regions; they also affected parts of the world that were not glaciated because of the related global perturbations in climatic conditions such as changes in precipitation and eustatic sea levels. As a consequence, groundwater recharge patterns were globally modified and affected groundwater flow dynamics at basinal to continental scales in a wide range of geological environments such as coastal aquifers, intercratonic sedimentary basins and crystalline rocks.

The study of the impact of glaciations on groundwater flow is important for several reasons. First, it can assist in explaining the origins of modern groundwater flow patterns, as well as the geochemistry of waters because it is now recognized that many large-scale groundwater flow systems are not in equilibrium with modern climatic conditions since they are continuing to evolve from past climatic periods (Grasby et al., 2000; Person et al., 2003). Pleistocene waters have geochemical properties that are different than autochthonous waters; their quality is usually good, and in some locations, they are an important source of freshwater (Edmunds, 2001). The sound management of these resources requires a sound scientific understanding of their origin, extent, and the driving forces acting on them. Glacial meltwater is also associated with the generation of biogenic gas resources that are exploited by the petroleum industry in the Michigan and Illinois Basins (McIntosh et al., 2002). Moreover, the lowering of sea level related to the growth of ice sheets have exposed coastal aquifers to freshwater recharge such that, in some locations, the freshwater/sea water interface observed today is not in equilibrium with the current sea level (Akouvi et al., 2008; Person et al., 2003). Pressurized groundwater below ice sheets may also be an important consideration with regard to issues such as the safe long-term disposal of radioactive wastes (Talbot, 1999). Because the suitability of deep geologic repositories must be demonstrated over large timescales, flow patterns under an ice sheet must be understood as they may change drastically.

Supporting evidence

One of the earliest works addressing the direct impact of glaciations on groundwater flow systems was published

by McGinnis (1968) who proposed a groundwater flow reversal close to the margins of the Laurentide Ice Sheet to explain the displacement of brines and formation of Mississippi Valley type (MVT) zinc-lead deposits in Illinois and Wisconsin. This publication did not receive much attention at that time, probably due to the fact that the origin of the MVT deposits were prior explained by another competing mechanism and partly because of the lack of supporting field evidence regarding glacial impacts. However, this publication introduced a new paradigm with regard to the driving forces for groundwater flow. The same concept was later proposed by Boulton et al. (1993), without apparent knowledge of the previous work of McGinnis. Boulton et al. (1993) proposed a theory that pressurized subglacial meltwater from ice sheets would substantially reorganize aquifer flow fields and that groundwater flow would be controlled by the continental-scale topographical form of the ice sheet's surface rather than by the land surface topography, as observed today. His theory was supported by the results from a numerical groundwater flow model that predicted hydraulic gradients sufficient to explain the sediment disruption observed in North-Western Europe. This theory is now widely accepted and has been extensively tested with field observations.

Geochemists also recognized early on that the groundwater chemistry in some regions could not be explained by the recharge of modern precipitation and that paleoclimatic conditions characterized by recharge waters having different geochemical signatures could explain the discrepancies (Clayton et al., 1966). Thus, groundwater chemistries observed today are believed to have recorded the evolution of past climate changes, and early applications of this discovery were tested in non-glaciated regions in order to identify past recharge conditions. For example, Edmunds and Wright (1979) used stable (^{18}O, ^{2}H) and radio-isotope (^{14}C) data measured in groundwaters from the Sirte and Kufra Basins (Libya) to determine the recharge history during the Holocene and the late Pleistocene. Andrews and Lee (1979) also used radio-isotopes (^{222}Rn, ^{4}He, ^{14}C) along with inert gases (Ar, Kr) to infer the temperature and timing of the recharge in England for the late Pleistocene.

In glaciated regions, subglacial recharge is suspected to have penetrated to significant depths in moderately permeable sedimentary aquifers (Siegel and Mandle, 1984) and crystalline environments (Clark et al., 2000). Glacial meltwater is characterized by low ^{18}O, ^{2}H, and total dissolved solids (Clark et al., 2000) and these characteristics are used as the primary indicators to identify the presence of glacial meltwater.

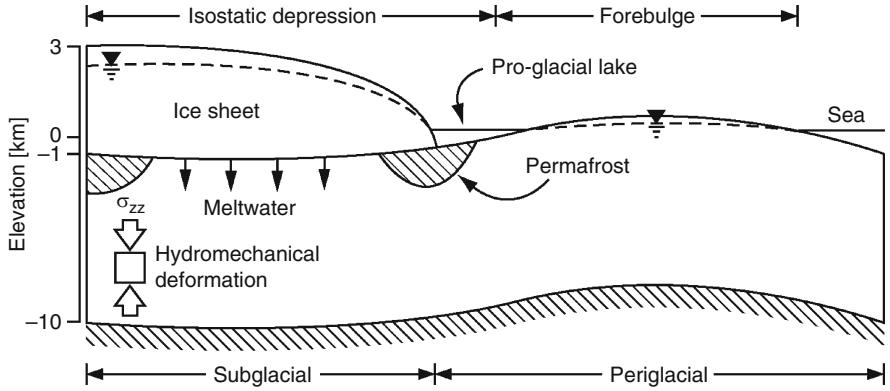
Several other techniques have been proposed for acquiring temporal information from groundwater systems. The techniques and applications are well described in the review by Metcalfe et al. (1998) for dating relative or absolute events such as groundwater recharge or enhanced flow rates. Among these techniques, the most appropriate for Pleistocene events are radioactive isotopes (e.g., ^{13}C, ^{14}C, ^{34}S, ^{222}Rn) to infer the groundwater age and dating groundwater "events" along with noble gas (Ar, Kr, Xe) to estimate groundwater recharge temperatures. The mixing of recharge water with in situ water, however, greatly complicates the interpretation of the geochemical data.

In the recent years, several new lines of evidence have been put forward to demonstrate the strong impact of glaciations on groundwater flow systems in a wide range of geological environments, in both glaciated and non-glaciated regions. This evidence is well summarized by Person et al. (2007) for North America and in a Geological Society of London Special Publication edited by Edmunds and Milne (2001) for Europe.

Important processes

Figure 1 exhibits the hydraulic conditions that may be encountered during a glaciation period. These conditions are much different than observed during the Holocene where the main driving force for groundwater flow is gravity-driven by the topographical forms of the landscape as described by the pioneer works of Hubbert (1940) and Tóth (1962). In the subglacial environment, large hydraulic heads can develop in warm-based regions below the ice sheet where the upward geothermal heat fluxes and subglacial frictional heating are sufficient to raise the temperature above the pressure melting point and thus generate subglacial meltwater. A portion of the pressurized meltwater is driven into the subsurface under ice sheet pressure, which induces a strong downward hydraulic gradient, such that the groundwater recharge rate is significantly modified as compared to values during interglacial periods. The subglacial meltwater that infiltrates into the subsurface will flow from high hydraulic head zones (i.e., under the ice sheet) to lower head zones, which can either be subglacial regions where there is no melting or to distal areas beyond the limits of the ice sheet. Groundwater flow lines therefore mimic in an ancillary way the nature of ice sheet flow lines, and the ice sheet topography has a dominant control on groundwater flow.

The quantity of recharge is dependent on the permeability of the substratum and is much larger for sedimentary basins than for igneous and metamorphic cratons such as the Canadian Shield and the Fennoscandian Shield. When the recharge event is large and sustained long enough, a reversal of the normal flow field can occur (Grasby et al., 2000). At the tip of the ice sheet, large subsurface hydraulic gradients form over short distances, but the permeability is greatly reduced by the presence of the permafrost. These conditions are likely to lead to hydrofracturing in sediments and rocks at the ice sheet margin (Boulton et al., 1993). Laterally beyond the permafrost zone, through local gaps in the discontinuous permafrost, strong upward groundwater flow is likely to occur that will lead to sediment liquefaction, sediment dyke



Glaciations and Groundwater Flow Systems, Figure 1 Conceptual model showing relevant processes that may impact groundwater flow systems during a glacial period. The driving forces for groundwater flow are much different than during interglacial periods such as the present time. Important processes include eustatic sea level changes, glacial isostasy (depression and forebulge are identified), permafrost development, hydromechanical deformation due to ice sheet loading, subglacial meltwater recharge, and pro-glacial/periglacial drainage network evolution. Subglacial and periglacial environments are identified and described in the text. The figure is conceptual and not to scale. The depth of 10 km is arbitrary. Modified from Lemieux et al. (2008a, b).

formation, and sediment expulsion structures (Boulton et al., 1993). Recent studies on the dynamic of groundwater recharge suggest that most subglacial recharge occurs during glacial progression while little occurs during glacial regressions, where exfiltration dominates the recharge/discharge dynamics across the land surface (Lemieux et al., 2008a).

In some portions of the subglacial environment, a cold base exists below the ice sheet where no subglacial water is generated and where permafrost occurs. These regions are believed to exist at the ice sheet margins and under the center of ice domes (Boulton et al., 1996; Tarasov and Peltier, 2007) and can reach a depth of 1,000 m in the periglacial environment. The permeability of soils affected by permafrost is greatly reduced (Burt and Williams, 1976) and prevents the movement of groundwater although there is no consensus on the permeability reduction because of the paucity of data. Continuous permafrost prevents surface water from recharging groundwater in the periglacial area and conversely from allowing groundwater to discharge to the surficial regime. Such an interruption in recharge has been documented by Edmunds (2001) for the East European Midlands during the 10–20 ka BP period.

In the periglacial environment, several large proglacial lakes formed during the last deglaciation period (e.g., Lake Agassiz) and their configuration, depth and extent was a result of the interactions between the location of the ice margin, the topography of the newly deglaciated surface, the elevation of the active meltwater outlet along the margins of the ice sheet, and differential isostatic rebound (Teller, 1987). These lakes can affect the ground thermal regime and contribute to the melting of permafrost. They will also strongly interact with the groundwater and have an important role in taliks development. They can also represent a driving force for groundwater recharge or be an outlet for deep pressurized groundwater. In any case, their presence strongly influences subsurface hydraulic gradients over large regions.

Dynamic eustatic sea level variations due to changes in the amount of water stored in ice sheets constantly modifies the sea shore position and coastal water levels during a glaciation cycle, thus exposing the continental shelf to meteoric recharge during glacial maximas. The dynamics of sea level change is such that it regresses more slowly than it transgresses. This has an important repercussion on coastal aquifers where the interface between freshwater and saline waters evolves accordingly. Person et al. (2003) have documented freshwater up to 150 km off the shore of New York, which is not in equilibrium with modern sea level. This could only be explained by meteoric or subglacial Pleistocene recharge.

The weight of an ice sheet causes the Earth's crust to deform such that an isostatic depression develops underneath and a forebulge forms in its distal surroundings. Isostatic depression exceeded 1 km at the last glacial maximum in North America. This modifies large-scale groundwater flow patterns because hydraulic potentials are lowered below the ice sheet and are increased in the forebulge. Another impact of the ice sheet is the additional weight imposed on the geologic medium. Depending on its elastic properties, which are a function of the rock type, compaction can reduce both the porosity and the permeability of the geologic material and hence lead to the development of abnormal pore pressures (Bekele et al., 2003).

Numerical studies have become powerful tools to study the complex interaction among the processes involved during a glaciation period and assess their respective impacts on groundwater flow systems. A comprehensive description of the theoretical

background and applications for basinal to continental scales are given by Person et al. (2007), Lemieux et al. (2008a, b, c), and Bense and Person (2008).

Summary

Pleistocene glaciations had a strong impact on groundwater flow dynamics in a wide variety of geological environments in both the glaciated and non-glaciated parts of the world. Several lines of evidence support this paradigm such as groundwater geochemical imprints, regional disequilibrium in subsurface pore pressures, and sedimentary structures. The study of Pleistocene hydrogeology is complex because of the range of geological and hydraulic processes involved during glacial cycles such as hydromechanical deformation due to glacial loading, glacial isostasy, eustatic sea levels' variations, proglacial drainage evolution, subglacial recharge, and permafrost development. Current groundwater flow in basins affected by Pleistocene glaciations cannot always be interpreted solely on the basis of Holocene conditions and it is likely that several thousands to tens of thousands of years of additional equilibration time will be necessary for systems to reach a new equilibrium state, depending on the system's inertia. On the other hand, the information recorded by the groundwater offers great potential to better understand past climates.

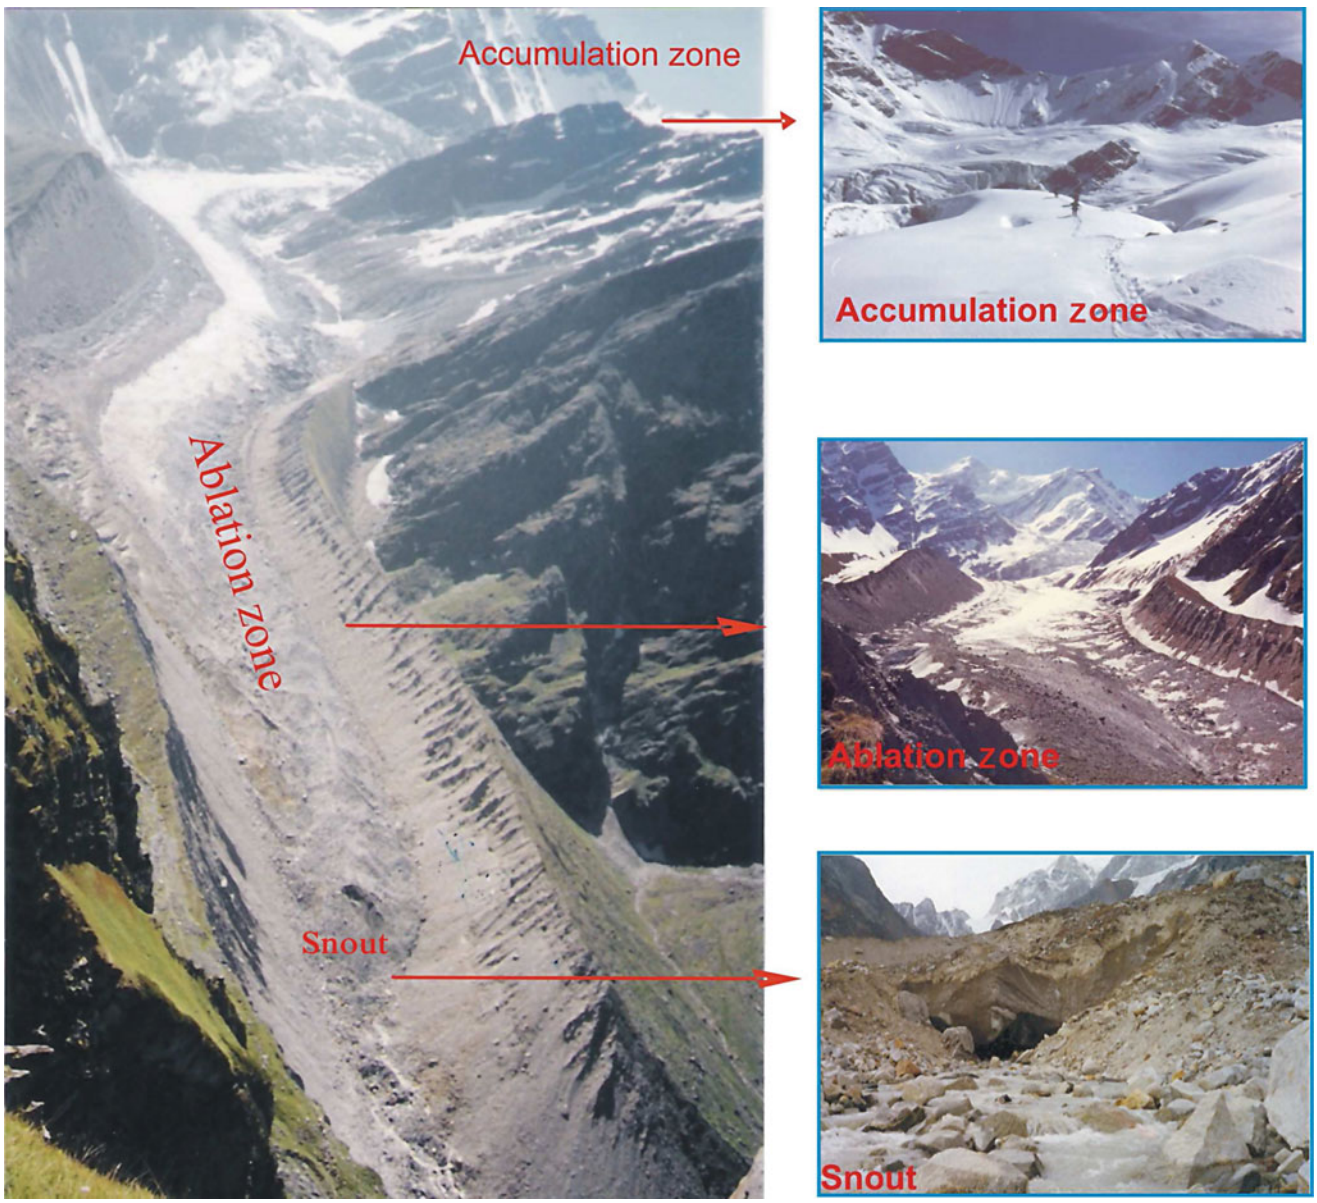
Wadia Institute of Himalayan Geology, Dehradun, India

A glacier is a hard, thick and compact ice mass on land that forms through the recrystallization of snow and moves forward under its own weight. Glaciers form over many years of packed snow in areas where more snow accumulates than it melts. A glacier is a dynamic and fragile ice body always moving forward, characterized by three basic components, that is, accumulation, ablation, and terminus zone (Snout) (Figure 1).



Glacier, Figure 1 Synoptic view of glacier (Dokriani Glacier, Garhwal Himalaya, India) and its components (Photo: Dobhal).

Accumulation Zone: The part of a glacier that is perennially covered with snow, extending between equilibrium line/firn line and brugschund called accumulation zone of the glacier. This occurs through a variety of processes including precipitation, firnification, and wind transportation of snow into a glacier basin from an adjacent area.

Ablation zone: The area extended between the snout and equilibrium line altitudes or firn line is defined as glacier ablation zone. This is the area where ice and snow are lost through a variety of processes including melting and runoff, sublimation, evaporation, calving, and wind transportation of snow out of a glacier basin.

Terminus (snout) zone: The end edge beyond which there is no glacier and from where a stream emerges is called snout/terminus of a glacier. Snout of the glaciers exhibit varying shapes and characters, depending upon the size of glacier, nature of valley, bed rock slope, and of course, mass balance of the glacier.

GLACIER BIRD OF THE ANDES

Douglas R. Hardy[1], Spencer P. Hardy[2]
[1]Climate System Research Center and Department of Geosciences, University of Massachusetts, Morrill Science Center, Amherst, MA, USA
[2]Hanover High School, Hanover, NH, USA

Definition

White-winged Diuca Finch (*Diuca speculifera*) is a bird species that uses glaciers in the High Andes for both roosting and nesting.

Many birds are well adapted to environments seasonally dominated by snow or sea ice, but excepting penguins, birds are not generally associated with glaciers. Even flying over mountain glaciers and ice caps can be hazardous to birds, subjecting them to low oxygen pressure, low temperatures, and harsh environmental conditions such as snowstorms; mortality has been documented from glaciers in Alaska, USA and Yukon Territory, Canada (Krajick, 2002), Greenland (Pfeffer W. T., 2009, personal communication), the Himalaya (Thompson L. G., 2007, personal communication), and on Kilimanjaro (Hardy D. R., 2008, unpublished data).

Conditions on glaciers are usually not well suited for nesting in particular, being cold, actively changing through accumulation and ablation, and at times wet. Until recently the ornithological literature contained only one detailed account of nesting on a glacier, the unusual circumstance where glaciers advancing into Alaska's Prince William Sound overran a Black-legged Kittiwake (*Rissa tridactyla*) colony (Irons, 1988). Previously used nest sites became unavailable and 77 kittiwake nests were constructed on the glacier face; all failed.

One bird species is exceptional, roosting at night within glaciers and perennially nesting on glaciers. This is the White-winged Diuca Finch (*Diuca speculifera* hereafter WWDF), found above 4,500 m elevation in the High Andes of Perú, western Bolivia, and northern Chile (Fjeldså and Krabbe, 1990). Their association with glaciers was first noted at Chacaltaya (5,200 m) near La Paz Bolivia, gathering for the night inside a crevasse (Niethammer, 1953), and Johnson (1967) provides a second-hand report – also from Chacaltaya – of the species nesting in a generalized "ice cave" at 5,300 m. Hardy and Hardy (2008) documented roosting and numerous glacier nests of WWDF in the Cordillera Vilcanota of southern Perú. Nests were found primarily on the near-vertical, retreating glacier margin of the Quelccaya Ice Cap, at elevations up to 5,300 m, over several consecutive years. Observed nests were both in situ on the ice and recently fallen. Supporting evidence, including WWDF eggs and feathers within glacier nests, remains on the ice of WWDF victimized by predation, as well as active WWDF in the area. Glacier nesting by WWDF occurs at Quelccaya Ice Cap despite subfreezing air temperature throughout the year, with extreme night-time radiational cooling whenever cloud cover is low. Furthermore, WWDF is among the highest-elevation nesting bird species of the Western Hemisphere.

GLACIER CAVE

Monohar Arora
National Institute of Hydrology (NIH), Rorkee, UA, India

Caves formed completely in ice are termed as glacier caves and are also very often called ice caves. Glacier caves almost always form from flowing water entering the glacier through cracks or crevasses, which are then enlarged over time, both by erosion and melting. Glacier caves serve as conduits for water through glaciers. Glacier caves are rarely extensive, and may come and go as glaciers recede. Glacier caves are very dynamic and change from year to year. Large glacier cave systems have disappeared as glaciers melt and retreat. The Paradise Glacier Cave system on Mt. Rainier was at one time several

kilometers long, but has melted away as the glacier has receded in recent decades of global warming. Glacier caves are also notoriously unstable, and people have been killed by chunks of falling ice. Glacier caves may be used by glaciologists to study the interior of glaciers. The study of glacier caves themselves is sometimes called glaciospeleology.

GLACIER FIELD STUDIES: IMPORTANT THINGS TO NOTICE

John F. Shroder
Department of Geography and Geology, University of Nebraska at Omaha, Omaha, NE, USA

Definition

Things to notice in field studies include a variety of structures and landforms of both ice and the rock substrate over which the ice rides and interacts.

Four important things

Several points to notice include the quick changeability of ice, whether the ice is present now or was in the past, problems of access onto glaciers, and whether work is to done above or below the equilibrium line.

Lability: In studies of glaciers in the field it is important to pay attention to the high lability of the ice; the fact that it changes more rapidly than any other landform, and what was there last season is likely to be significantly altered in this one. And safety is a paramount concern in such rapidly shifting environments, with deadly crevasses potentially opening up overnight to swallow up the unwary. Field work in these dynamic environments is always interesting and if done well, can be richly rewarding because there is so much to see and to record.

Glacierization versus glaciation: An important first step in glacier field studies is the recognition that two major approaches can be undertaken at the outset: (1) studies of *glacierization* wherein you are working mostly on the surface of any existing ice mass or around its edges, with rare deep probes through the use of drill cores, hotpoint penetration of the ice for installation of cameras, velocity tracking devices and other such internal monitors, and ice penetrating radar, or other remote-sensing techniques to investigate the ice interior; and, (2) studies of *glaciation* where you are observing the results of past glaciations on the rock substrate that was once beneath a thick ice cover. In either case, one is attempting to discover the fundamental ways in which natural processes produce the resulting landforms developed in and of the ice, or in bedrock and in the clastics derived from the bedrock and deposited on it.

Above and below equilibrium line: In working directly upon the ice itself, the position on the ice above or below the equilibrium line where one is located commonly determines what can be observed and some of what one can do, and it very much determines the level of safety and ease of transport from one location to another. Several additional variables that produce significant ice landforms and that control access and trafficability on the ice can also be divided into those above the equilibrium line and those below. Above the equilibrium lines in both alpine and continental ice masses, crevasses are commonly hidden beneath treacherous snow bridges and travel across such regions must be done carefully. In alpine environments above the equilibrium line, the chief dangers at the edges of the glaciers are avalanches of ice and snow down from the great heights on the peaks. At the equilibrium lines, slush avalanches of water-saturated snow on the glacier surface itself commonly transfer significant water and ice masses to lower elevations across the snow lines. Snow pits that are commonly dug to the depth of a few meters above the equilibrium line in mass balance studies reveal the annual increments of snow and firn accumulation that become glacial ice over in 5–10 years' time. Commonly passing through the equilibrium lines from higher to lower altitudes in alpine areas are the unstable ice-block seracs in ice falls, the wave ogives below them, and the lower elevation meltwater streams and lakes. In alpine areas, depending upon the level of lateral ice and snow avalanching that can provide profuse rock rubble to the glacier surface, various thicknesses of debris covers can result. Close to the end of the melt season in any area, the equilibrium lines can be marked where such rubble streams emerge from beneath the snows of the prior season. Above is the zone or accumulation, below, the zone of wastage.

The debris covers on alpine glaciers close to equilibrium lines commonly emerge as lateral moraines that can combine as medial moraines between two or more glaciers merge. These medial moraines at first maintain a certain lithological integrity that exactly samples whatever rock types existed in the surrounding rock walls above that particular ice stream. Further down the ice stream, such medial moraines can merge with others and eventually with the combining of many other tributary glaciers and continued ablation of the ice mass beneath the debris, a more pervasive debris cover results, in which all the sampled rock lithologies become rather chaotically mixed.

Glacier access: Travel over such debris-covered ice is much less dangerous than over the upper firnfields that bridge crevasses, but care must still be exerted where sub- or en-glacial water channels melt out unseen and unstable domes or other openings in the ice beneath thin debris covers thereby producing unsafe situations. In general the thicker the debris cover, and hence the greater its weight, the more stable it is likely to be to support human or pack animal transit. Aside from the shear difficulty of such travel across such potentially unstable rock blocks, however, the occasional shifting of debris covers down the fronts of melt-out ice cliffs also requires vigilance to avoid hazard. With work on surging glaciers, travel through the commonly bewildering and hazardous morass of crevasses may be quite impossible, but some transit can

be done along the common sinuous medial moraines that have also been produced by the surge.

Cold-based ice at high latitudes that is frozen to its bed can present other problems of access in that in many places it rests on the landscape with near vertical walls that are subject to periodic collapse. Once up on such ice, however, data collection can be reasonably straightforward, although care must still be exerted when near surficial meltwater channels, and glacial moulin or meltwater "swallowholes."

Where moving off the ice and onto the lateral margins of alpine or continental glaciers, lateral moraines of tills, and other ice-marginal phenomena are commonly encountered. These include all sorts of full and drained proglacial lakes; Gilbert-type deltas in these existing or former water bodies; kames and kame-terrace sediments that are sorted and stratified by the meltwaters; polygenetic eskers of sub-, en-, and supra-glacial origin, with or without internal ice; various outwash plains pocked with water-filled or dry kettle holes; and other such characteristic glacial landforms and sediments. Walking over these commonly water-saturated sediments can be interesting as they may not support such weight. Commonly in alpine environments with existing glacierization, or below the glacier termini, on the slopes above the existing ice, or in other nearby formerly glaciated valleys, a full suite of landforms and sediments will exit that help in interpretation of what is likely to be concealed beneath the present ice cover.

Summary

Important things to notice in glacier field studies are somewhat in the eye of the beholder but ice, sediment, and landforms can be highly varied and present a host of features to observe and record.

GLACIER HYDROLOGY

Pratap Singh
Tahal Consulting Engineers Ltd, New Delhi, India

Glacier hydrology

Hydrology of glacierized catchments is being different from nonglacierized basin as usual, because of presence of seasonal snow and ice distribution within the catchments. The study of glaciers forms a part of surface-water hydrology, but because a part of runoff from snow and glaciers behaves like subsurface flow, groundwater hydrology concepts are also invoked. Flow in the stream is made up of the flow due to direct response of the basin to precipitation and the flow from snowmelt/glacier melt and baseflow components. Hydrology of glacierized catchments is an understanding of the Earth's physical processes, which regulate melting processes in hydrological cycle. In order to understand hydrology of glacierized catchments, it is important to understand the physics of snow and glacier melt with other components such as distribution of snow within catchment, energy, and mass balance components.

Any change in hydrological cycle altering implications of climate change, Glaciers are retreating, ice sheets are melting and collapsing, and early snowmelt is augmenting warming rates. Water has the property to move in a hydrological cycle in which it is moved throughout the Earth as it is taken in by plants and animals, condensed and precipitated, infiltrated, as well as by other processes. One of the most significant impacts of climate change is predicted to be shifts in storm intensities, a rise in sea level, and increasingly rapid snow and ice melt.

The runoff generated from the melting of glaciers plays a vital role on the rivers of the highland areas worldwide such as the Alps and the Himalayas and ensures the continuous availability of streamflow for hydropower projects. The snow and glacier melt runoff is considered as highly dependable flow and used for irrigation, drinking water, and generating hydropower particularly during summer, when demand is at peak for power and irrigation. It has been demonstrated that glaciers act as natural frozen reservoirs in the upper part of the basin and provide flows in a regulated manner for the operation of base load and peaking hydropower projects and fresh water supply in lowland areas.

Seasonal and diurnal variations

The presence of snow and glaciers in the upper part of the basins form a unique reservoir of fresh water. For example, in the Himalayan region, glacier meltwater supports rivers such as the Indus, the Ganga, and the Brahmaputra, which are the lifeline of millions of people. The water flowing in these Himalayan rivers is a combined flow from rain, snow, and glaciers. Snow and glacier runoff plays a vital role in making all these rivers perennial, whereas the rainfall contribution during monsoon period is critical for storages in various reservoirs. The summer and spring runoff, comprising mostly of snow melt and glacier melt is a source of water for irrigation, hydroelectric power production, and drinking water supply. Meltwater replenishes stock ponds, infiltrates the soils, and recharges the ground water. The runoff generated from the ground water storage becomes important during the lean season. The water yield of a high Himalayan basin is roughly double that from an equivalent basin area located in the peninsular part of India. This higher water yield is mainly due to the large inputs from the snow and glaciers.

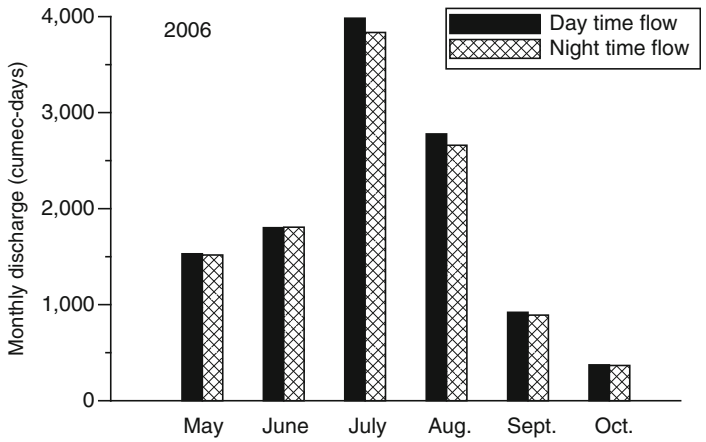
Diurnal variation in streamflow generated from snow and glacier covered part of the basin provides an

understanding of drainage processes of the basin. The daily cycle of solar forcing yields major changes in snow and glacier melt and streamflow over the course of each day, and the difference between the time of highest melt rate and the time of peak discharge provides a measure of average runoff travel times through the river basin.

Discharge variation consists of a cycle of rising and falling flow superimposed on baseflow. A variation in discharge in a glacier-fed river occurs on hourly, daily, and annual cycles based on the prevailing weather systems. The pattern of hydrographs for different years shows very clearly that discharge starts increasing from May onward, reaches its maximum in July and August and after that it starts reducing. Both limbs of hydrograph are almost flat during early and later part of melt season. Rising and falling limbs of the hydrograph become steeper with advancement of the melt season but the rising limb of the hydrograph is always steeper than the recession limb. Such diurnal variations in hydrograph with season can be explained by the changes in physical features of the basin with time.

Runoff delaying and storage characteristics

The runoff from snow and glacier covered basins is mostly temperature controlled and behaves similarly to regulated flow from a water storage. A good estimation of runoff from such basins is very useful for the operation of run-of-the-river hydro projects. Snow and ice storage works as a natural frozen reservoir in the basin, which gradually releases the flow. During the summer period, in the glacier-fed streams only a portion of the meltwater produced each day emerges as runoff from the snout of the glacier on the same day. The remaining meltwater is stored within the glacier. Thus, a considerable contribution to streamflow is received from the meltwater stored in the glacier. Even at diurnal cycle, the runoff also contains a part of this stored meltwater. This shows that the streamflow of a glacier-fed stream is controlled by storage characteristics of the glacier and determined by delayed response of the basin. The size of the glacier, extent of snow cover, depth of snow over the glacier, and drainage network of the glacier are important factors that control the flow rate and volume of the water emerging as runoff. The discharge time response is also a function of the ablation and accumulation area ratio. Runoff dominated by meltwater from the accumulation area has a longer time of concentration as compared to the meltwater generated in the ablation area. The meltwater storage characteristics of two glaciers have been studied using continuous hourly discharge data. Daily (24-h) streamflow records have been subdivided into daytime flow (09:00–20:00 h) and nighttime flow (21:00–08:00 h). Monthly daytime and nighttime discharges for summer months for Gangotri Glacier in Garhwal Himalayas (Haritashya et al., 2006; Singh et al., 2010) are shown in Figure 1. The magnitude of the streamflow during daytime and nighttime indicates that the volume of the nighttime flow is comparable with the daytime flow. Such trends of the daytime and nighttime flows are observed for all the years. As such, very little or no melting takes place on the glacier surface during the night period, but still a high amount of discharge is observed in the stream during the nighttime. It shows that meltwater produced during the daytime is partly stored in the glacier and released later, while such trends in the rain-fed rivers do not exist. This analysis suggests that meltwater storage characteristics of the glacier are much stronger in the early part of the melt season and reduces as the melt season develops. Trends of variations in the ratio of daytime flow to nighttime flow with melt season can be explained on the basis of availability of snow cover on the glacier body and progressive development of the drainage network in the glacier. The greater extent of snow cover in the early part of the melt season along with a poorly developed drainage network amounts to a more delayed response of the meltwater from the basin to the outlet, resulting in reduced difference between daytime and nighttime streamflows. Reduction in the extent of snow cover area and progressive development of



Glacier Hydrology, Figure 1 Monthly distribution of daytime and night time observed discharge near the snout of Gangotri Glacier (Uttarakhand) for summer 2006.

a drainage network with melt season also attribute to a faster response of meltwater in mid or late melt season, which also increases the difference in the daytime and nighttime flows.

GLACIER LAKE OUTBURST FLOODS

Lasafam Iturrizaga
Department of Geography/High Mountain Geomorphology, Institute of Geography, University of Göttingen, Göttingen, Germany

Synonyms

Aluviones; Débâcles; Glacial outwash floods; Gletscherlauf (German); Jökulhlaup (Icelandic); Megafloods and superfloods (Quaternary large-scaled glacier floods)

Definition

Glacier lake outburst floods (GLOFs) refer to sudden and in some cases cyclic release of meltwater from a glacier-dammed or moraine-dammed lake, which can result in a catastrophic flood. Thorarinsson (1939) introduced the term "jökulhlaup" for glacial floods due to the cataclysmic drainage of subglacial lakes in Iceland. It was originally referred to outburst floods triggered by volcanic activity and has been subsequently transferred to a variety of other types of glacial floods. It has become a widely used synonym for describing catastrophic glacial floods in general.

The size of glacial lakes varies considerably and the lakes may hold up to tens of millions of cubic meters of water. Glacier lake outbursts produce flows of water that may be an order of magnitude greater than average rainfall-derived peak flows. Geomorphological impacts and damages of infrastructures can occur up to tens to hundreds of kilometers downstream. Their competence and capacity is high enough to transport large amounts of debris, so that they may occur as hyperconcentrated flow or even debris flow. Catastrophic dam failure may release the reservoir water over a time span of hours to days. Peak flows as high as 30,000 m^3 have been recorded for moraine-dammed lakes, but they are much higher for glacier-dammed lakes. In case the discharge exceeds a flood volume of about $>10^6$ m^3 or peak discharge $>10^6$ m^3/s (Martini et al., 2002; Korup and Tweed 2007) glacier lake outbursts are termed as megafloods. These extremely large paleofloods, which occurred mainly during the end of the Pleistocene, were also termed as superfloods (Rudoy, 2002). Glacier lake outbursts may be caused by different kinds of dam failures depending on the type of natural barrier (Clague and Evans, 1994; Tweed and Russell, 1999). Floods resulting from glacier lake outbursts may pose a severe threat to settlements and their infrastructure. As the spatial interconnection of glacier areas and sedttlement zones has generally increased in the last decades, new concepts and technologies in hazard assessment, evaluation, and mitigation have been developed (Richardson and Reynolds, 2000a, b; Huggel et al., 2004; Kääb et al., 2005a, b; Allen et al., 2009).

Introduction

Glacier lake outbursts have contributed to the largest flood events worldwide and caused large-scaled geomorphological landscape transformations with specific landform assemblages. Glacier lakes generally occur in all glaciated landscapes in different varieties and with specific trigger mechanisms in terms of their catastrophic outbursts. The appearance of glacier lakes and associated floods provide landscapes to study Pleistocene, Holocene, and historical glaciation extent and is therefore an important paleoclimatic key indicator for reconstructing landscape environments and past climate. Moreover, the formation of glacier lakes and subsequent outbursts provide an obvious indicator for glacier dynamics and fluctuations. A striking shift in the distribution pattern of glacier lakes has occurred in the course of the general worldwide glacier recession during the twentieth century. In many glacierized areas, the glacier wastage produced an increase in the number of glacier lakes and lead consequently to an aggravation of the glacier hazard situation of the more and more densely populated glacier forefields and forelands. This is especially true for glaciers that are exploited economically in terms of irrigation and hydropower. Therefore, research on the controlling factors on the development of glacier lakes and glacier lake outbursts in regard to hazard mitigation has increased exponentially in the last decade. Nevertheless, in some regions the glacier recession has caused the disappearance of glacier lakes and produced a decline of glacial flood inundations.

Extensive review papers have been written on different topics of glacier lakes and outbursts (Blachut and Ballanytyne, 1976; Tweed and Russell, 1999; Herget, 2003) providing preferentially case examples from the higher latitudes. This entry gives an overview of the main types of glacier lakes with a special emphasis on lakes in high mountain regions, i.e., on floods occurring in more confined valleys. Glacial lakes are generally impounded either by a glacier or by a moraine or they occur in proglacial depressions caused by glacial overdeepening in the bedrock or sediment. The source area of the lake water may be the meltwater of the damming glacier or the adjacent glaciers. At temperate glaciers, large amounts of meltwater originate as well from basal melting

(Benn and Evans, 1998). The lake size ranges from several square meters up to a million of square kilometers. In principle, three different types of lakes are distinguished: (a) glacier-dammed lakes, (b) moraine-dammed lakes, and (c) internal glacial lakes. Internal glacial lakes (englacial and subglacial) have been discussed elsewhere in this encyclopedia.

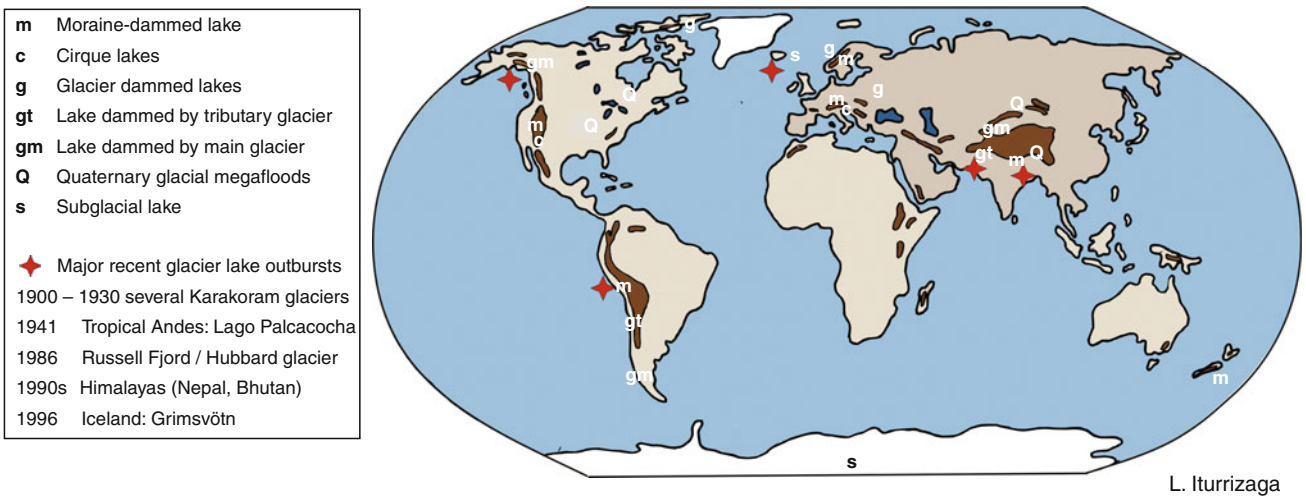
Worldwide distribution of glacier lakes prone to lake outbursts

Recent glacier-dammed, moraine-dammed, and internal glacial lakes arise at different scales in the glacierized landscapes of all geographical latitudes. In this regard, regional individual distribution patterns are recognizable (Figure 1). They are a response of the glacier type and therefore of the climatic-controlled nourishment conditions of the glacier, the glacier size, the topographical conditions, and the debris transfer system.

In the Tropics, moraine-dammed lakes occur especially in the Peruvian Andes in the Cordillera Blanca (Huascaran Massif) (8°–10°S) (Ames, 1998). In particular the small, clean-ice glaciers have shrinked rapidly in the last decades due to the fact that they are subject to a all-season ablation regime in the lower glacier parts (Kaser and Osmaston, 2002). In the course of the twentieth century, some of the most devastating glacier lake outbursts have occurred in this region (Carey, 2005; Vilímek et al., 2005). In the inner Tropics, North of 8°S glacier lakes are mostly absent. The topographical preconditions on the steep-sided volcanoes with their small mountaintop glaciations prove to be unfavorable for the formation of moraine and glacier-dammed lakes.

A further distribution area of moraine-dammed lakes is located in subtropical latitude between 28°–34°N in the Himalaya Range, especially in Nepal, Bhutan, and China. The Environmental Programme of the United Nations (UNEP) and the International Centre of Integrated Mountain Development (ICIMOD) have monitored 2,323 glacier lakes in Nepal (Mool et al., 2002a, b). In contrary, in the westward adjacent Karakoram (35–36°N) glacier-dammed lakes are the main type of glacier lakes, mainly generated by advancing tributary glaciers (Hewitt, 1982; Iturrizaga, 2005a, b, c). High-magnitude glacier floods occurred especially at the end of the Little Ice Age until the 1930s. Even nowadays, glacier lake outbursts happen, but to a far lesser extent. In the mid latitudes, such as in the European Alps or the Canadian Rockies with a comparative smaller glacierized area and shorter glaciers, moraine-dammed lakes and numerous new cirque lakes have formed in overdeepened rock and sediment basins (e.g., Trift glacier, Swiss Alps). Another principal distribution area of glacier-dammed lakes is located in the high latitudes (about 60°N) in Alaska (e.g., Abyss Lake) (Post and Mayo, 1971; Stone, 1963; Sturm et al., 1987). The often dendritic trunk glaciers impound the meltwater of their retreating tributary glaciers. Further ice-dammed lakes can be found in Greenland (Russell, 2007) and to a lesser extent in Norway (Howarth, 1968; Knudsen and Theakstone, 1988; Russell, 1994; Breien et al., 2008).

In regard to the hypsometric distribution, glacier-dammed lakes occur from sea level in polar regions up to the high altitudes of the extreme high mountain areas. The largest lakes are located mostly up to 1,500 m below the equilibrium altitude line (ELA), where the meltwater of extensive catchment areas may be impounded by the natural dams. The moraine-dammed lakes arise commonly in the lower part of the ablation area of the glaciers. Some of the highest moraine-dammed lakes appear in the Chinese Himalayas at 5,700 m a.s.l. (Longbasaba and Pida lakes, Xin et al., 2008). The different thermal regimes of



Glacier Lake Outburst Floods, Figure 1 Recent worldwide distribution of glacier lakes and potential glacier lake outbursts areas as well as key localities of Quaternary megafloods. Internal glacier lakes (supraglacial, englacial, subglacial) may exist at all glaciers causing catastrophic floods.

the glaciers (cold and temperate glaciers) have different characteristics for lake formation and corresponding outburst mechanisms.

Quaternary glacier-dammed lakes (megafloods)

Glacier lake outbursts originating from glacier-dammed lakes have contributed to the largest and geomorphologically most significant flood events in the Quaternary (O'Connor and Costa, 2004). During the outbursts of megafloods, gigantic landscape transformations have taken place in only a few hours or days similar to volcanic eruptions, tsunamis, or earthquakes.

After an initial disagreement with the scientific main stream, the reconstruction of the Missoula Flood in North America by Bretz (1923) got widely accepted (Baker et al., 1988). The Missoula Flood area has become a key locality for the landform assemblages of cataclysmic floods. At the end of the Pleistocene before about 16 ka, a southern ice lobe of the Laurentide Ice Sheet impounded during the Wisconsin-Glaciation the Clark Fork River. The maximum lake volume of the Lake Missoula amounted up to 2,184 km^3 with a lake depth of 635 m at the ice dam (Baker and Bunker, 1985). Repetitive lake outbursts showed peak discharges in the order of about 17×10^6 m^3/s (for comparison the Amazonas has a discharge of 370,000 m^3/s, 1953). The Missoula Flood left behind characteristic landforms consisting of (a) erosional forms (Scabland topography, Bretz, 1923) (e.g., cataract complexes, dry falls, spillways, cavitations, P-forms, shorelines) as well as (b) depositional forms (expansion, longitudinal, point and pendant bars, eddy bars, slackwater deposits, and giant or mega ripples).

A Holocene proglacial lake formed at the southern margin of the Laurentide Ice Sheet before about 12 ka, the Lake Agassiz (Clarke et al., 2003), which covered an area of about 1 Mio. km^2 with a water volume of 163,000 km^3 (Teller et al., 2002). The lake drained catastrophically at 8.45 ka into the Hudson Bay. The glacier lake outbursts supposed to be one of the main trigger of the 8.2 ka cooling event. The incoming fresh water from the ice-dammed lake caused a desalinization of the North-Atlantic and lead to the subsequent collapse of the Gulf stream (Clarke et al., 2003). This event accelerated the debate of climate change.

Glacier lakes occurred during the early and middle Weichselian (90–80 ka) and (60–50 ka) at the ice front of the Scandinavian Ice Sheet in Western Russia as well as at the southern margin of the ice sheet, which covered parts of the Barents and Kara Lake (Grosswald, 1980; Mangerud et al., 2004) outreached by far the size of present glacial lakes. It is assumed, that their outbreak had a significant impact on the sea ice formation in the Arctic Ocean and on the regional climate.

A different type locality for the outbreak of glacier-dammed lakes is situated in the Altai Mountains (Southern Siberia) (Baker et al., 1993; Rudoy, 2002; Carling et al., 2002). A glacier dam, 15 km long and several kilometers in width, impounded repetitively the drainage of the Chuja and Kuray Basins and formed a glacial lake (607 km^3) with a maximum depth of 650 m at the ice barrier. The last cataclysmic glacier lake outbursts happened 13 ka during ELA-depressions of 800–1,200 m. The lakes were still in existence about 5 ka. These glacial superfloods had a discharge of about 18×10^6 m^3/s and boulders with a diameter of 11 m have been transported. The outburst landscape is similar to that of the Missoula Flood. Moreover, huge fluvial gravel dunes or megaripples (giant current ripple relief) have been deposited in the Chuja Basin, which are up to 23 m high and 320 m long, and giant diluvial ramparts and terraces-bars (Photos 1 and 2). Interestingly, the landforms have been previously mistaken for glacial deposits. The reconstruction of megafloods in North America and

Siberia has been the base for interpreting landforms of paleofloods on Mars (Baker, 2001; Fairen and Dohm, 2003).

In the extreme high mountain ranges, such as in High Asia, the number of glacier dams may have been higher than today during the deglaciation of the Last Glacial Maximum (LGM) and during Postglacial times. This is shown by expansive lake sediment sequences throughout the Karakoram valleys (Paffen et al., 1956; Owen, 1996; Cornwell, 1998), such as Lake Guricot in the Astor Valley (Scott, 1992), the Malungutti lake in the Shimshal valley (Iturrizaga, 2005c) and in the lower Chapursan valley (Iturrizaga, 2008). Already in the end of the nineteenth century, glacial lake outburst floods have been discussed as transport agent for the "Punjab erratic boulders" located in the Peshawar Basin at altitudes of only 300–400 m a.s.l. (Cornwell, 1998). As source area of these boulders has been considered a 750 m high ice dam, the Darel-Shatial-moraine in the Indus valley at about 900 m a.s.l. (Bürgisser et al., 1982; Burbank, 1983; Desio and Orombelli, 1983; Shroder et al., 1989; Cornwell, 1998), which would be one of the largest Pleistocene ice barriers in High Asia. In the basin of Chilas, megaripples have been identified (Shroder et al., 1989). However, not only ice-dammed lakes have produced high-magnitude floods in the Indus valley but also landslides, such as the Lichar landslide in 1841, close to the western side of the Nanga Parbat area, 30 km south of Bunji, which reached down to 300 km south of Attock (Shroder, 1993). This fact makes it rather difficult to unravel the source areas of specific flood deposits. In this regard, it has been argued that many of the dams considered as glacier dams, such as the 600 m high Katzarah glacier dam (Dainelli, 1922), were not stable enough to impound a lake of a size of over 170 km. It is doubtful that ice dams provide the conditions for the undisturbed deposition of lake sediments of the size of several hundred meters in thickness (Hewitt, 1998). According to this argument, the existence of rock avalanche barriers is more likely than glacier barriers. The lakes in High Asia have been much smaller in size than those described from Northern America and Northern Eurasia, but due to the high relief energies the outburst floods might have had a tremendous geomorphological impact.

Megafloods have been as well proposed for the outlet glaciers of the Pleistocene (LGM) south Tibetan ice sheet between Cho Oyu and Shisha Pangma (Kuhle, 2002). New field evidence showed further Holocene moraine dams, which may have caused giant (1,011 m^3) lakes with a maximum depth of 680 m in the Tsangpo River gorge in Tibet (Montgomery et al., 2004) with peak discharges higher than the Missoula and Altai floods.

Glacier-dammed lakes

Glacier-dammed lakes may be impounded by the trunk and tributary glacier in different topographical constellations or by small lateroglacial ice lobes. They are also known as ice-dammed lakes in the literature (Blachut and Ballantyne, 1976; Tweed and Russell, 1999). However, glacier barriers of the subtropical high mountain regions are characterized by a high content of debris incorporated in the supraglacial and lateral moraines. This debris material plays a vital role in the mechanics of the glacier lake outbursts and during the subsequent flood events. Therefore, the initial water flood may transform into a hyperconcentrated flow and finally in some cases into a debris flow. For this reason, the superordinated term "glacier-dammed lake" is used, to which the ice-dammed lakes are subordinated. The latter occurs mainly in high latitudes in moderate to low mountain relief with comparatively little glacial sediment transfer. Glacier-dammed lakes are in most cases a reaction of glacier front oscillations and form generally during periods of glacier advance. On a wider time scale, they occur especially during the wastage of an ice-stream network in the transition to individual valley glaciers (Figure 2).

Glacier-dammed lakes are at present time comparatively short-lived and survive often only several months or years. Therefore, lake sediments are rarely deposited. The lake basins fill up rather quickly. Subsequently, a catastrophic drainage may occur. They empty commonly in summer time at the period of highest meltwater discharge.

Types of glacier dams

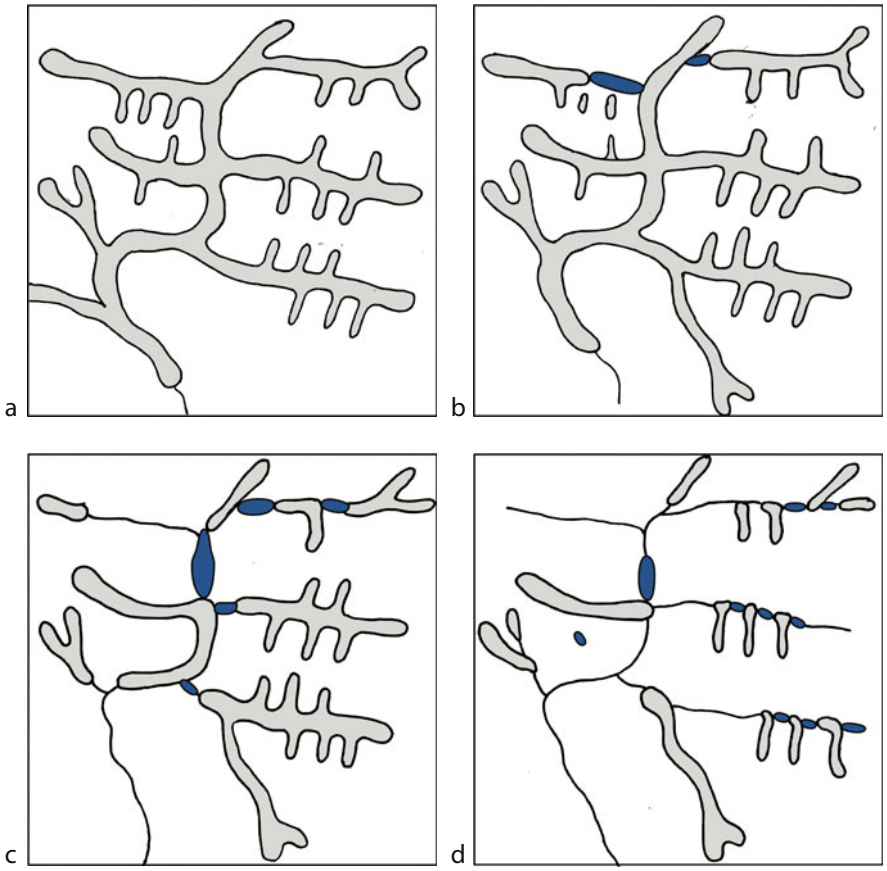
Tweed and Russell (1999) have summarized the existing classifications of types of glacier-dammed lakes in regard to their topographical settings (Maag, 1969; Blachut and Ballantyne, 1976; Costa and Schuster, 1988) and added the subglacial calderas and englacial or subglacial water bodies as result of volcanic activity.

In principle, the following main categories of glacier dams are differentiated representing the source areas for most of the present glacier lake outbursts.

Tributary glacier dam

A tributary glacier advances into the trunk valley and impounds the river converting it into a lake (Photos 3 and 4). The length of the cross-valley barrier amounts generally not more than 1–2 km with an absolute height of about 250 m. The lowest point of the glacier barrier is located in the contact zone of the glacier tongue and the adjacent valley flank. This is the locality, where the dam may fail in different ways. During a long-lasting glacier terminus position, the glacier may be framed by lateral moraines, which then are an important part of the glacier dam. In case of a glacier advance, the glacier tongue is commonly heavy crevassed. The lateral moraine acts as an additional and rather impermeable barrier.

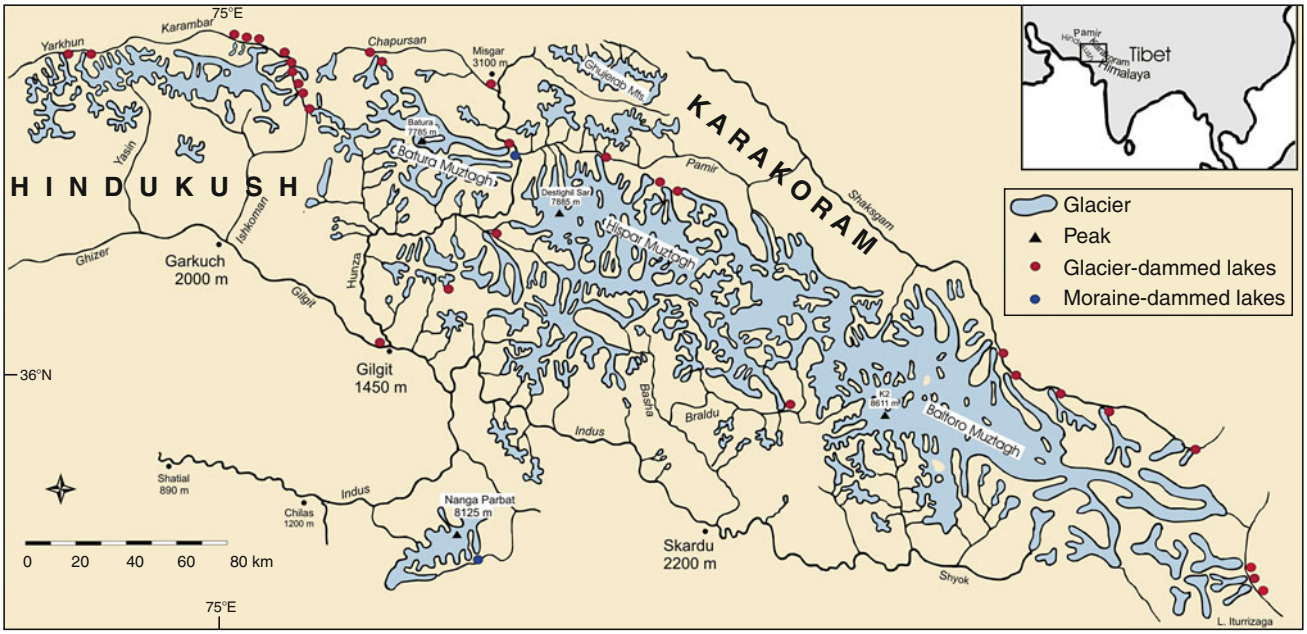
At present time, tributary glacier barriers are widely distributed in the Karakoram and Hindukush Mountains (Figure 3), which show the greatest glaciation with the longest valley glaciers outside of the polar region. The LGM-ice-stream network (Derbyshire et al., 1984; Kuhle, 2001) has disintegrated into numerous valley glaciers during the deglaciation, which are as long as 72 km (Siachen glacier).



Glacier Lake Outburst Floods, Figure 2 Disintegration of an ice-stream network (**a**) into individual valley glaciers and the transition from main valley glacier-dammed lakes (**b**) to tributary glacier-dammed lakes (**d**). Stage (**c**) shows transitional forms of tributary glacier lakes and proglacial moraine-dammed lakes (double dam formation, cf. Figure 10).

Glacier Lake Outburst Floods, Photo 3 Glacier dams in the Karakoram Mountains. The Khurdopin glacier (47 km long) has been notorious for glacier lake outburst in the twentieth century. The photo shows the 3 km long debris-covered glacier tongue and the Virjerab lake basin. The Virjerab river drains even today subglacially (Photo: L. Iturrizaga, 18.07.2001).

Glacier Lake Outburst Floods, Photo 4 Multiple glacier dams in the Hindukush Mountains. The Chillinji glacier has blocked the Karambar valley about 100 years ago. The glacier tongue is surrounded by up to 250 m high lateral moraines. During dam failure the moraine material is transported with the flood waters causing in some cases hyperconcentrated flows. Most of the Karakoram and Hindukush glaciers are avalanche fed glaciers and highly dynamic (Photo: L. Iturrizaga, 09.2002).



Glacier Lake Outburst Floods, Figure 3 Distribution of glacier-dammed lakes in the Karakoram and E-Hindukush Mountains.

In historical times, about 22 tributary glaciers formed glacier-dammed lakes in the upper Indus catchment area, from which 12 dams were responsible for outburst floods (Hewitt, 1998). Since 1826, 35 glacier lake outbursts have been monitored (Hewitt, 1982), although this number only includes a small selection of past flood events. Two localities were notorious for glacier lake outbursts in the last two centuries: the tributary glaciers of the Shyok valley (East Karakoram) (Mason, 1935; Hewitt, 1982; Feng Qinghua, 1991) as well as side glaciers of the Shimshal valley (North West Karakoram) (Iturrizaga, 1997, 2005c) (Figure 3, Photo 3). The topographic setting is at the current stage of glaciation in the Hindukush–Karakoram region favorable for the formation of this dam type: Tributary glaciers with catchment areas of over 7,000 m in height descend down to low altitudes below 3,000 m into the glacier-free trunk valleys and block temporarily the main river. A remarkable large number of glaciers terminate at confluence positions. Among them occur a lot of white, transversal glaciers in N-aspect. The Karakoram rivers show discharge rates of up to 1,000 m^3/s (Ferguson, 1984). Therefore large-sized lakes, several kilometers in length, may be impounded in a short time period. Lake volumes of up to 3.3×10^9 m^3 are reported from prehistorical glacier dams (Hewitt, 1982). In this region, a seasonal pattern dominates the outburst chronologies. The failures of glacier-dammed lakes mostly occurred between July and August during the time of the highest discharge. Most of the dams fail periodically with irregular possible return intervals of about 1–2 years. The lakes often drain in successive years due to internal changes in the ice barrier itself.

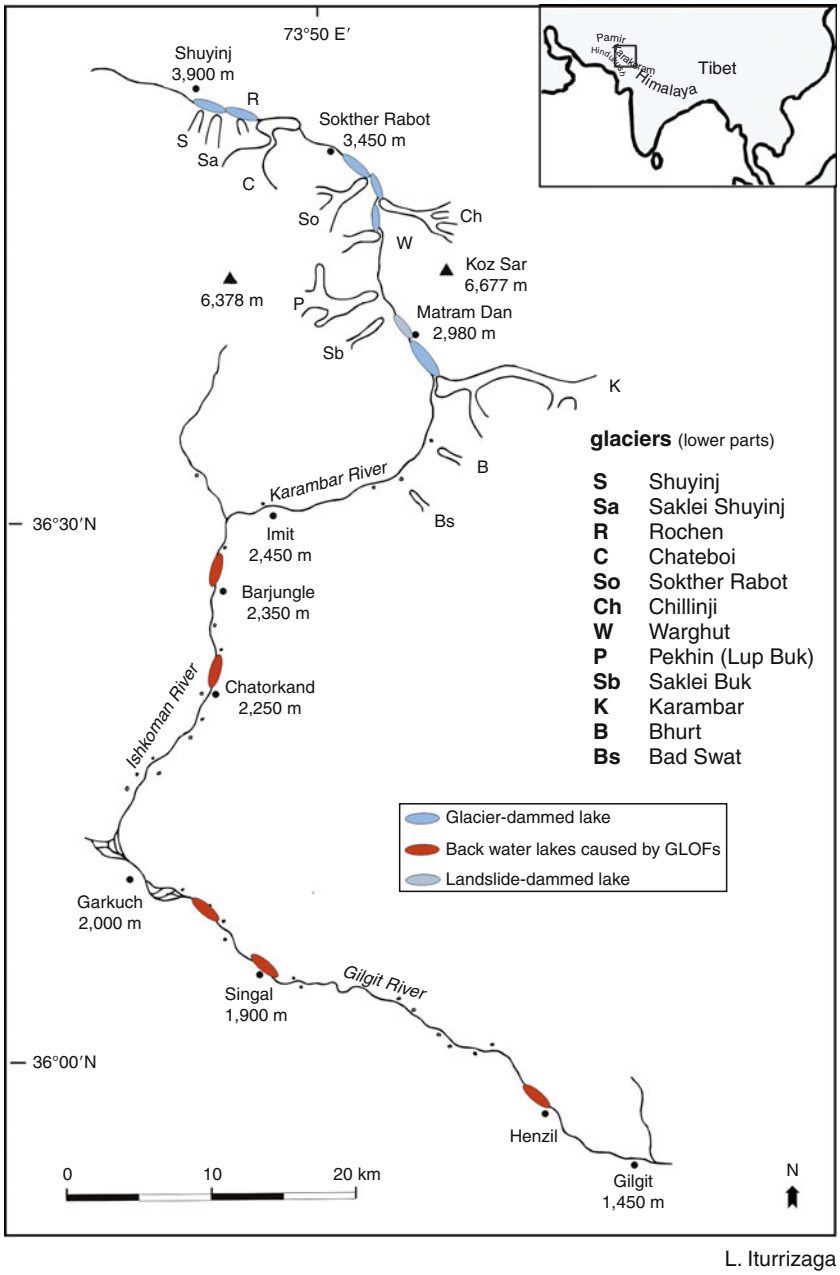
In some valleys, numerous tributary glaciers have formed glacier barriers in the same main valley, so that several glacier lakes may have existed synchronously (Figure 4). In this topographical constellation, an outburst of an upstream-located glacier lake may have triggered the sudden drainage of a lower glacier lake and therefore induced a glacier lake outburst cascade (Iturrizaga, 2005b). Moreover during those flood events, backwater lakes may form further downstream at valley constrictions (Figure 4). In the Karambar valley (Hindukush) at several locations, even about 100 km downward of the glacier dam, backwater lakes developed (Iturrizaga, 2006, Figure 5).

Glacier-dammed lakes are often formed rather spontaneously by surging glacier (Iturrizaga, 2011). In the Aconcagua Mountain Range (Argentinean Andes), the Grande del Nevado Glacier (8 km long), terminating at 3,165 m and flowing down from Cerro de Rio Blanco, has impounded the Rio Plomo and transformed it into a lake, measuring 60×10^6 m^3 in size (Helbig, 1935; Espizúa and Bengochea, 1990). The outbreak in January 1934 produced a flood wave with a run-out-distance of 150 km. In 1984/1985, the Grande del Nevado Glacier has advanced about 2.7 km in less than in 2 months leading to a lake with a surface of over 3 km^2 (Espizua and Bengochea, 1990).

Main valley glacier dam

A main valley glacier barrier blocks the discharge of one or more of its surrounding glaciers in its catchment area.

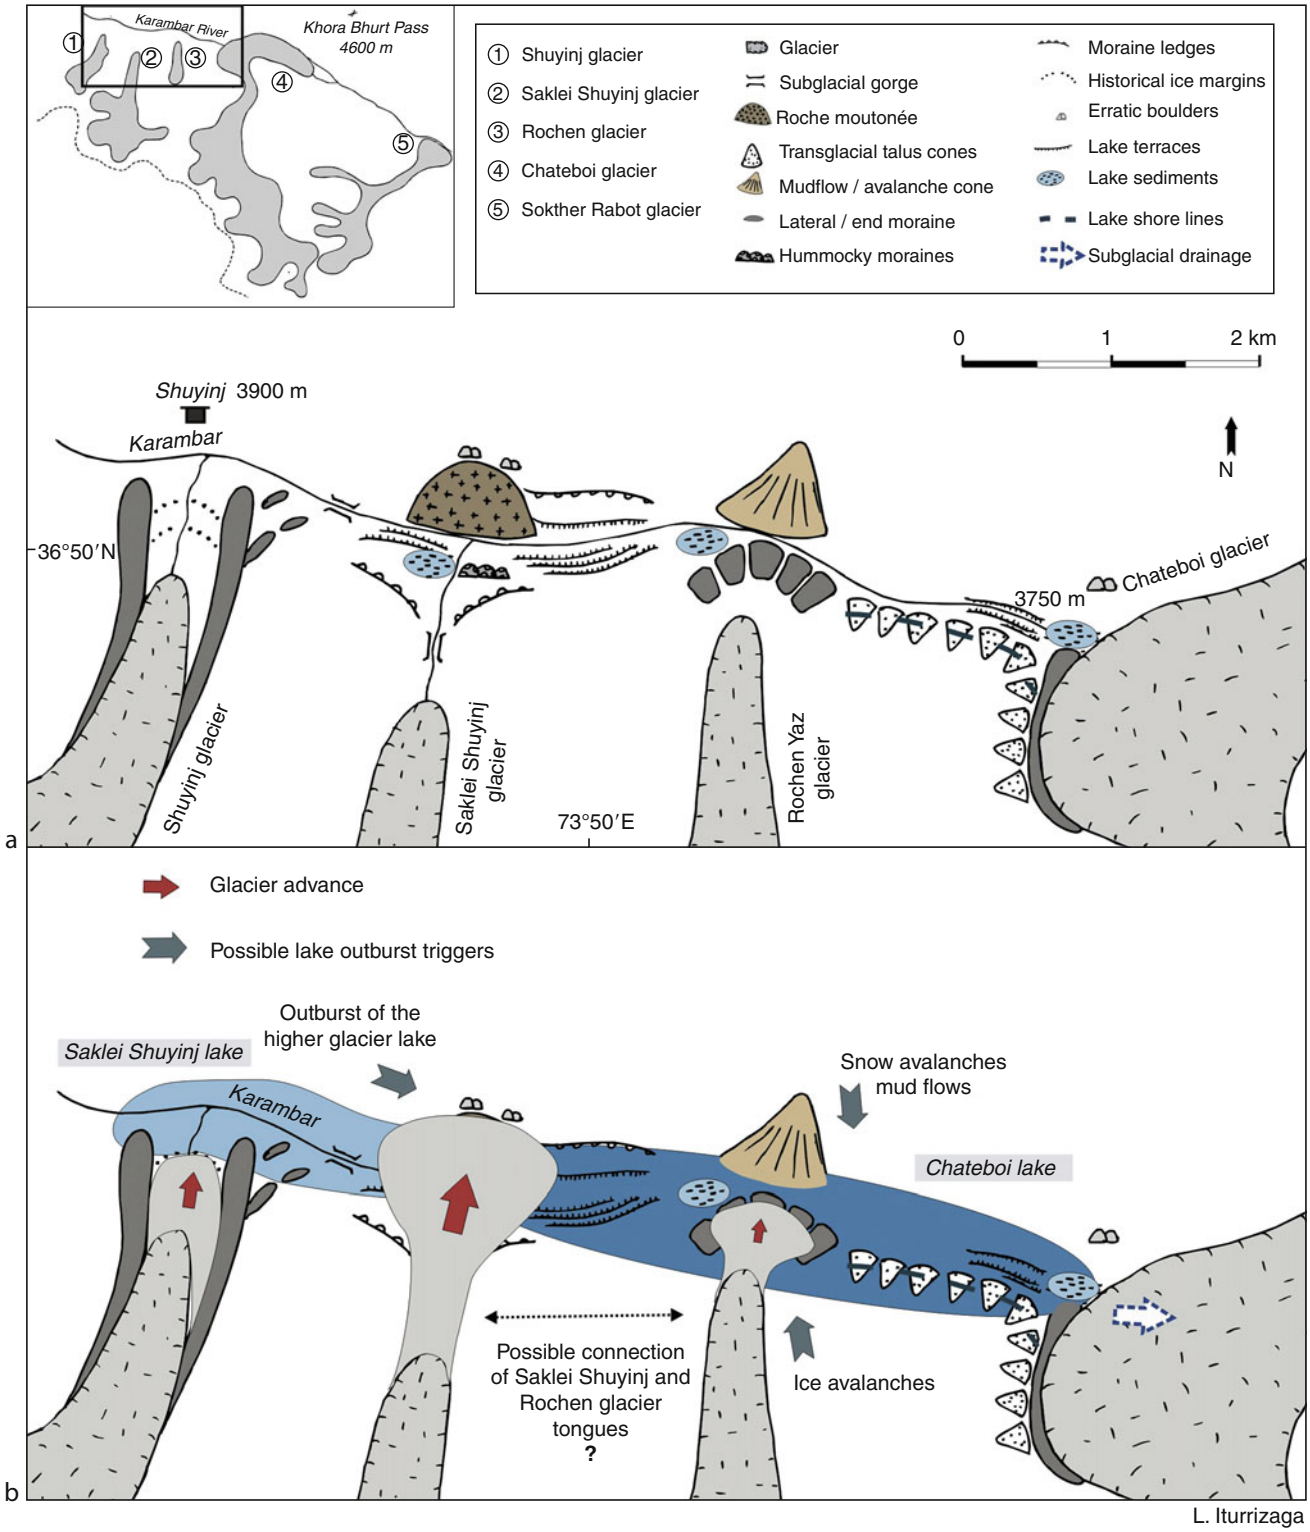
1. This may be the case when a tributary glacier recedes from a dendritic main glacier (e.g., Tulsequah Glacier



Glacier Lake Outburst Floods, Figure 4 Multiple glacier dams in the Karambar valley in the Hindukush Mountains.

Lake, 195 m in depth, British Columbia, Marcus (1960), Inyltschik glacier, Merzbacher Lake, Tienshan with a depth of 130 m, a length of 4 km, and a width of about 1 km, Mayer et al., 2008). The main distribution area of the glacier dam type is located in Alaska, where over 750 glacier lakes have been monitored (Stone, 1963). The glacier tongues terminate often at sea level and are formed by tidewater glaciers. In case of potential glacier lake outbursts, the run-out-distances are comparatively little. The ice-dammed Lake George (65 km^2), 50 m in depth, impounded by the Knik glacier, east of Anchorage in the Chugach Mountains, showed large annual outbreaks from 1918 to 1967 (Post and Mayo, 1971; O'Connor and Costa, 1993) as a result of downwasting of the ice barrier. Its lake basin is (Inner Lake George) created by an end moraine from the tributary glacier, named Colony glacier. The end moraines are deposited against the lateral margin of the ice barrier of the Knik glacier.

A well-known example from the Alps for the main valley glacier dam is the Lake Märjelen (2,350 m a.s.l.), which was impounded by the longest glacier of



Glacier Lake Outburst Floods, Figure 5 Glacier-dammed lake formation by small tributary glaciers in the upper Karambar valley (Hindukush).

the Alps, the Aletsch glacier, at its margin. It is a transitional form between a lake dammed by the main glacier and a lateroglacial lake. About 25 glacier lake outbursts occurred in-between 1816 and 1896 and devastated the Massa valley downvalley.

2. A main valley glacier barrier may also be formed by the advance of the main glacier, sealing off the discharge of the less or non-glaciated side valleys that show mostly lower catchment areas. This type of glacier barrier is at present rather rare.

Lateroglacial glacier-dammed lakes

At some glaciers, small ice lobes form at the glacier margin in times of irregular ice flow are known as ice-marginal lakes. However, in order to define the lateral location and excluding the proglacial location, the term "lateroglacial" had been introduced (Iturrizaga, 2003, 2007). These ice lobes may in turn block the creeks of the lateroglacial valleys, which flow parallel to the glacier. These lakes mostly drain subglacially through the main glacier. Due to their small volume they do not generally generate high-magnitude floods, but nevertheless they are hazardous.

A special case are lakes that are caused by ice avalanches (Gietro Glacier, European Alps), which may reform as regenerated glaciers at the base of the mountain. In 1595, an outburst flood killed about 140 people in the Val de Bagnes (Tufnell, 1984).

Trigger mechanisms for dam failures of glacier-dammed lakes

Commonly glaciers experience a variety of trigger mechanism, such as fluctuations in ice-dam thickness and length and varying water supply. The initial dam failure often takes places by sub- and englacial gradual widening of the internal glacial conduits due to frictional heat and erosion (Nye, 1976) or by flotation of the ice dam (Thorarinsson, 1939). A variety of trigger mechanisms have been discussed. Most of the assumptions are rather theoretical for the individual glacier lake outburst as direct observations of dam failures are extremely seldom. Trigger mechanisms for dam failures have been mainly described on the base examples of glaciers of higher latitudes. The following listing provides an overview about the main causes of dam failure (Tweed and Russell, 1999):

Simple overspilling

When the lake depth overtops the glacier barrier, supraglacial drainage may take place. Predestined for processes of overspilling of the dam are cold-based glaciers, which are frozen to their glacier bed and characterized by a dry and dense ice, so that they are more impermeable for water (Liestøl, 1956). Moreover, a high debris content of the glacier supposed to be favorable for increasing the density of the glacier and preventing flotation processes (Knight, 1999). Highly crevassed glaciers, which are very common among advancing glaciers, are unfavorable for this outburst mechanism. Overspill processes may be generated by mass movements falling into the glacier lake and causing subsequent displacement waves.

Hydrostatic flotation of the glacier dam

Hydrostatic flotation of the glacier dam is a function of the specific density of glacier ice and water and may be altered by the debris content in the glacier ice. The buoying effect of the ice takes place when the water column of the lake has reached about 90% of the height of the glacier dam (Thorarinsson, 1939). The presence of debris may influence this process, as it increases the density of the ice. Subglacial hollows, which develop under thin glaciers especially at obstacles, may be opened and act as major drainage pathways. After the uplift of the ice barrier, a progressive base water flow occurs at the glacier bed. The emptying of the lake is dependent on the transport capacity of the subglacial channel. The process of flotation was described in detail for the subglacial lake drainage at Grimsvötn in Iceland (Thorarinsson, 1953).

GLEN mechanism

The GLEN mechanism (Glen, 1954) is based upon the assumption that the water pressure of the lake may deform the glacier ice and therefore creates or opens drainage channels at the base of the glacier through the ice, whereby frictional melting processes are involved. At a certain critical height of the water column, the horizontal stress exceeds the vertical stress by the amount of P.

$$P = (pw - pi)\, gh$$

where pw is density of the water, pi is density of the ice, g is gravitational acceleration, and h is height of the water column.

The critical height has been controversially discussed, but generally it is assumed that a height of 150–200 m (Glen, 1954) is necessary for plastic deformation of the glacier ice to operate at the base of the glacier.

Subaerial breach-widening

During the process of subaerial breach-widening, the glacier dam ruptures suddenly or is detached from the adjacent valley flank. Subaerial breach-widening is supposed to be a common outburst trigger in the European Alps (Häberli, 1983) and at glaciers in Alaska (Stone, 1963). It mainly occurs at tributary glaciers that have advanced into main valley. The melting may take place in the contact zone between rock and ice (Walder and Costa, 1996). After the dam break, typically a short, but high-magnitude flood is released from the lake.

The break of the Chong Khumdum glacier in the Karakoram is a case example for a sudden break of the dam (Hewitt, 1982), even though the drainage has been initially started through subglacial drainage conduits.

Subglacial volcanic activity

Subglacial volcanic activity may generate subglacial geothermal heat leading to a thinning of the ice dam or warm

up of the lake water. Moreover, it may accelerate the melting of englacial and subglacial drainage tunnels. A volcanic eruption destabilizes the glacier barrier or even may disrupt it completely (Björnsson, 2003; Magnús, 1997).

Siphoning effect

The mechanism of siphoning at glacier dams is based on changes in water pressure conditions in an existent sub- and englacial drainage system within the glacier barrier (Whalley, 1971) with that the glacier lake is connected. The siphoning process is launched, when the water pressure in the lake exceeds the water pressure of the drainage system. The difference in hydrostatic pressure results in a kind of pull effect caused by the subglacial drainage system. Subsequently, the lake is emptied through the internal conduits in the glacier. At the end of the ablation area, the pressure in the englacial drainage channels is to be lesser than in the lake and the lake may be initiated to drain. It is assumed that the drainage terminates when the pressure conditions are inverted again.

Seismic activity

As in all failures of natural dams, seismic activity in the form of earthquakes and faulting may be involved in the destabilization of the glacier barrier. However, there are few recent examples to underpin this obvious causal relation.

As shown in many natural settings, a combination of the individual trigger mechanisms is highly probable. Moreover, different trigger mechanisms could be responsible for repetitive lake outbursts from same glacier dam.

Moraine-dammed lakes

Moraine-dammed lakes are at their present extent a rather young geomorphological landform. In the textbooks of glacier science of the mid-twentieth century, they have been hardly mentioned as a type of glacial lake. Moraine dam failures resulted in devastating destructions of settlement areas, infrastructure, and loss of human life.

Moraine-dammed lakes are impounded in-between the end moraine complex and the vanishing glacier tongue (Photos 5 and 6). In general, moraine-dammed lakes may be classified in two types that may occur (a) at steep hanging glaciers and (b) at more gently inclined valley glaciers (Figure 6). Smaller lakes are typically associated with shorter and steeper glaciers. Glacier shrinkage commonly takes place by thinning and subsequent ice frontal retreat. In the final stage, the glacier tongue may lose the contact to the lake. The majority of moraine-dammed lakes are retained by moraines of Neoglacial Times and the Little Ice Age. The horizontal extent of the lake is limited along cirque glaciers by the toe of the head wall. At valley glaciers, the maximum reported length for any lake in the Himalayas is about 3.3 km at the Lake Tsho Rolpa (Nepal).

The terminal moraine complex consists of the end moraine, the laterofrontal moraine, and the lateral moraine

Glacier Lake Outburst Floods, Photo 5 Moraine-dammed lakes. Moraine-dammed lake at the Morsarjökull (Iceland) which is dammed by several end moraines. Glaciotectonic processes played a role in forming the depression upstrream of the end moraine complex (Photo: L. Iturrizaga, 09.07.2003).

Glacier Lake Outburst Floods, Photo 6 Moraine-dammed lakes. Moraine-dammed lake basin at the base of the Kanchenjunga South Side (Sikkim Himalaya). The lake has outbursted and left behind the characterical V-shaped incision of the end moraine and a debris flow cone (Photo: L. Iturrizaga, 09.04.2002).

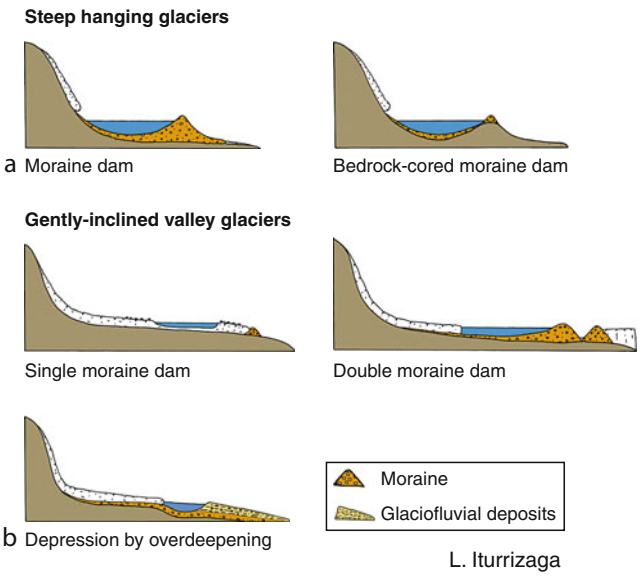
(Figure 7). The end moraine may be the result of a single glacier advance or of several subsequent glacier advances. The inner slopes of the moraines are predominantly extremely oversteepened (up to 80°) and the outer slopes are mostly inclined more gently (20°–35°). The absolute height of the end moraine reaches up to 200 m, whereby the actual dam height of the lake is much smaller. The moraine embracement is often intersected in a narrow and highly instable ridge. The composition of the sediment matrix is diamict. The higher the compaction and the smaller the porosity, the more stable is generally the dam. Glacier lakes in old tongue basins from pre-Neoglacial times are in principle rather stable. Dead ice cores and permafrost lenses may contribute significantly

to the stability of the dam. Water outlets at the outer slopes of the lateral moraines, showing a lesser temperature than the glacier lake, may indicate the presence of ice lenses within the moraine (Lliboutry et al., 1977). Moraine dams may entirely be closed (Tap glacier, Himalaya) or they may also be markedly incised and show a permanent outlet (Müller glacier, New Zealand).

The main distribution areas of hazardous moraine-dammed lakes are the Himalayas and the Andes. In Nepal, over 2,000 glacier lakes exist, of which about 20 have been classified as hazardous. The largest lakes are the Tsho Rolpa, Imja, Lower Barun, and Thulagi lakes, which are situated at an altitude between 4,000 and 5,000 m. The Tsho Rolpa (76×10^6 m^3) with a depth of 130 m and a width of 500 m, is located at an altitude of 4,580 m at the head of the Rolwaling valley and has formed during the last 40 years at the glacier tongue of the Trakarding Glacier (Everest, Nepal) (Figure 8) (Yamada, 1998; Reynolds, 1999). In the Rolwaling valley, the height of the valley floor decreases from 4,500 m to 1,700 m at the confluence with the Bhote Khosi over a vertical distance of only 20 km, providing a rather steep thalweg and high erosional flow velocities of potential floods.

The largest moraine-dammed lakes in the Himalayas are actually dammed by two moraine barriers (Figure 7): the end moraine of the parent glacier and the lateral moraine by a tributary glacier (Tsho Rolpa glacier lake, Imja glacier lake).

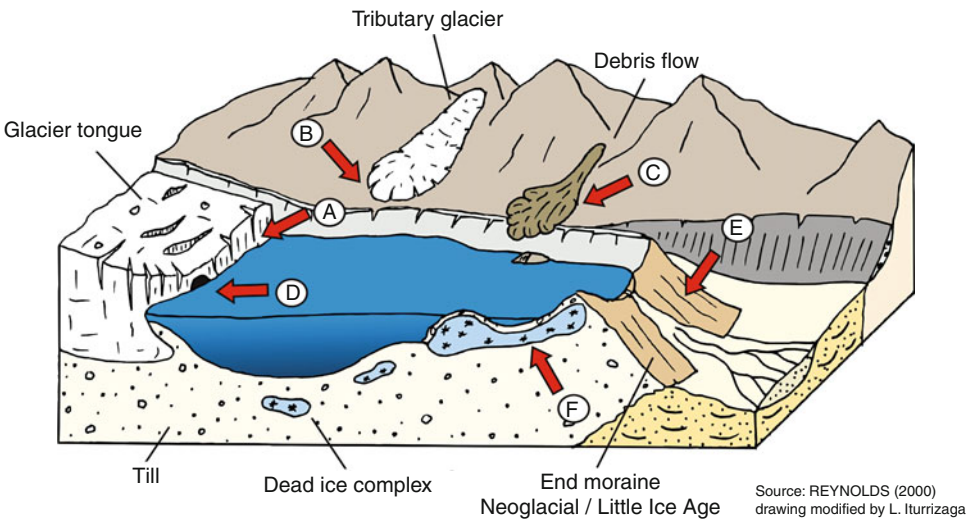
In the Cordillera Blanca (Peru) four major lake outbursts occurred between 1938 and 1950, following the glacier ice losses of the 1920s and 1930s (Lliboutry et al., 1977). The most devastating was the 1941 event, in which the Lake Palcacocha drained catastrophically. The event triggered a debris flow (8×10^6 m^3) that destroyed one-third of the town Huaraz. Over 6,000 inhabitants lost their life.



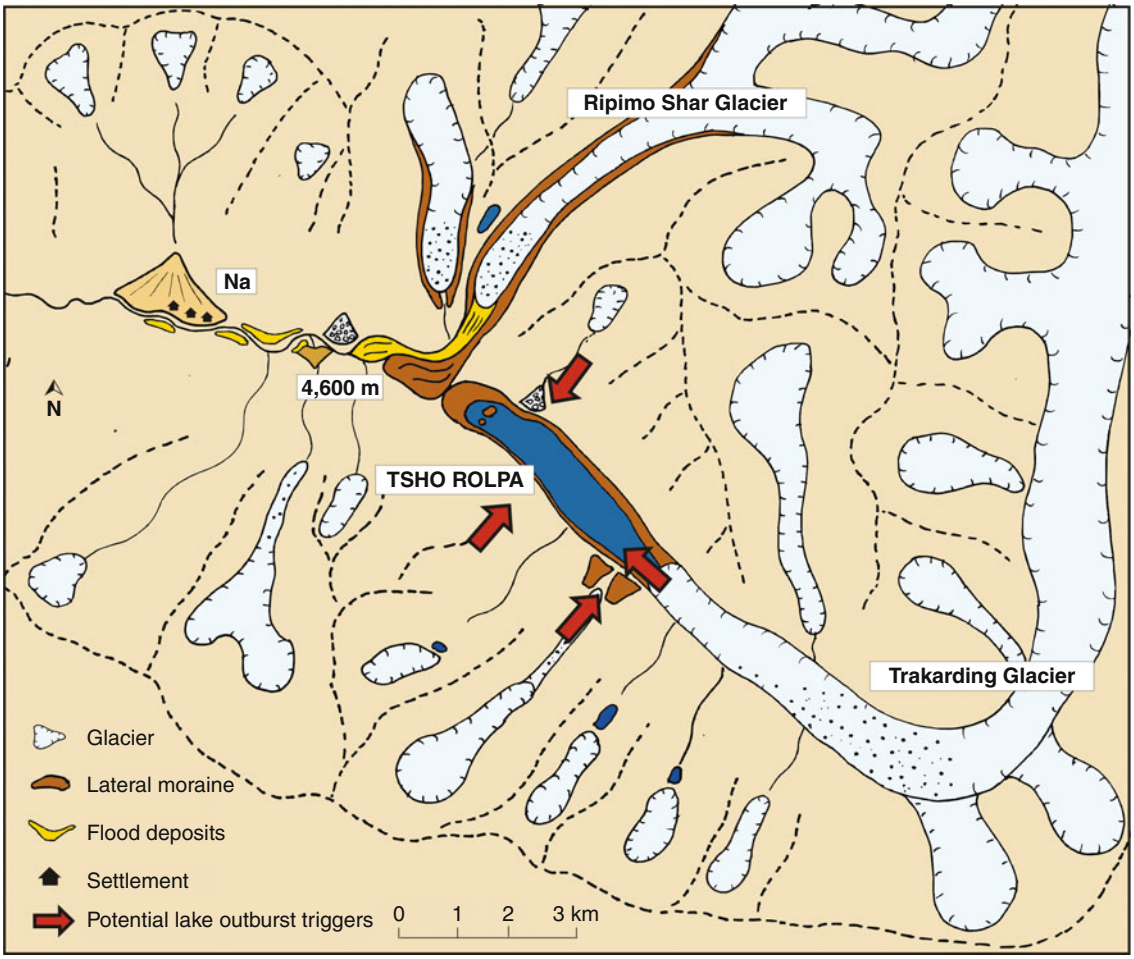
Glacier Lake Outburst Floods, Figure 6 Types of moraine-dammed lakes at short, steep hanging glaciers and gently sloped valley glaciers.

Development of moraine-dammed lakes

The water supply of the moraine-dammed lakes takes place by supraglacial, englacial, and subglacial meltwater, by glacier calving, by tributary rivers, and by precipitation in the form of rain and snow. The amplitude of the lake level may vary several meters during the course of the year



Glacier Lake Outburst Floods, Figure 7 Cross section of a moraine-dammed lake and potential triggers of lake outbursts **A** calving, **B** ice avalanches, **C** debris flows, **D** sudden meltwater drainage (sub-, en-, or supraglacial), **E** failure of the moraine dam, and **F** meltout of dead ice cores.



Glacier Lake Outburst Floods, Figure 8 The Tsho Rola Lake with a double dam formation of the former main valley glacier barrier of the Ripmo Shar glacier and the end moraine of the Trakarding glacier.

(3.4 +/– 0.7 m at Lago Paron in the Peruvian Andes, Lliboutry et al., 1977). At valley glaciers, the moraine-dammed lakes possess mostly an oval to elongated form and grow upvalley in longitudinal direction. The lowest point of the lake is situated in the upper third. Debris-covered, warm-based glaciers proved to be very favorable for the development of moraine-dammed lakes. The lake formation is linked with the surface gradient of the glacier (Reynolds, 2000). Larger supraglacial lakes may develop on valley glaciers up to a surface gradient of 2°.

Important for the formation of a large supraglacial lakes is that glacier maintains a stable terminus position over a longer time period. Moreover, the presence of some stagnant ice is favorable. Especially the long valley glaciers are gradually downwasting and thinning and not responding with an immediate glacier front retreat on a negative mass balance.

The initial stages of moraine-dammed lakes at valley glaciers are generally in the form of small supraglacial ponds of a debris-covered glacier. They gradually coalesce to a larger unified lake over time. The formation of supraglacial lakes may begin at undulations or at obstacles at the underground or at crevasse zones (Blachut and Ballantyne, 1976). At first, a vertical expansion of the supraglacial depression occurs at the glacier surface until the shift toward a lateral lake expansion by retreat of the steep ice cliffs. During the enlargement of supraglacial lakes, differential melting und backwasting processes and topographical inversions play a major role, which may result in the development of glacier karst and sink holes (Clayton, 1964). Crucial for the survival of the lakes is that they are not connected to a subglacial or englacial drainage system.

In the following, the lake expands horizontally and also inundates the end moraine. The growing of the supraglacial lake is subject to self-reinforcing processes with increasing vicinity to the end moraine. Due to its higher insolation absorption, the moraine material possesses a higher temperature than the glacier ice (Lliboutry et al., 1977). The direct contact to the lake water favors the

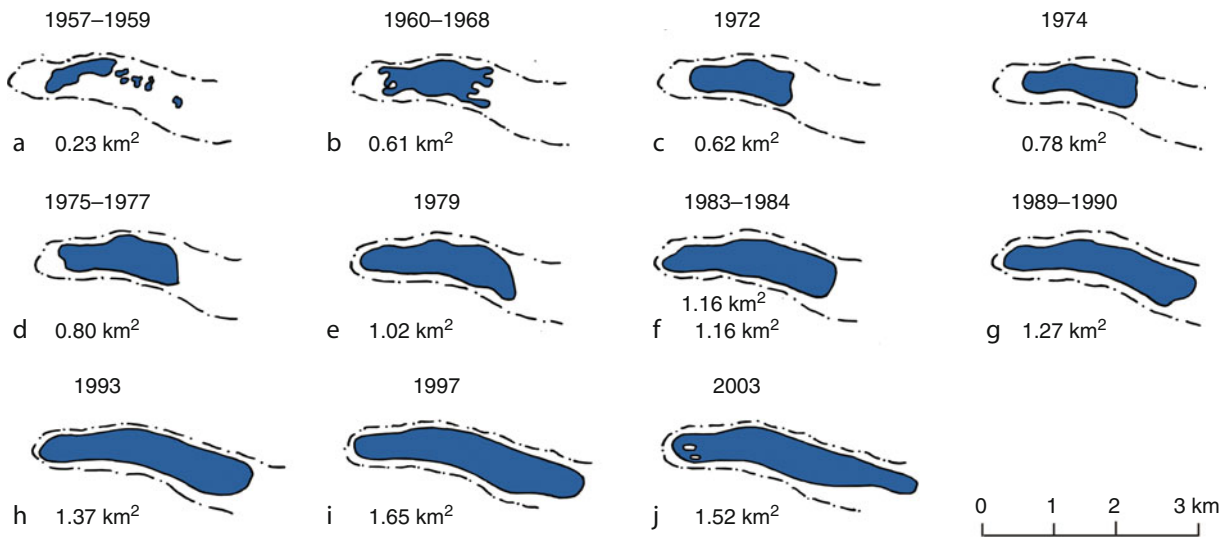
melting of the glacier tongue. The lake formation often starts 1–2 km upvalley of the end moraine, due to the fact that the glacier tongue area is heavily debris-covered. Therefore, the lakes are not that deep and their volume may be overestimated easily.

Progressive enlargement of supraglacial lakes is well researched for glaciers of the Himalayas (Ageta et al., 2000; Benn et al., 2001; Chikita, 2008; Delisle et al., 2003; Fujita et al., 2008; Komori et al., 2003; Reynolds, 2000). In Nepal, glacier lakes increased between 33 and 71 m/a since their formation (Yamada, 1998). The surface area of Tsho Rolpa grew from about 0.23 km^2 in 1959 to 0.62 km^2 by 1972 and 1.3 km^2 by 1990 (Yamada, 1998) (Figure 9). Imja Glacier lake increased from a few small ponds in the 1950s to a single body of water with a surface area greater than 0.5 km^2 in 1984 (Watanabe et al., 1994). In general, the moraine-dammed lakes are not more than 150 m deep. During the lateral expansion of the lake, the lake water may undercut the inner slope of the lake and trigger mass movements into the lake. The Tsho Rolpa is classified as the most dangerous lake in Nepal. The Trakarding glacier recedes by 20 m/a and has increased its size by around eight times in the last decades.

Trigger mechanisms for lake outbursts of moraine-dammed lakes

The failure of moraine dams occurs through a variety of different mechanisms (Reynolds, 2000; Clague and Evans, 2000) (Figure 7).

1. A very common outburst mechanism is the generation of displacement waves generated by ice avalanches or rock fall into the moraine-dammed lake (Dig Sho outburst in Nepal in 1985, Vuichard and Zimmermann, 1987). Subsequently, the flood creates a characteristic V-shaped incision into the moraine (Photo 6) or surges through an existent outlet channel and widens it rapidly. The natural spillway may be enlarged subsequently by retrogressive erosion.
2. Glacier calving may induce displacement waves overtopping the moraine dam. At the glacier tongue, crevasses are located immediately behind the ice cliff and undercutting at the water line may accelerate the calving processes (e.g., Thulagi glacier, Nepal). Calving of glaciers into glacial lakes increases the lake size. Floating glacier tongues are considered to be highly dangerous. They can collapse catastrophically into the lake.
3. Wastage of ice cores increases the volume of the lake and poses a serious risk to dam stability (Richardson and Reynolds, 2000b). Average rates of subsidence due to melting of buried ice in the moraine dam at Imja glacier (Nepal) amounted up to 2.7 m/year (Watanabe et al., 1995).
4. Earthquakes may lead to a dam failure by mass movement and destabilization of the dam (1941 Palcacocha, Huascaran, Peru, Lliboutry et al., 1977).
5. The moraine dam may gradually become instable by seepage, piping, and the enlargement of drainage conduits in the moraine. This natural process is sometimes accelerated accidentally by artificial drainage measurements and leaking of the pipes (e.g., Tsho Rolpa, Grabs and Hanisch, 1993).
6. Catastrophic sub- or englacial drainage of the glacier tongue area into the moraine-dammed lake may lead to a sudden rise of the water level in the proglacial lake (Passu glacier, Karakoram Mountains, in January 2008).



Glacier Lake Outburst Floods, Figure 9 Development of the Tsho Rolpa glacier lake (Reynolds Geo-Sciences Ltd. (2000), Drawing: L. Iturrizaga.

7. Heavy rainfall or snow melt may increase the lake level abruptly and lead to an outburst (Clague and Evans, 2000).

Hazard potential by glacier lake outbursts

Among glacier hazards, glacier lake outburst floods possess the most far-reaching impact zone. The devastating effect itself is significantly dependent from the peak discharge, which is in general much higher than that of floods triggered by rainfall or snowmelt (Clague and Evans, 2000). General hydrology of such floods has been discussed in a separate article entitled *Hydrology of jökulhlaup.*

From the historical record, glacier hazards are comparatively well described from the European Alps, where during the Little Ice Age (1600–1850) especially advancing tributary glaciers have dammed the main valley (e.g., impoundment of the Saaser Vispa by the Allalin glacier). In the Ötztal, the Vernagt glacier and Guslarferner sealed off the Rofental and impounded in 1848 a lake (3×10^6 m^3) with a subsequent outburst flood (Hoinkes, 1969). In total, over 200 glacier lake outbursts have been recorded in the Alps.

The general glacier shrinkage around the world during the twentieth century (Oerlemans, 2001) has lead to a remarkable shift in the glacial landscape systems and therefore in the glacial hazard potential (Evans and Clague, 1994; Häberli et al., 1999; Huggel, 2004; Kääb et al., 2005a, b; Baudo et al., 2007). The glacier retreat has become obvious in the accelerated formation of moraine-dammed lakes in the Himalayas since 1950s (Yamada, 1998; Kattelmann, 2003; Kattelmann and Watanabe, 1997) and the Peruvian Andes (Ames, 1998; Reynolds, 1992; Georges, 2004; Hubbard et al., 2005). With the augmented settlement density in high mountain regions, the hazard potential has increased in some areas. This is especially true for oasis settlements that are dependent on the irrigation of glacial meltwater (Iturrizaga, 1997).

Glacier hazards have reached a wider recognition by the outbreak of the Dig Tsho August 4, 1985. The lake outburst has been triggered by an ice avalanche, falling into the lake and caused a 5 m high flood wave. This type of lake outburst may be one of the major hazards in high mountain areas in the future. A lot of glaciers are in the transition from small-sized valley glaciers, reaching just the foot of the mountain, to hanging glaciers. However, most of the settlements in the Himalayas are located at the slopes or even on mountain ridges, in a rather flood-save location. In contrary, in the Karakoram almost none moraine-dammed lake exist. The main hazards are generated by the outburst of glacier-dammed lakes, which may be several times larger than moraine-dammed lakes. Moreover, their formation and outburst is highly unpredictable. Glacier advances in this region would lead to an increase in glacier-dammed lakes and in turn to a higher hazard potential. A lot of the settlements are situated in flood-prone areas as the slopes are covered with talus accumulations, which are not suitable for housing. Moreover, the oasis settlements are in many cases directly located in the glacier forefields. Settlement loss by glacier lake outbursts amounts up to 300 m in width were reconstructed in the Shimshal valley (Iturrizaga, 1997, Photo 7).

In the Peruvian Andes (Cordillera Blanca), 100 new proglacial lakes have formed during the last century (Ames, 1998). In the 1930s only 30 lakes were monitored, whereas in the 1990s 138 lakes were counted (Ames, 1998; Kaser and Osmaston, 2002). Several glacier lake outbursts, partially triggered by earthquakes and involving subsequent ice avalanches, have seriously affected the settled mountain valley (Welsch and Kinzl, 1970; Patzelt, 1983). Richardson and Reynolds (2000b) have carried out an intensive evaluation with regard to dam stabilities as a base for measurements of technical prevention.

The subsequent technical measurements maybe undertaken to mitigate the risk of the outburst of a moraine-dammed lake (Lliboutry et al., 1977; Grabs and Hanisch, 1993; Richardson and Reynolds, 2000b):

- Selective blasting of instable areas of the parent rock or of the overhanging glacier.
- Installation of mesh wires as protection against rock fall.
- Stabilization of the moraine wall by injection of a cement core.
- Installation of mesh wire at the outer slope of the moraine dam as protection against erosion.
- Artificial heightening of the moraine dam for avoiding the spillover of a displacement wave.
- Lowering of the lake level in order to decrease the pressure on the moraine dam, to reduce the water volume in case of an outburst.
- Drainage of the lake by (a) the stepwise deepening of the natural spillway channel and thus increasing the

Glacier Lake Outburst Floods, Photo 7 The village of Shimshal has lost about 300 m of land by glacier lake outbursts of the Khurdopin glacier (Photo: L. Iturrizaga, 07.07.2001).

drainage rate, effusion of the channel with cement and paving with stones, (b) blasting of parts or the entire moraine dam in its initial stage as prevention measurement (evacuation of the inhabitants), (c) pipes through or below the moraine and stabilization of the pipes with cement, (d) drillings through the bedrock below the moraine dam.

- Method of lowering the lake level by a hydraulic syphon technique with plastic pipes. This method is cost efficient and easily transportable. The system uses the energy, which is produced by the hydraulic gradient between the higher inlet and the lower outlet. The pipes are located at the inlet several meters below the lake level and at the foot of the moraine dam. Leaking of the pipes may be serious problem in destabilizing the dam. In case of a glacier tongue that floats on the lake, the ice may become instable and produce a lake outburst.

Downstream of the moraine dam, the common engineering protection measurements against floods may be installed.

The technical opportunities to prevent an outburst of a glacial-dammed lake are rather limited and in most cases financial funding is as well a key restriction. In general, the hazard potential of glacial-dammed lakes by tributary glaciers has decreased due to the common tendency of glacier retreat.

However, there has been substantial progress in hazard management of moraine-dammed lakes in regard to stabilization techniques and the application of hydraulic siphon techniques. Glacier lake monitoring and potential outburst risks are more and more monitored and evaluated by the analysis of satellite images (Huggel, 2004; Huggel et al., 2004; Quincey et al., 2007; Barry et al., 2008). Statistical remote sensing-based studies have been carried out for estimating the probability of catastrophic drainage from moraine-dammed lakes in southwestern British Columbia (McKillop and Clague, 2007). Flume tanks, which are artificial river channels, have been used to simulate natural river channels and get more insights into glacier lake outbursts sedimentation patterns (Rushmer, 2007). Carrivick (2006) and Herget (2005) have reconstructed computer-based large magnitude floods in two-dimensional (2D) and three-dimensional (3D) flows. These calculations may also be useful for hazard management of artificial dam failures. However, the outbursts of sub- and englacial water pockets, which represent in many mountain areas a serious hazard, are still rather unpredictable (Glacier du Trient). In the European Alps, about 60–70% of the glacier lakes are ice-marginal lakes and 30–40% are water pockets (Häberli, 1983). There are also indications that in the Karakoram Mountains the number of supraglacial lakes is increasing and related with that the danger of englacial lake outbursts (Iturrizaga, 2011). In Nepal, 34 of the existing lakes in the Dudh Khosi catchment area have been increased in size and 24 new lakes have been developed (Bajracharya and Mool, 2009). However, the lake size does not necessarily correspond with a higher risk, as the recent assessment for the Imja Glacier has shown (Watanabe et al., 2009).

Summary

Glacier lakes are indirectly a result of climatic changes expressed by glacier fluctuations. During the earth history glacier lakes have survived only a short time period, but glacier lake outbursts had a profound impact in shaping the landscape. The dominant type of glacial lakes may shift over time from glacier-dammed lakes to moraine-dammed lakes in different glaciation situations in dependence of the topographic setting. In the course of deglaciation, the types of glacier will change and therefore the type of glacial lakes. Glacier-dammed lakes occur mainly in times of glacier advance, but there are also some constellations in which they are the result of glacier retreat. Moraine-dammed lakes are mainly linked to glacier retreat regimes. During the Pleistocene glaciation, ice barriers of several hundred meters in height supposed to have existed. These large ice dams have no pendant at recent times. In general, the number of glaciers increases in the period of deglaciation from an ice-stream network to individual glaciers. Only some glaciers are prone to the formation of moraine-dammed lakes. Their size is in general much smaller than the glacier-dammed lakes. However, glacier lake outbursts from these small lakes can attain extremely high peak discharges by sudden dam failure. As a consequence of topographical and climatic conditions, glacier dynamics and the sediment transfer system glaciers are prone for the formation of moraine-dammed lakes. Therefore, a characteristic distribution pattern of glacier lake types can be recognized in individual mountain areas. In terms of natural hazards, sudden outbursts from small lakes with high peak discharges may have a more severe impact on human settlement than the drainage of large ice-dammed lakes. Not all glacier lake outbursts have to be necessarily released as water floods. They may also occur as debris flow with a high hazard potential.

GLACIER MASS BALANCE

Wilfried Haeberli
Glaciology, Geomorphodynamics & Geochronology, Geography Department, University of Zurich, Zurich, Switzerland

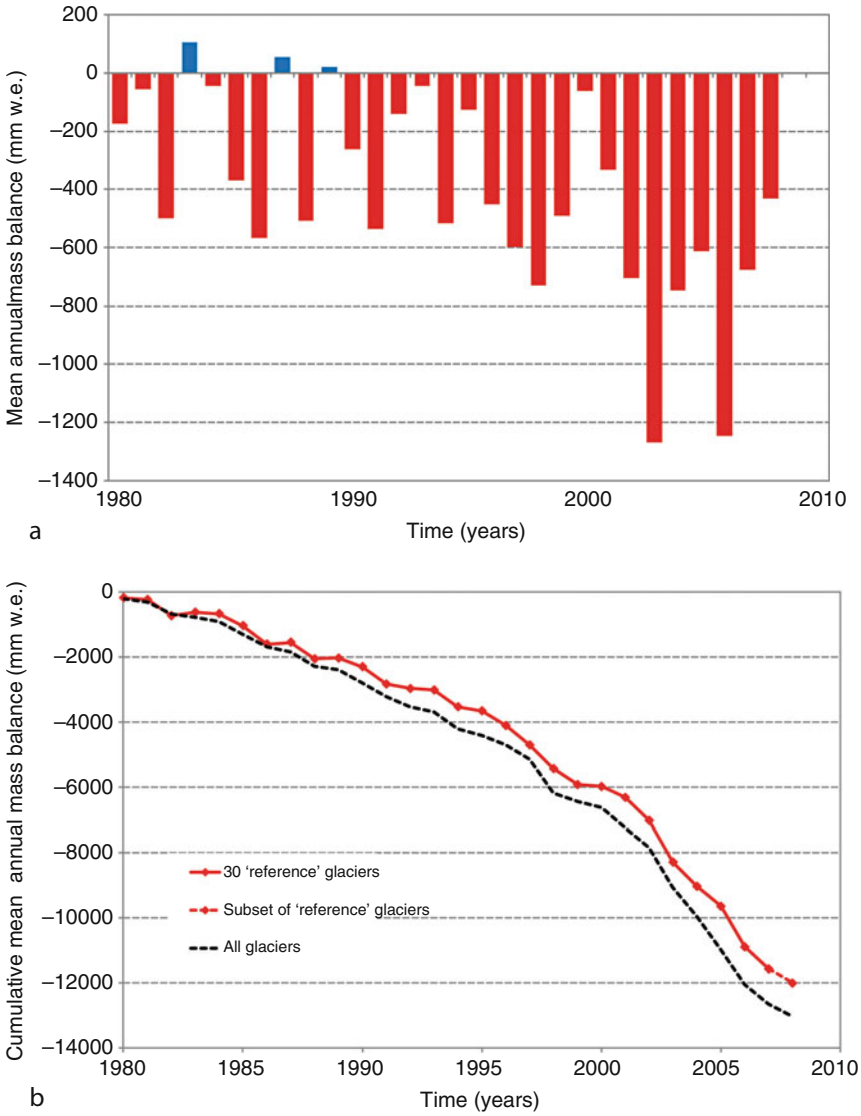
Definition

The mass balance of a glacier is the sum of all processes that add mass to a glacier and remove mass from it. Accumulation or addition of mass most commonly takes place in the form of snowfall, often modified by wind and avalanches. Melting of snow and ice is the predominant form of ablation or removal of mass, but calving of tidal glaciers, ice avalanching from steep hanging glaciers or evacuation of windblown snow in dry areas or during cold/dry seasons can locally be of high relative importance. A general overview of the physical processes involved was given by Oerlemans (2001), Kaser et al. (2003) provided a manual for field measurements with related technical nomenclature, Haeberli et al. (1998) compiled an overview of monitoring strategies with their historical background, and described the existing data basis in the international glacier monitoring network. Kaser et al. (2006) and Zemp et al. (2009) summarized the development of glacier mass balance during the past decades (cf. earlier compilations by Dyurgerov and Meier, 1997 and Braithwaite, 2002). Assessments of worldwide glacier mass balance are also regularly contained in the IPCC reports (IPCC, 2007 and earlier issues).

Background and significance

The loss or gain of glacier mass is a direct, undelayed response of a glacier to climatic conditions. It constitutes a key indication of climate change and affects the water cycle and landscape evolution in cold regions on earth (IPCC, 2007; UNEP, 2007). Long-term monitoring of glacier mass balance forms an essential part of internationally coordinated glacier observation (Haeberli, 2004) by the World Glacier Monitoring Service (WGMS) under the umbrella of ICSU (FAGS), IUGG (IACS), UNEP, UNESCO, and WMO within the framework of the Global Terrestrial Network for Glaciers (GTN-G) as part of the Global Terrestrial/Climate Observing System (GTOS/GCOS). Worldwide results from regular measurements are reported through a special biennial "Glacier Mass Balance Bulletin" (WGMS, 2009 and earlier issues) and as part of the more comprehensive series of "Fluctuations of Glaciers" (WGMS, 2008a, b and earlier issues) covering 5-year intervals. Figure 1 illustrates the information from long-term measurements reported in the Glacier Mass Balance Bulletin. Annual and cumulative mass balance are expressed as thickness change in water equivalent (corrected for snow/ice density) averaged over the glacier surface area. The annual values document the interannual variability and the predominant yearly losses, both being of a comparable magnitude. The cumulative values reflect the striking clarity of the negative mass balance as a consequence of increasing temperatures and the overall acceleration of loss rates due to various interactions and feedbacks. Since the turn of the millennium, the mean measured loss rate between 1980 and 1999 roughly doubled and the previous record loss in 1998 was exceeded already three times, in 2006 even by a factor of about two.

Integrative strategies of global climate system observation and related glacier monitoring build on a tiered system of approaches, which help bridging the gap between



Glacier Mass Balance, Figure 1 Graphs of annual (**a**) and cumulative (**b**) mass balance from about 30 reference glaciers as periodically published in the Glacier Mass Balance Bulletin of the World Glacier Monitoring Service. (From WGMS, 2009.)

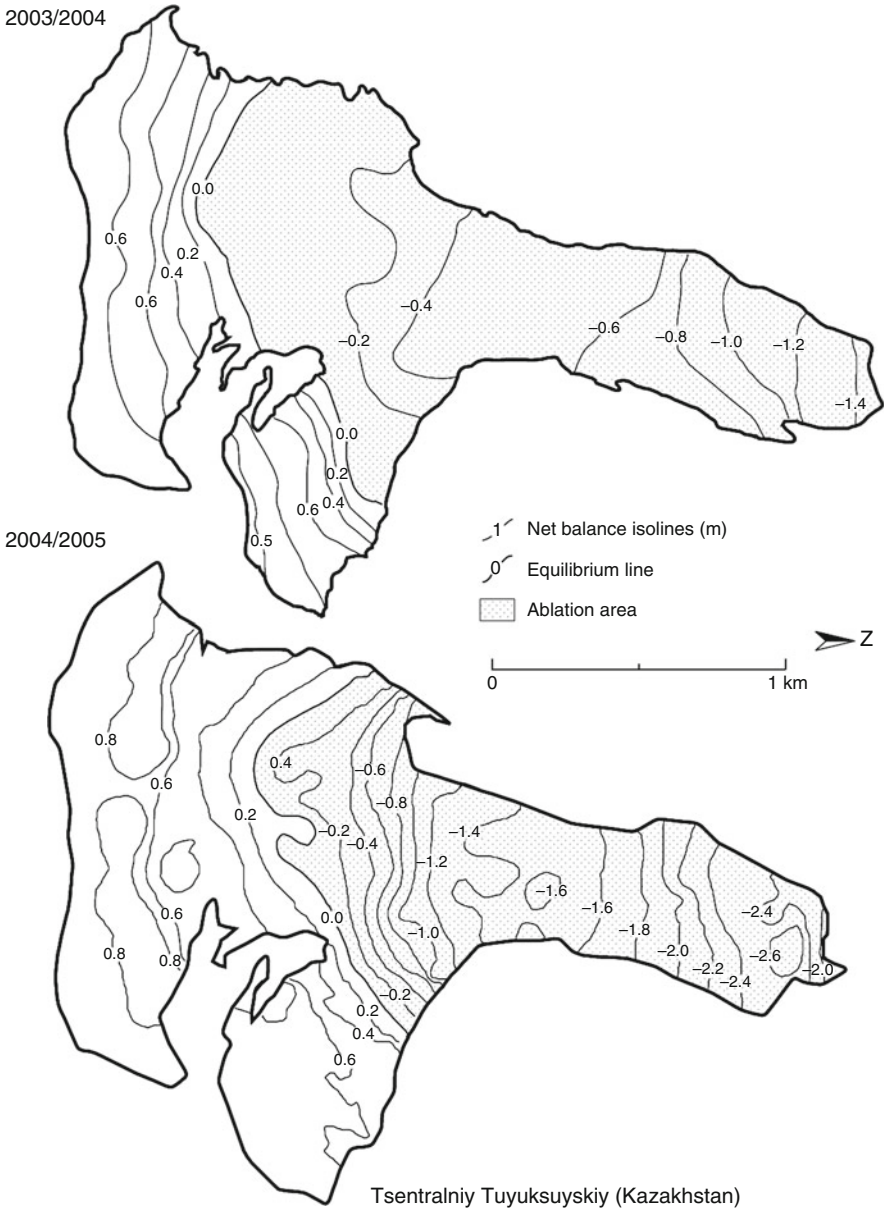
detailed local process-oriented observations and global coverage at the pixel resolution of satellite sensors (Haeberli, 2005). The following elements are parts of this tiered approach:

- Extensive and integrative glacier mass balance and flow studies within major climatic zones for improved process understanding and calibration of numerical models;
- Regional observations with cost-saving approaches and monitoring of large glacier ensembles within entire mountain ranges using satellite-based information.

The existing variability of measurement and analysis techniques, as well as application aspects related to long-term studies of glacier mass balance can be structured and explained along such a hierarchical product-oriented perspective.

Integrative, process-oriented mass balance determination

Detailed process understanding and the development and calibration of numerical energy/mass balance and flow models constitute the basis for sensitivity experiments on climate–glacier relations and for extrapolation of mass balance values measured on a few glaciers to regions with less comprehensive measurements or for reconstruction backwards and scenario calculations forward in time. This requires intensive, seasonal, or even more frequent field measurements of mass balance in combination with determinations of glacier flow and hydrometeorological data



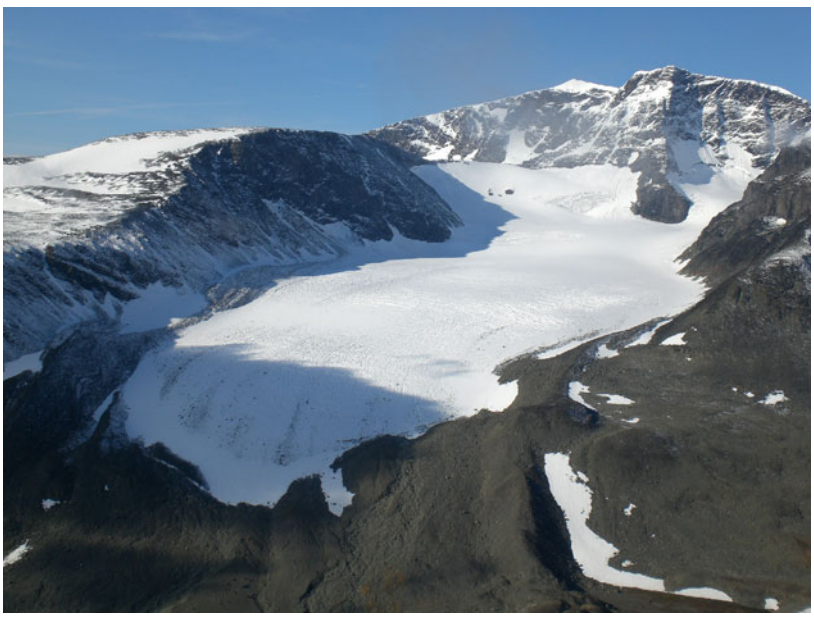
Glacier Mass Balance, Figure 2 Maps of mass balance distribution on Tuyuksu glacier (Kazakhstan/Tien Shan) at the end of the hydrological years 2003/2004 and 2004/2005 from stake/pit-measurements (direct glaciological method). (From WGMS, 2009.)

collection. Networks of ablation stakes and snow pits for accumulation measurements – the so-called direct glaciological method – provide high-resolution quantitative information on spatio-temporal patterns of mass gain and mass loss. Inter- and extrapolation of point measurements to the entire glacier surface area (Figure 2) often uses experience from expert knowledge and earlier, more detailed measurements, patterns of summer snow melt, which remain relatively stable in time, relations between mass balance and altitude, or distributed energy balance modeling using digital terrain information. Such approaches involve uncertainties that must be reduced by repeated mapping of surface area and surface elevation by the so-called geodetic (i.e., terrestrial)-photogrammetric (i.e., air-/spaceborne) method (e.g., Cogley, 2009; Haug et al., 2009; Thibert and Vincent, 2009). Carefully calibrated time series have systematic errors of less than 5 cm water equivalent per year (Thibert et al., 2008). The most commonly used time basis is a fixed-date system with (spring) measurements at the end of the (cold) accumulation period for determining winter balance and (fall) measurements after the (warm) ablation period defining annual balance; summer balance is then calculated by subtracting winter balance from annual balance. Other systems,

however, also exist (stratigraphic system relating to recognizable summer melt surfaces in the firn area) and glaciers in monsoonal climates have specific conditions with accumulation and ablation taking both place in an "active season." The measured and calculated volume change is corrected for density and divided by the surface area to provide a specific mass balance (unit: meters of water equivalent per year). This value represents an easily understood "average rate of thickness change" and is comparable worldwide between large and small glaciers.

Following a number of early observations at individual stakes (e.g., Mercanton, 1916, cf. Huss et al., 2008, 2009), long time series of detailed process-oriented mass balance observations covering entire glaciers and thus enabling worldwide inter-comparability were first initiated in Scandinavia (Storglaciären in Tarfala/Sweden since 1946, Figure 3; Storbreen Jotunheimen/Norway since 1949). These long-term observational time series in Scandinavia were later completed by comparable programs in various parts of the world, providing fundamental insights into basic phenomena and processes of climate/glacier relations (Kuhn, 1981; Oerlemans, 2001). Ablation through melting is the result of the energy balance, involving solar radiation, sensible and latent heat fluxes, while accumulation is primarily related to (solid) precipitation (e.g., Hock, 2005). As air temperature has an influence on all parts of the mass balance via solid–liquid precipitation, longwave radiation, turbulent exchanges, evaporation/condensation and sublimation, it has a predominant influence on glacier mass balance (Braithwaite, 2006; Ohmura, 2001). This predominant influence of air temperature on glacier mass balance together with the efficient mixing of the atmosphere and the well-known relation between air temperature and altitude is the basis for a number of somewhat simplified but nevertheless most important and useful analysis concepts. Such concepts are applied in mass balance modeling, using either full energy balance approaches or statistical relations between measured mass balances and meteorological parameters (for instance, positive degree-days and solid precipitation).

The dependence of glacier mass balance on air temperature causes mass balances to be spatially correlated over large regions (spanning several 100 km: Letréguilly and Reynaud, 1990; Cogley and Adams, 1998). For the same reason, mass balance primarily changes with altitude, from highest ablation at lowest parts to accumulation at higher elevations on the glacier. The equilibrium line where accumulation equals ablation and mass balance is zero separates accumulation from ablation areas on glaciers. As the sum of positive temperature decreases in a non-linear way with altitude, mass balance gradients tend to be smaller at higher altitudes and accumulation areas correspondingly larger than ablation areas for conditions of zero mass balance (continuously updated values can be found in the Glacier Mass Balance Bulletin, cf. Bahr et al., 2009). In humid-maritime regions, large amounts of ablation are required to compensate for heavy snowfall; the equilibrium line remains at altitudes with relatively high air temperature, enabling intense sensible heat flux and strong ice melt during extended ablation seasons. Temperate glaciers at melting temperature, exhibiting high mass turnover and rapid flow dominate these landscapes. The lower parts of such temperate glaciers commonly extend into grassland and forested valleys where summer



Glacier Mass Balance, Figure 3 Storglaciären near Tarfala in the Kebnekaise region, Swedish Lapland, Photo Th. Koblet. (From WGMS, 2009.)

warmth and winter snow accumulation prevent the development of permafrost (Haeberli and Burn, 2002). Ice caps and valley glaciers of Patagonia and Iceland, the western Cordillera of North America and the coastal mountain chains of New Zealand and Norway are features of this type. In contrast, dry/continental conditions such as they exist in northern Alaska, arctic Canada, subarctic Russia, parts of the Andes near the Atacama desert, or in many central-Asian mountain chains force the equilibrium line to rise to elevations with low air temperatures, short ablation seasons, reduced sensible heat flux, and limited amounts of ice melting (e.g., Braithwaite et al., 2003). In such regions, polythermal or cold glaciers, lying far beyond tree line and often even beyond tundra vegetation, have a low mass turnover, less rapid flow, and are associated with severe periglacial conditions and permafrost (Shumskii, 1964; Haeberli and Burn, 2002). Gradients of mass balance versus altitude can be an order of magnitude higher for temperate glaciers in humid-maritime regions (characteristic annual values are around 1 m of water equivalent per 100 m of elevation difference) than on polythermal/cold glaciers in dry/continental regions (characteristic annual values are about 10 cm per 100 m of elevation difference). In dry/continental regions, the firn of the accumulation zone is cold, causing meltwater produced at the surface to refreeze below surface and not to leave the glacier. For a given increase in temperature, therefore, such glaciers loose considerably less mass than temperate glaciers in maritime regions, where surface melt from the entire glacier surface runs off. As a consequence, there is a strong temperature effect on the sensitivity of glacier mass balance and atmospheric temperature rise. Such differences in mass balance gradients and thermal conditions represent the regional/climatic sensitivity of glacier mass balance (e.g., Kuhn, 1984). As changes in specific mass balance are the product of a shift in equilibrium line altitude (ELA) and the gradient of mass balance with altitude as weighed by the distribution of glacier surface area with altitude (hypsometry), the latter represents the local/individual or topographic part of the glacier mass balance sensitivity. The cumulative mass balances reported for individual glaciers thus not only reflect regional climatic variability but also mark differences in the sensitivity of the observed glaciers. Concerning evolution in time, positive feedbacks relating to surface albedo via changing snow/firn cover or dust deposition (Paul et al., 2005; Oerlemans et al., 2009) and to changing surface elevation can have strong impacts (Raymond et al., 2005) and may even cause self-reinforcing "runaway effects" (down-wasting rather than retreat of glaciers where "vertical" thickness loss is faster than the capacity of a glacier to "horizontally" retreat); increasing debris cover, on the other hand, tends to decouple glaciers from atmospheric influences, and can markedly slow down ice melting and strongly retard tongue retreat (e.g., Smiraglia et al., 2000).

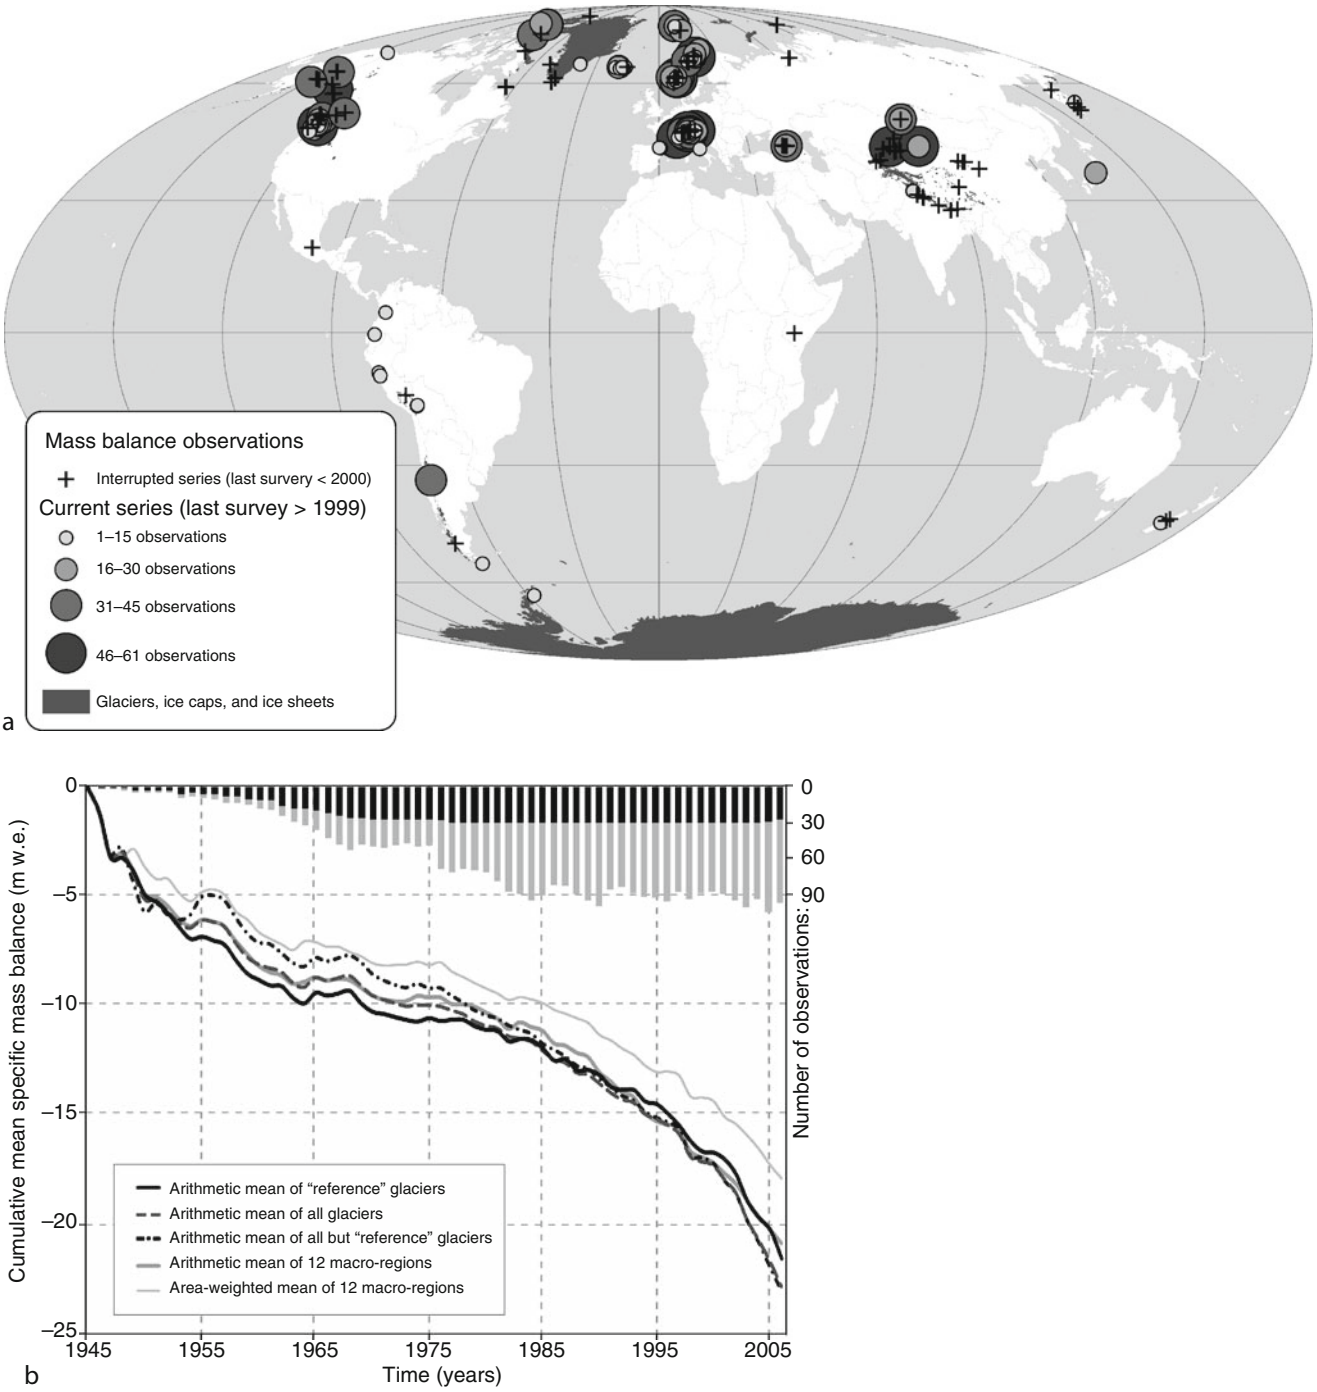
Coupled mass balance and flow models parameterized with data from detailed mass balance observations have been used to simulate glacier reactions to scenarios of climate change (e.g., Oerlemans et al., 1998). Continued atmospheric temperature rise could indeed cause the complete vanishing of glaciers, which constitute the presently existing in-situ mass balance network. In the European Alps, for instance, several glaciers with long observational series of mass balance could disappear within the first half of our century and three of them (Sarennes, Careser, and Sonnblick, cf. Carturan and Seppi, 2007; Le Meur et al., 2007) may even not survive more than a decade or two from now. In order to save the continuity of the mass balance network, mass balance measurements are now being started on still larger- and higher-reaching glaciers. This is, in fact, an urgent task if sufficient overlap in time ought to be assured (Zemp et al., 2009).

Regional observations and monitoring of large glacier ensembles

Long-term integrated mass balance observations are highly demanding. The number of corresponding time series is therefore small (order of magnitude about 10, number changing in time, cf. extensive information in the Glacier Mass Balance Bulletin). A much larger number of glaciers can be observed using reduced stake networks, but still providing annual mass balance values. Repeated glacier inventories and new satellite-based technologies even allow for the calculation of mass changes of large glacier ensembles in entire mountain ranges over time periods of decades (e.g., Larsen et al., 2007, Schiefer et al., 2007). Together with flow considerations and energy balance modeling, calculations are possible of past and potential future regional glacier mass changes. This field of research has been rapidly expanding during the past decade. The following may illustrate characteristic examples.

The annual specific balance as a regional signal can be obtained most economically using geodetic/photogrammetric volume change determinations repeated at time intervals of several years to a few decades in combination with observations on a minimum of three strategically selected index stakes (Haeberli et al., 1998): two stakes should be monitored near the equilibrium line and at some suitable site in the accumulation area where the surface area is most extended and one near the glacier front to determine ablation gradients and to convert cumulative glacier length changes into cumulative mass balance values (Haeberli and Hoelzle, 1995; Hoelzle et al., 2003). Data interpretation can be made by applying a simplified version of the linear balance model (Reynaud et al., 1986), which assumes the mass balance variation at each point of the glacier to be proportional to the mass balance variation of the entire glacier. This concept is an important working tool building on the basic experience that the spatial distribution of mass balance often remains highly similar from year to year: close to the average equilibrium line altitude where surface area and, hence, the influence on the overall mass balance of a glacier is largest (Braithwaite, 2006), the temporal variability in the overall mass balance gradient remains small.

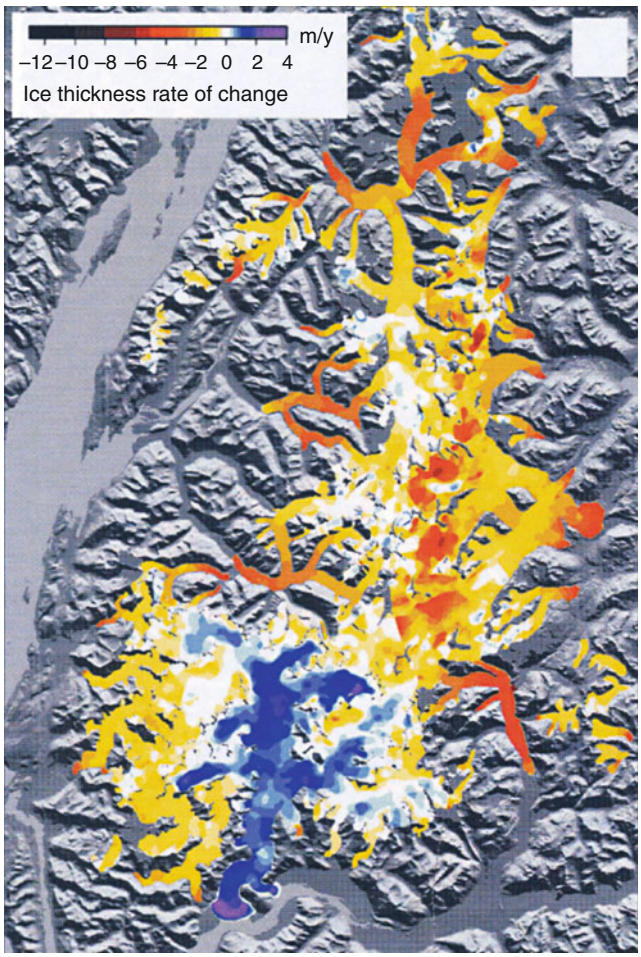
The third stake recommended for a minimum stake network should be installed at the glacier terminus in order to check on the reliability of the linear balance model and to introduce adequate corrections if necessary (cf. Kuhn, 1984; Oerlemans and Hoogendorn, 1989). Many mass balance programs follow this concept or similar simplified approaches. In total, several thousand mass balance values have been reported (until 2008) from 228 glaciers



Glacier Mass Balance, Figure 4 Worldwide distribution of long-term mass balance observations (**a**) and evolution of averaged (cumulative) mass balance since 1945. (From Zemp et al., 2009.)

worldwide (Zemp et al., 2009). The sample is strongly biased towards the Northern Hemisphere and Europe and only 30 glaciers have uninterrupted series going back to 1976 (cf. Figure 1). Various statistical techniques have been applied to summarize the data. The results of these approaches differ by less than 0.1 m water equivalent per year, which roughly corresponds to the uncertainty of carefully calibrated time series. Figure 4 shows the averaged development during the past six decades, indicating a strong ice loss as early as the 1940s and 1950s followed by a moderate mass loss until the end of the 1970s and a subsequent acceleration, which continues until now. The compilation also shows an increasing uniformity of the development at a global scale. Reconstruction of past glacier mass balances based on mass conservation and cumulative length change reveal that present loss rates start exceeding characteristic loss rates during the twentieth century (Hoelzle et al., 2003), since the end of the Little Ice Age (Haeberli and Hoelzle, 1995) or even during the past millennia (Haeberli and Holzhauser, 2003). Such reconstructions have a poor time resolution (decades), but are independent of direct mass balance measurements or climatic data. Mass balance reconstructions using numerical mass balance models driven by meteorological data and tuned to data measured in the field confirm this general finding and provide annual values (Huss et al., 2008, Nemec et al., 2009). Annual values reconstructed in this way, however, are not independent of climatic/meteorological data and must be clearly separated from directly measured and independently determined glacier information. The combination of the two approaches, however, increases the confidence in the reported values. They leave no doubt that striking worldwide mass losses of glaciers have taken place during the past century (Ohmura, 2006) and tend to continue at an accelerating rate. In the European Alps, for instance, glaciers have lost about half their total volume (roughly −0.5% per year) between 1850 and around 1975, another 25% (or −1% per year) of the remaining amount between 1975 and 2000, and an additional 10–15% (or −2% to −3% per year) in the first 5 years of this century (Haeberli et al., 2007). Scenario calculations concerning effects of global atmospheric warming (Nesje et al., 2008; Paul et al., 2007; Zemp et al., 2006) clearly confirm earlier regional projections (Haeberli and Hoelzle, 1995) that many mountain ranges could lose major parts of their glacier volumes within the twenty-first century and that the strongest melting in such regions is likely to take place during the coming decades. The rate of mass loss is, in fact, higher than can be explained by radiative forcing and meteorological effects alone. Feedback mechanisms, especially related to albedo lowering (Oerlemans et al., 2009), are therefore likely to play an increasing role.

In recent years, the striking development of glacier mass loss at a global scale and at fast if not accelerating rates was accompanied by rapid developments in observational methodology. Prominent technologies, such as airborne laser altimetry in combination with kinematic GPS (Abdalati et al., 2004); spaceborne digital elevation models (DEMs) from SRTM, ASTER, or SPOT (e.g., Berthier et al., 2004, 2010; Larsen et al., 2007; Rignot et al., 2003; Schiefer et al., 2007; Surazakov and Aizen 2006); and distributed modeling of the climatic accumulation areas or the mass and energy balance for individual glaciers (Arnold et al., 2006) or large glacier ensembles (Machguth et al., 2006a; Zemp et al., 2007), open new dimensions for monitoring and analyzing glacier mass balance and glacier mass changes. The difficulties are still considerable but the perspectives are most promising. Correct determination of complex precipitation and accumulation patterns influenced by wind drift and avalanching remains a fundamental problem for distributed energy and mass balance modeling for large glacier ensembles (Machguth et al., 2006b). The related



Glacier Mass Balance, Figure 5 Mean annual surface altitude changes of the Juneau Ice Field and its glaciers (southern Alaska) during the past decades (variable time basis) on the basis of DEM-differencing using the Shuttle Radar Topography Mission (SRTM) and older Geological Survey Maps. (From Larsen et al., 2007, reproduced by permission of American Geophysical Union)

uncertainty requires to check the measurements with independent evidence from laser altimetry, which enables very high precision to be reached, or by differencing of DEMs, which is less precise but nevertheless able to document the very large changes during time periods of decades (Kääb, 2008). The example from southern Alaska shown in Figure 5, for instance, shows average thickness losses for a great number of small and large glaciers of several meters per year, in general peaking at the lowermost, flat parts of the glacier tongues. For the first time, such DEM differencing helps establishing, how representative mass balance observations at single glaciers are with respect to all glaciers of a mountain range (Paul and Haeberli, 2008) or even all glaciers on earth. This is especially important with respect to the calculation of glacier contributions to sea-level rise, which mainly involves the largest glaciers on earth with strong dynamic effects – especially calving of tidewater glaciers – on surface mass balance and mass loss (Meier et al., 2007).

Summary

Glacier mass balance as the difference between mass gain through snow accumulation and mass loss through melting and sometimes calving is a rather direct result of fluctuating atmospheric conditions and a key natural indicator of global climate change. International monitoring strategies combine in situ observations at networks of stakes and snow pits (direct glaciological method for process understanding and annual to seasonal time resolution) with repeated mapping (geodetic/photogrammetric method for calibration of field measurements and determination of overall volume/mass change). Modern remote sensing techniques include laser altimetry, radar, gravimetry, and differencing of digital elevation models (DEM) for large glacier ensembles. Long-term in situ mass balance measurements for entire glaciers started after World War II, today involve regular observations at about 100 glaciers worldwide, and reveal a trend of rapidly accelerating mass loss during the past decades.
